7 8 ABSTRACT

9 The worldwide increase of damages produced by floods during the last decades strengthens the
10 common perception that flood risk is dramatically increasing due to a combination of different causes,
11 among which climate change is often described as the major driver. Nevertheless, the scientific
12 community is increasingly aware of the role of the anthropogenic pressures (e.g. steady expansion of
13 urban and industrial areas in dyke-protected floodplains) that may strongly impact the flood risk in a
14 given area by increasing potential flood damages and losses (i.e. so called “levee effect”). The scientific
15 literature on quantitative assessments of the “levee-effect” or robust methodological tools for
16 performing such assessments is still sparse. We refer to the dyke-protected floodplains of the middle
17 and lower portion of River Po (Northern Italy), a broad geographical area (~46 000 km²) with two
18 specific research questions in mind: (i) has the flood risk increased over the last half century? And, if
19 so, (ii) what are the main drivers of this change? First, we assess the flood-hazard evolution by
20 analysing three long series of daily streamflow available at different gauging stations. Secondly, we
21 quantitatively assess the temporal variability of the flood exposure and risk by looking at the evolution
22 in time of anthropogenic pressures (i.e. land-use and demographic dynamics observed from 1950s).
23 To this aim, we propose graphical tools (i.e. Hypsometric Vulnerability Curves-HVCs) that are suitable
24 for assessing vulnerability to floods over large geographical areas. Our study highlights the absence of

statistically significant trends in annual statistics of the observed streamflow series and a stable population density within the dike-protected flood-prone area. Nevertheless, the proposed flood-vulnerability indexes show a significant increase of the exposure to floods in residential settlements, which has doubled since the 1950s.

Key Words: “Levee effect”; exposure to floods; flood hazard and risk assessment; Po river; Hypsometric vulnerability curve.

1 Introduction

1.1 Flood-risk change: evidences, main drivers and open problems

Freshwater flooding (such as river floods, flash floods, urban inundation due to drainage problems, etc.) is the most impacting natural disaster in terms of number of people affected and economic damages (see e.g. EM-DAT; <http://www.emdat.be/>). Referring to the EM-DAT data-set, Jonkman (2005) analyzed the disasters occurred over the time period 1975-2001 and showed that floods are the most frequently recorded natural hazards occurring world-wide and, even though droughts and earthquakes might be more significant in terms of loss of life, floods are the events that most directly hit the largest number of people (around 2.2 billion of people between 1975-2001).

The common perception of an increasing frequency of floods and inundation phenomena during the last decades is often supported by a growing concern on climate change (e.g. European Environmental Agency-EEA, 2005; Wilby et al., 2008). In fact, some studies in the literature (e.g. IPCC, 2013, and Stern Review, 2007) seem to indicate that flood damages are expected to increase in the near future as a consequence of a global climate change (see e.g. Hall et al., 2005; de Moel et al., 2011a). Climate change has increased worldwide the interest on understanding the interaction between human activities and the hydrological cycle. The scientific literature provides numerous studies that analyze long time series of hydrological variables (such as rainfall, river discharges,

temperature, etc.) to investigate the presence of significant trends in different contexts and at different scales (Petrow and Merz, 2009; Hamed, 2008; Vorogushyn and Merz, 2013; Villarini et al., 2011). However, it is worth noting that flood damages are the result of a complex system of factors that influence the overall dynamics and impacts of flood events (see e.g. Merz et al., 2010; Elmer et al., 2012), and climate variability is only one component.

Many studies highlighted that the economic and social development in flood-prone areas are key elements for a correct interpretation of the increase of flood losses observed during last decades (see e.g. Ludy and Kondolf, 2012; Di Baldassarre et al., 2013, and references therein). For instance, considering the flood-related costs recorded in Europe over the time period 1970-2006, Barredo (2009) shows that there is no evidence of a positive trend on normalized damages; that is, a large portion of the growth of nominal losses associated with floods can be explained by the evolution of exposure to floods and wealth in floodplains. Similar results have been found looking at the damages and costs associated with hurricanes in United States between 1900 and 2005 (see Pielke and Landsea, 1998, and Pielke et al., 2008) and to globally observed disasters associated with water (see Neumayer and Barthel, 2011; Barredo, 2009). All these studies show that there are no clear evidences of an increasing trend in the normalized economic damages, even though the difficulties in considering the overall mitigation measures enforced by authorities or individuals prevent one to infer that historical data do not show a clear positive trend in the frequency and/or intensity of weather-related natural disasters (Neumayer and Barthel; 2011). Thus, even though historical data do not provide incontestable proofs of the loss increase due to climate change, caution is needed in the evaluation of the overall effects of climate change and the precautionary principle should, in any case, support the reduction of possible human impacts (Neumayer and Barthel; 2011).

These considerations are supported by investigations performed on flood risk projections over the future decades in different areas and contexts of the world (see e.g. Elmer et al., 2012; De Moel et al., 2011a; Bouwer et al., 2010). These studies highlight how land-use changes and economic development of hazard-prone areas (i.e. flood-risk exposure) may have an effect on the increase of flood losses that is comparable to, if not higher than, what is commonly associated with the expected

climate change. For instance, population growth and the increase of exposed wealth in flood-prone areas may significantly increase potential damages during flood events, and may end up being the main factors controlling the increase in recorded damages (Bouwer et al., 2010).

These considerations strengthen the interpretation of floodplains as complex human-water systems, in which the interactions between the two elements is so strong that the current floodplain configuration is actually the result of the interplay between human activities (such as flood controls, land-use changes and other measures that may affect the frequency and magnitude of flooding events) and hydrological dynamics (e.g. the frequency and severity of floods may constrain the development of human settlements) (Di Baldassarre et al., 2013; Schultz and Elliott, 2012).

A typical expression of this strong interaction is the so-called “levee effect” (Tobin, 1995), also named “levee paradox” or “call-effect”, according to which the flood-prone areas protected by a levee system attract and encourage new human settlements. The increase of the overall vulnerability of the areas may potentially result in higher damage in case of extreme flood events that cannot be restrained by the existing levee system, or in case of levee-system failures (i.e. what is usually identified as “residual flood risk”; see e.g. Castellarin et al., 2011a; Di Baldassarre et al., 2009). Investigating a specific case study in California, Ludy and Kondolf (2012) clearly point out that the presence of a levee system changes the perception of the flood likelihood in people living in the dyke-protected areas, which are perceived as completely safe from inundations. This feeling ends up increasing the vulnerability of floodplains, even in areas that were already affected by inundations, where the demographic and economic growth experienced after the inundation, due to the enhancement of the levee system, led to a well-being condition that is higher than before the inundation (Schultz and Elliott, 2012).

All these considerations underline the necessity to analyze flood risk and its evolution in time by means of holistic approaches, which take into account the interaction between social and hydrological factors characterizing a large geographical areas. A better understanding of the interplay between these elements represents a fundamental piece of information for the identification of robust large

103 scale flood-risk mitigation strategies and the definition of viable development plans for flood-prone
104 areas. However, although the “levee effect” phenomenon (Tobin, 1995; also named “call-effect”) is
105 frequently mentioned, the literature on its objective quantification is still very sparse and many
106 studies refer to estimates evaluated on each case study (see e.g. Merz et al., 2009).

107

108 **1.2 Study aims**

109 Our study focuses on the middle-lower portion of the Po river and aims at analyzing the evolution
110 during the last half century of residual flood risk in the dyke-protected floodplains. The hydrological
111 behaviour of the Po river basin has been investigated in several previous studies (see e.g., Zanchettini
112 et al., 2008; Montanari, 2012 and references therein), nevertheless the scientific literature does not
113 report any comprehensive analysis of the historical flood-risk dynamics for the entire middle-lower
114 portion of the Po river nor of the influence on this dynamics of the main controlling factors (e.g. human
115 activities that developed during last decades, climatic variability, etc.). In particular, we address the
116 investigation of the evolution in time of flood hazard and exposure to floods, being the flood risk of a
117 given area the combination of the probability of inundation (e.g. flood hazard) and of the expected
118 adverse consequences (i.e. flood exposure and damage susceptibility of the flood-prone areas, see e.g.
119 EXCIMAP, 2007).

120 First, we analyse long streamflow series available at different gauging stations located along the
121 study reach, statistically falsifying the hypothesis of changes in flood-hazard during the last half
122 century similarly to what have been shown for other regions of the world (see e.g. Kundzewicz et al.,
123 2005; Svensson et al., 2005). Second, we propose a simplified and robust approach for the
124 quantification of flood-risk dynamics associated with the evolution of exposure to floods. Third, we
125 quantitatively assess the evolution of flood risk in the dyke-protected floodplain of the study reach,
126 assessing the anthropogenic pressure by referring to land-use (i.e. focussing on residential areas) and
127 demographic dynamics observed from 1950s.

In particular, since the study area is protected against 200-year flood events (Po River Basin Authority-Adb-Po, 1999), we focus on the residual risk dynamics, thus referring to a specific low-frequency flooding scenario for which the protection measures are insufficient (see Section 5.1 for more details). We propose simplified flood-vulnerability indexes based on land-use and topographic information that are particularly suitable for large spatial scales, which we use to (1) assess the importance of the different elements contributing to the definition of flood risk and, (2) represent the evolution in time of flood exposure and residual flood risk in the flood-prone area of interest. Finally, we quantitatively assess whether during the last half-century the study area experienced the so called levee-effect, and to what degree it impacted the residual flood risk.

Our manuscript is structured as follows: Section 2 illustrates the study area and data used for the analysis; Section 3 investigates the flood-hazard evolution during the last half century; Section 4 describes the methodologies used for investigating the flood-exposure evolution; Section 5 presents the selected inundation scenario and methodologies used for the large-scale estimation of flood damages; Section 6 reports the results of the study. Finally, Section 7 reports a comprehensive discussion of the results.

2 Study area and available data

The study area consists of the alluvial plain of the Po river, the longest Italian river that flows eastward through the Northern part of Italy for about 650 km. With a total extent of about 71 000 km² the Po river basin is the wider Italian catchment and covers a large portion of the Emilia-Romagna, Lombardy, Piedmont, Aosta Valley and Veneto (see Figure 1). This area, in particular the Alpine foothills and flat portion of the basin, represents one of the most developed and populated area of Italy: more than 45% of employed Italians live here producing almost 40% of the total Italian Gross Domestic Product (GDP) (Po River Basin Authority, AdB-Po, 2006; www.adbpo.it).

Figure 1

154 The middle-lower stretch of the Po river flows across a flat and fertile alluvial area, named
155 Pianura Padana (overall extent of around 46 000 km²), where the flood-prone areas that are closer to
156 the Po river, or its major tributaries, are protected from frequent inundations by means of a complex
157 system of embankments and other hydraulic structures (e.g. pumping stations, sluice gates, etc.) that
158 are monitored and maintained by the Interregional Agency of the Po River (AIPO;
159 www.agenziainterregionalepo.it) and by the Po River Basin Authority (AdB-Po).

160 The current embankment system represents the result of the people struggle during the last
161 centuries to prevent the loss of their properties and assets due to floods. From 1705 to 1951 Pianura
162 Padana was hit by 18 major floods with 225 embankment failures along the main river or its major
163 tributaries (Govi and Turitto, 2000). In the inundations aftermath the embankment system was
164 continuously strengthened and extended, increasing from a total length of about 1 500 km on 1878, to
165 more than 2 900 km after the flood event of the 1951, when the lower stretch of the Po river
166 experienced a catastrophic flood event that caused a large inundation (~1 080 km²; see Masoero et al.,
167 2013) and severe damages (e.g., 100 victims, 900 houses seriously damaged and around 200 000
168 refugees; Amadio et al., 2013).

169 Castellarin et al. (2011a) and Di Baldassarre et al. (2009) clearly emphasized this aspect showing
170 the evolution in time of the overall length of the embankment system along the Po river and major
171 tributaries between 1800 and '50-'60s and the associated increasing trend in the sequence of annual
172 maximum water level at the Pontelagoscuro streamgauge (see Figure 1), located at the catchment
173 outlet (see also Heine and Pinter, 2012). During the last decades (i.e. from 60's) the actions of
174 adjustment of the levee system along the lower portion of the river mainly focused on the
175 strengthening of the existing embankment, while further embankment widening and raising were
176 implemented after the flood event of October 2000 (see Coratza, 2005; Castellarin et al., 2011a). The
177 current river configuration is reported in Figure 1 (box), which shows the main river stretch, the main
178 embankment system, as well as the area that can potentially be flooded in case of catastrophic flood

179 events (blue polygons). This area, named “Fascia-C” (literally C-Buffer, which we consistently use in
180 the remainder), is characterized by an overall extent of $\sim 6\,100\text{ km}^2$ and was identified by the Po River
181 Basin Authority (AdB-Po, 1999) as the envelope of all areas associated with a non-negligible residual
182 risk of being flooded, that is areas that can be flooded in case of sudden and unpredictable failures of
183 the embankment system (i.e. breaches in the embankments along the main river or tributaries that are
184 triggered e.g. by piping during major floods) or in case of flood event with a recurrence period higher
185 than the one adopted for the design of the embankments (i.e. ~ 200 year, AdB-Po, 1999). The box on
186 Figure 1 shows the C-Buffer area divided into different compartments defined referring to the layout
187 of natural and man-made structures (e.g. embankments for the Po river and its main tributaries, rivers,
188 roads, etc.; see also Castellarin et al., 2011b).

189 Despite the existence of a non-negligible residual risk in the C-Buffer (i.e. the levee failure
190 occurred in 1951 is an evidence of the residual risk that still exists in the flood-prone area), the feeling
191 of safety ensured by the embankment system attracted human settlements and the area itself went
192 through a significant economic development during the 20th century. In the light of these
193 considerations, together with the availability of historical land-use information (see Section 2.1 for
194 details), we investigate the factors that driven the evolution of the residual flood risk in the flood-
195 prone areas during last decades, focusing in particular in the period that goes from 1950s up to now.

196

197 2.1 Available data

198 We refer to data of various type collected from different sources. The following list briefly
199 summarizes the data set used for the analyses, while further information on the actual utilization of
200 these data are provided in Sections 3, 4 and 5:

- 201 - *Streamflow data*: Table 1 summarizes the characteristics of daily streamflow series recorded
202 at streamgauges of Moncalieri, Piacenza and Pontelagoscuro (see Figure 1), with lengths of 42,
203 85 and 89 years, respectively.

- *Land-use maps*: land-use maps are available for the C-Buffer and different time periods from cartographic offices of Emilia-Romagna and Lombardy administrative districts (see Figure 1). In particular, land-use information is retrieved from aerial imagery available for 1954 (G.A.I-Gruppo Aereo Italiano and WWS flights) and 2008 (AGEA-2008), with a resolution of about 150 m and 75 m, respectively, and classified referring to the standardized classes aggregation adopted by the CORINE (COoRdinated INformation on the Environment) project (EEA, 2009).
- *Demographic dynamics*: number of inhabitants available throughout Italy since 1861. The Italian National Statistical Institute (ISTAT; <http://www.istat.it>) provides information on the population dynamics with ten-year frequency at each census sections.
- *Assets economic values*: economical values of residential buildings in the alluvial area. The Italian Revenue Agency (Agenzia delle Entrate (AE); <http://www.agenziaentrate.gov.it>) provides the open-market values for different assets, taking into account different classes for residential and industrial buildings and the overall economic well-being of the region (see Section 5.2 for more details).
- *Topographic information*: topography of the study area is retrieved from TINITALY/01 (Tarquini et al., 2007). Created by using heterogeneous elevation datasets (i.e. contour lines, elevation points, etc.), TINITALY/01 represents the most accurate Digital Elevation Model (DEM) covering Italy. It is characterized by a horizontal resolution of 10 m and a vertical accuracy (i.e. root mean square errors ranging from 0.8 to 6 m) higher relative to other global DEMs (i.e. SRTM, ASTER; see Tarquini et al., 2012).

3 Flood-hazard evolution – trend detection in streamflow series

3.1 Methods

Many studies investigated the streamflow regime of the Po river (see e.g., Visentini, 1953; Piccoli, 1976; Marchi, 1994). Zanchettini et al. (2008) analyzed the long-term daily streamflow variability at

229 Pontelagoscuro (see Figure 1) by referring to a time series longer than 200 years, in which some daily
230 streamflow values were re-constructed from historical information on water surface. The analysis
231 highlighted an increase in the streamflow values observed at the streamgauge of Pontelagoscuro
232 during last decades, concluding that this increase could be mainly attributed to the massive
233 embankment works implemented along the river network during previous decades, rather than to
234 climate changes. The authors also pointed out the existence of perturbation periods (mainly associated
235 with droughts) lasting for several years. More recently, Montanari (2012) reached similar conclusions
236 by investigating the variability of daily streamflows observed along the Po river and some its major
237 tributaries. The study highlighted the presence of local perturbations (i.e. periods characterized by
238 water scarcity, or water abundance), whose memory lasts for long periods of time (i.e. several years),
239 which can be associated with the size of the drainage area. Even though this evidence suggests the
240 presence of long-term persistence that would be worth investigating, the research of trend interested
241 only the gauged section of Pontelagoscuro and was made by means of a linear regression application.

242 In this study, we further analyse the variability of the daily streamflow regime of the Po river by
243 testing for trends the daily streamflow series collected at three gauging sections along the main
244 stream: Moncalieri, Piacenza and Pontelagoscuro (see also Figure 1 and Table 1). The streamgauges
245 are located along the same river and therefore the observed daily streamflow series are necessarily
246 statistically correlated to each other, which is likely to result in similar outcomes of statistical testing
247 (see Douglas et al., 2000). Nevertheless, we considered all three series since they refer to rather
248 different drainage areas and periods of time (see Table 1 and Figure 1). In particular, we adopted the
249 non-parametric Mann-Kendall (MK) test (Mann, 1945; Kendall, 1975), that is one of the most robust
250 trend detection method applied in many studies to different hydrological variables (see for example
251 Yu and Wang, 2004, and references therein) and spatial scales (see e.g. Douglas et al., 2000; Hamed,
252 2008; Villarini et al., 2011). The MK test analyses the ranks of the observations rather than their actual
253 values, it is non-parametric (distribution-free) and less sensitive to outliers than other parametric
254 approaches, therefore the MK test appears to be particularly suitable for detecting statistically
255 significant trends in hydrological time series (see Yue et al., 2002, Petrow et al., 2009). However, the

256 presence of serial correlation among the daily streamflow data may impact the power of MK test (von
257 Storch and Cannon, 1995). To overcome this problem we applied the trend free pre-whitening (TFPW)
258 procedure to the study series; TFPW removes serial correlation from time series, and hence it
259 eliminates the effect of serial correlation on the MK test (see Yue et al., 2002, for details). In particular,
260 we perform a two-sided trend test at 5% significance level through the MK-TFPW procedure on the
261 sequences of annual maxima (AMS), mean (MEAN) and standard deviation (SD) of daily streamflows.

262 *Table 1*

263
264 **3.2 Results and Discussion on flood-hazard evolution**

265 Figure 2 shows the annual sequences of maxima (AMS), mean (MEAN) and standard deviation
266 (SD) of daily streamflows at Moncalieri, Piacenza and Pontelagoscuro, along with the related linear
267 regression lines fitted over the observation period. Table 2 reports the results of the Mann-Kendall
268 (MK) trend analysis test, listing Sen's slope value, β , test p -value, and increase/decrease of the
269 statistics over the observation period, Δ .

270 Figure 2 clearly highlights the absence of significant and consistent long-term trends on the daily
271 streamflow statistics (i.e. AMS, MEAN, SD) computed for the three streamgauges over the
272 corresponding observation periods. Considering Moncalieri cross-section, Sen's slopes, β , appear to be
273 limited for all considered statistics, pointing out a small increase in the annual maxima and mean
274 discharge values (β equal to 2.09 and 0.31 m³/s/year, respectively; see Table 2), while the river daily
275 streamflow variability (i.e. SD) is almost constant over the period (β =-0.02 m³/s/year). p -values
276 reported for Moncalieri indicate the absence of statistically significant long-term trends at 5% level.
277 Similar results are observed at Piacenza, where MEAN and SD do not show significant changes over
278 the observation period, even though AMS is associated with a limited increase (β equal to 2.02
279 m³/s/year), which is consistent with the one observed for Moncalieri. The slight increase of annual
280 maximum daily discharges in the upstream cross-sections of Moncalieri and Piacenza (see Figure 1) is
281 confirmed at Pontelagoscuro, where this feature appears to be emphasized (see Figure 2 and Table 2).

AMS series at Pontelagoscuro is associated with a slope β of 13.2 m³/s/year, with an overall increase of about 1178 m³/s for 90-year observation period; although not negligible, this trend is not significant from a statistical viewpoint (p-value = 0.106).

Furthermore, concerning the non-significant positive trend associated with the last 90 years of observations, it is worth highlighting that the same analysis repeated for the data observed after 1950 results in a statistically non-significant negative trend of -2.73 m³/s/year. Finally, Pontelagoscuro MEAN sequence does not evidence any change during the observation period, while SD shows an overall increase of about 225 m³/s, which is significant at the 5% level (see Table 2).

The extended analysis of historical stream flow series carried out in our work confirms the findings of previous studies (e.g. Montanari 2012; Zanchettini et al., 2008) and highlights the absence of statistically significant trends on streamflow series along the overall river reach (see Figure 2). The impact of the flood-hazard variability in the assessment of the residual flood risk dynamics during the last half century appears to be practically negligible and statistically not significant, making reasonable the hypothesis of stationarity of the streamflows data set. On the basis of these considerations the likelihood of extreme flood events responsible for the residual flood risk in the area of interest (such as flood events with return period higher than 200 years) can be considered not significantly changed during the last half century.

Table 2 – Figure 2

4 Evolution of exposure to floods: simplified tools for large-scale applications

4.1 Land-use dynamics

We investigate the land-use evolution in the Po river basin focusing in particular on Emilia-Romagna and Lombardy administrative districts (see Figure 1), which cover entirely the C-Buffer (i.e. the floodable area in case of the Tr-500 flood event; see box in Figure 1). Our analysis considers land-use maps available for 1954 and 2008 (see Section 2.1). The maps were constructed on the basis of

307 historical aerial photographs with different spatial resolution (150 m and 75 m for the 1954 and 2008
308 maps, respectively), however the land-use classifications adopted in both cases are consistent and
309 enable one to compare the two time periods. The land cover data in both maps use a hierarchical
310 structure similar to the one adopted by the CORINE project (EEA, 2009), in which different soil-uses
311 are organized by means of several levels of aggregation. In this study the evaluation of the flood
312 exposure evolution is performed referring to urban and residential areas only. Table 3 reports the land
313 cover categories used for the different maps adopting the CORINE classification as reference.

314 *Table 3*

315 We evaluate the expansion of urban and residential areas by referring to two different spatial
316 scales. First we consider a local scale by referring to C-Buffer compartments only (see Figure 1).
317 Second, we evaluate the land-use evolution at a larger scale (i.e. regional analysis), comparing the
318 overall extension of urban areas in 1954 and 2008 in Emilia-Romagna and Lombardy districts. Results
319 obtained for the local (C-Buffer) and regional (large-scale) analyses can then be compared to gain a
320 deeper understanding of the evolution of exposure to floods, providing interesting insights to foster
321 the discussion on the effectiveness of the “levee-effect” (or “call effect”) on the floodplains areas (see
322 Sections 6 and 7).

323 We use the land-use maps described above to derive a large-scale assessment of the exposure to
324 floods in the C-Buffer. In particular, we combined the land-use class of interest (i.e. urban settlements)
325 of each compartment with the digital description of the topography (i.e. 10 m DEM; see Section 2.1) to
326 retrieve a simplified altimetric description of urban and residential areas through a so-called
327 hypsometric curve, which we named Hypsometric Vulnerability Curve (HVC). The hypsometric curve
328 of a given area reports on the x-axis the percentage (or the portion) of area characterized by elevations
329 lower than the value reported on the y-axis. HVCs of each compartment of the C-Buffer combine land-
330 use information with information on elevation retrieved from the 10 m DEM. Zhang et al. (2011) firstly
331 proposed the use of hypsometric curves in the Florida Keys for the evaluation of the impact of
332 different scenarios of sea level rise on human population and real estate property.

Figure 3

As an example, Figure 3 reports a schematic representation of the HVC defined for a specific compartment and land-use class. We construct the urban and residential areas HVCs for each compartment for 1954 and 2008 in a GIS (Geographic Information System) environment. HVCs represent a valuable tool for a preliminary assessment of the exposure to floods of each compartment, and, when one can construct curves relative to different time periods as in our case, these curves can be particularly useful for characterizing the dynamics of urban areas over a given historical period (e.g. in the dike-protected floodplain of the Po river over the last half century). The schematic representation of Figure 3 illustrates HVC and the information that can be retrieved from such a curve. For instance, the HVC graphically represents the altimetric characteristics of a specific land-use class in a given compartment (e.g. residential settlements), and HVCs of different periods enable one to assess how and where (i.e. closer or farther to the river) a specific land-use class developed over time (see Section 6.1 and Figure 7 for details). Furthermore, assuming the dashed line of Figure 3 as a hypothetical inundation level, its intersection with the HVC identifies the extent of the affected area and may be particularly useful for a prompt assessment of flood damages (see Section 5.2 for details).

4.2 Population dynamics

The number of people living in flood-prone areas represents a fundamental element for the evaluation of the exposure to floods and is a key factor of the “levee effect” phenomenon (see e.g. Di Baldassarre et al., 2010, 2013; Barredo, 2009). Accordingly, we analyze the population dynamics in the Po river basin, assessing if the strengthening of the levee system carried out during last century (see Section 2 and also Di Baldassarre et al., 2009, and Castellarin et al., 2011a) is associated with any population growth in the flood-prone areas in spite of the residual flood risk. In particular, we evaluate the population dynamics from 1861 to 2011 considering the number of inhabitants recorded by the

359 Italian National Statistical Institute (ISTAT) (census data are provided with a 10-year frequency) and
360 provided for each Italian municipality. Once collected, the population data have been gathered
361 together distinguishing between Emilia-Romagna and Lombardy regions and all of the compartments
362 of the C-Buffer (see Figure 1).

363 Given the extent of urban areas and the overall number of inhabitants living in a specific
364 municipality within a C-Buffer compartment we estimate the population density under the hypothesis
365 of a uniform distribution over the urban extent. The population density of a specific compartment is
366 calculated as the weighted average among different municipalities, weighting that data proportionally
367 to extent of urban areas. Then, we derive the Hypsometric Inhabitant Curves (HICs) for 1954 and
368 2008 by combining the average population density with the altimetry of the urban area in a given
369 compartment (see the procedure adopted for the HVC construction; Figure 3). HICs are curves that
370 report the overall number of inhabitants living in a compartment below a given elevation: they
371 integrate information on the number of people living in a specific compartment with the overall extent
372 of urban areas, obtained from land use maps, and elevation retrieved from a DEM of the area of
373 interest. The curves may represent useful tools for a preliminary evaluation of the exposure to floods
374 of a specific area. For instance, HICs may enable one to estimate the number of people that could be
375 affected by a given inundation scenario over a floodplain area; alternatively, HICs constructed for a
376 given inundation scenario and floodplain compartment by considering census data and land-use maps
377 for different years may effectively summarize the impacts of demographic dynamics on flood risk.

378

379 **5 Damage calculation for urban areas**

380 Flood risk management recently shifted its main focus from flood hazard (i.e. hazard reduction) to
381 a risk-based view (i.e. risk reduction) (see e.g. Vis et al., 2003; Merz et al., 2010; De Moel et al., 2012).
382 This approach considers the interplay between hydrological and socio-economic factors and the
383 calculation of the expected flood damage represents a fundamental piece of information for the overall
384 flood-risk mitigation process. The evaluation of the overall costs of natural hazards, such as flood

385 events, is a challenging task due to the variety of damage types that may be directly or indirectly
386 related to the hazard. Meyer et al. (2013) recently summarize these costs distinguishing four different
387 categories identified in relation to their nature and to the methodologies adopted for their assessment:
388 direct and indirect costs, business interruption costs, and intangible costs. Considering flood events,
389 direct costs represent the damages occurred to properties (e.g. buildings, stocks, cars, infrastructure,
390 etc.) physically hit by the flood. Business interruption costs result from the interruption of the
391 economic activities in the flooded areas, for example because of inaccessibility or because of the
392 destruction of the working instruments (see Meyer et al., 2013). Indirect costs summarize all the
393 economic losses that can be related to direct and indirect (e.g. business interruption) damages,
394 occurred both inside or outside the affected area, even considering the effects on a broad timeframe
395 after the event (see Carrera et al., 2015 for more details). Finally, intangible costs consider the impact
396 on services, goods or human beings which have not a market value and for which the damage
397 estimation in monetary terms is not trivial, if not impossible (e.g. health and environmental impacts,
398 damages to cultural heritage, etc.; Meyer et al., 2013; Markantonis et al., 2012).

399 Concerning the estimation of different types of flood losses the literature provides a series of
400 methodologies of various complexity based on different type of data and assumptions, and suitable for
401 different scales of application (see Meyer et al., 2013, for a comprehensive review of these
402 approaches). Traditionally, the flood damage assessments mainly refer to direct losses in view of the
403 greater ease with which they can be estimated. In particular, the scientific community proposes
404 simplified damage models that estimate the expected direct flood damages by means of depth-damage
405 functions (also named susceptibility functions), where the economic damage of a specific element (e.g.
406 a building) is a non-decreasing function of the water depth, which is sometimes integrated with some
407 other hazard factors (i.e. flow velocity, duration, pollution, etc.; see Jongman et al., 2012). More
408 recently, sophisticated multi-parameter models have been proposed for a local estimation of losses in
409 private households and companies (e.g. FLEMO; see Kreibich et al., 2010; Elmer et al., 2010). Even
410 though the former approach is less accurate and associated with a larger degree of uncertainty (see
411 e.g. Apel et al., 2008; De Moel et al., 2011b), in the light of the large spatial scale of interest (i.e. overall

C-Buffer area) we estimate the expected flood damage referring to a simplified approach based on the joint use of a depth-damage curve and the previously defined HVCs.

Differently from previous applications, where hypsometric curves were used only for identifying the extent and amount of affected properties (see Zhang et al., 2011 for sea level rise scenarios), we propose an original application of HVCs in combination with a given inundation scenario and specific depth-damage curves (e.g. accurately identified for a specific land-use or buildings type, see Section 5.2 for a detailed description about flood damage estimation) that enables the user to calculate the flood losses. We focus on direct damages (i.e. direct tangible damage) for residential building, while we neglect all other costs in this preliminary application.

5.1 Inundation scenario

For the evaluation of the flood hazard we refer to the inundation scenario generated by the numerical model developed by Castellarin et al. (2011b) whom implemented a quasi-two-dimensional (quasi-2D) model (Willems et al., 2002) for the Po river stretch considered herein (from Isola S. Antonio to Pontelagoscuro, ~350 km; see Figure 1). The model describes the main river reach by means of cross-sections retrieved from a detailed digital elevation model (LiDAR, with a spatial resolution of 2 m), while all dike-protected floodplains are represented as storage areas connected to each other and/or the main channel by means of weirs mimicking the system of minor levees. Adopting a similar modeling strategy, all C-Buffer compartments are represented as storage areas and connected to the main river, or dike-protected floodplains, by means of lateral structures that reproduce the main embankment crests. Volume-level curves regulate the hydraulic behavior of all storage areas, and, in case of inundation of a dyke-protected floodplain or C-Buffer compartment, the simulated water level is computed as a function of the water volume exchanged with the main river and/or adjacent storage areas. Volume-level curves were estimated referring to LiDAR imagery (2 m resolution) for the dyke-protected floodplains and to a 10 m resolution DEM (Tarquini et al., 2007) for C-Buffer compartments. The quasi-2D model was calibrated referring to the historical flood event

438 occurred in October 2000 and then used for simulating a major flood event, hereafter referred to as
439 Tr500, which represents a low frequency/high intensity event associated to a return period of ~500
440 years (see Castellarin et al., 2011b for details).

441 The main embankment system of the middle and lower portion of the Po River is designed to
442 cope with flood events associated with return periods up to ~200 years, which are significantly less
443 intense than the Tr500 event identified in Castellarin et al. (2011a and 2011b). Considering the
444 homogenous protection level ensured by the major embankment system along the entire study reach
445 we referred to the Tr500 event as the reference flood scenario, thus limiting the estimation of the
446 residual flood risk to the likelihood of this extreme event, neglecting the hazard related to flood events
447 associated to return period lower than 500-year but not contained by the embankment system or to
448 possible levee failures. Considering these latter possibilities (e.g. breaches on the embankment due to
449 seepage, piping, etc.) in our study we do not explicitly consider the possibility of levee failures for
450 more frequent events. Nevertheless, the proposed approach is perfectly suitable for applications that
451 for example adopt comprehensive multivariate Monte Carlo resampling techniques for a thorough
452 characterization of the flooding hazard in the region of interest (see e.g. Vorugushyn et al., 2010;
453 Domeneghetti et al., 2013).

454 The Tr500 inundation scenario is modelled by simulating failures along the embankment system
455 (i.e. formation of breaches in case of overtopping of main embankments, see configuration BREACHBL
456 in Castellarin et al., 2011b). Dike overtopping may occur in BREACHBL if the water level exceeds the
457 crest elevation of the embankments, under this circumstance, as consequence of the flow erosion on
458 the out-board side of the levee, the quasi-2D model simulates the formation of a levee-breach
459 according to literature information on width, depth and time of full development recorded for the Po
460 river (see e.g. Govi and Turitto, 2000). The numerical model enables the simulation of multiple
461 breaching events as a result of concurrent overtopping phenomena along the main embankment
462 system, thus enabling the inundation of several C-Buffer compartments during a single major flood
463 event (see details in Castellarin et al., 2011b). In order to better highlight the role of the exposure to
464 floods on the evolution of the flood risk the numerical simulations are performed, for both the periods

of interest (i.e. 1954 and 2008), referring to the actual levee system configuration, thus neglecting the strengthening of the levee system eventually performed during last 50 years. Furthermore, the absence of consistent and statistically significant long-term trends on the streamflow series recorded along the Po river (see also Section 3.2) enables the use of the same inundation scenario for the entire period of interest (i.e. from 1954 to 2008), thus facilitating the evaluation of the flood exposure evolution on the overall flood risk.

5.2 Estimation of direct economic losses

It is well known that the estimation of direct damages associated with a flood event is a challenging task which is affected by a large amount of uncertainty (Cammerer et al., 2013). Concerning Italy, Molinari et al. (2014) related this uncertainty with the lack of high quality post-flood event damage data, which are necessary for a proper calibration and validation of damage models. In our analysis, considering the scale of interest (i.e. large scale analysis: middle-lower portion of the Po river) and the nature of the proposed approach (i.e. simplified numerical tools to evaluate the flood risk), the quantification of the flood exposure is performed by referring exclusively to the economic value of private buildings prone to inundation events, neglecting other direct (e.g. damages to public or commercial buildings) and indirect costs.

The Italian Revenue Agency (*Agenzia delle Entrate*, AE) publishes the economic value (E [€/m²]) of different types of private buildings (e.g. civil houses, offices, stores, etc.) in each Italian administrative district (spatial scale of municipality) every six months (economic values of public buildings are not provided by AE and thus excluded from the present investigation). Table 4 reports an example of monetary estimates available for buildings of each municipality conditioned upon the definition of use (i.e. residential, commercial, services or productive) and typology (i.e. detached house, box, stores, etc.). Focusing on residential buildings and assuming an unique building type (i.e. civil houses on Table 4), we define the reference economic value (E [€/m²]) for urban settlements within any given compartment of the C-Buffer as the average of the E values provided for all the

municipalities, weighted proportionally to their urban extent located within the C-Buffer (see Table 5). Therefore, the overall value of urban properties can then be approximated by the product of the average economic value and the overall urban area extent in the compartment, which we obtained from the land-use maps available for 1954 and 2008 (see Section 4.1).

It is worth noting that the damage evaluation relies on the assumption of a constant economic value for urban buildings over the period of interest (i.e. 1954 and 2008). Without lack of generality, our analysis considers two different land use maps, yet, for the sake of comparison, we refer to 2014 economic value of buildings for both historical land-use scenarios.

The literature provides a wide set of depth-damage curves that offers the possibility to cover different applications contexts, considering different types of buildings (i.e. residential, commercial, industrial, etc.; see e.g. Thieken et al., 2008) and the effect of factors which may influence the expected damages (i.e. contamination, levels of private precaution, etc.; see e.g. Kreibich et al., 2010). These curves generally express the percentage of damage of a specific asset as a function of the water depth and are constructed on empirical damage data (i.e. historical inundation) or using expert judgment and synthetic analysis.

Among the available curves, we refer to the damage-curve implemented in the Multi-Colored Manual (MCM; Penning-Roswell et al., 2010) that estimates the expected losses for residential buildings as a function of the local water depth (see Figure 4). The MCM is one of the most advanced models for flood-damage estimation within Europe (Jongman et al., 2012) and represents a viable tool for the estimation of the losses related to floods.

Figure 4

Combining the MCM susceptibility curve and the overall economic value of residential buildings, we compute the expected damage in a given C-Buffer compartment for a given inundation scenario through a procedure that is schematically illustrated in Figure 5. The horizontal blue line of Figure 5a

517 represents the maximum water level [m a.s.l.] resulting from the quasi-2D simulation of the
 518 inundation scenario of interest (see also Section 5.1). As already pointed out, the extent of the
 519 inundated urban area (A_{tot}) can be easily retrieved from the intersection between the elevation of the
 520 maximum water level (blue line in Figure 5a) and the HVC of the flooded compartment. The damage
 521 (D) to urban settlements is associated with the local water depth (h) by means of the depth-damage
 522 curve (see Figure 5b for a schematic example). This curve also identifies a water-depth value (h_{100})
 523 associated with 100% of damage, meaning that for buildings hit by water depths equal or higher than
 524 h_{100} the flood-loss coincides with the value of the buildings. Based on this hypothesis, one can estimate
 525 the extent of urban area where the damage is maximum (A_{100} [km²] in Figure 5a) by subtracting h_{100}
 526 (i.e. water depth equal to 3 m for the MCM depth-damage curve; see Figure 4) to the maximum flood
 527 elevation (blue line in Figure 5a). Everywhere in A_{100} the water depth is higher than h_{100} and therefore
 528 the flood damage can be estimated as:

$$D_{100} = E \cdot A_{100} \quad (1)$$

529 where E [€/m²] indicates the overall average economic value of residential buildings in the
 530 compartment (see Table 4). In the remaining portion of the inundated urban area ($A_{tot} - A_{100}$ in Figure
 531 5a) the flood damage, D_h , depends on the local water depth and can be expressed as:

$$D_h = \int_{A_{100}}^{A_{tot}} E \cdot d[h(A)] dA \quad (2)$$

532 where the percentage of losses $d(\cdot)$ is a function of $h(A)$ through the depth-damage curve (see Figure
 533 4). According to eq. (1) and (2) we calculate the total direct damage in the compartment, D , as:

$$D = D_{100} + D_h \quad (3)$$

534 It is worth noting that the damage estimate provided by eq. (3) could be easily extended to other
 535 buildings typologies (see Table 4) or land-uses by considering a better knowledge of these assets

536 within a given compartment and their economic values, that is resorting to a set of different
537 hypsometric and depth-damage curves, possibly differentiated within the same compartment.

538 *Table 4, Table 5, Figure 5*

539

540 **6 Results of the flood-exposure analysis**

541 **6.1 Urban areas dynamics**

542 Table 6 summarizes the main features of the Tr500 inundation scenario, listing the C-Buffer
543 compartments that are flooded due to overtopping of the levee crests and consequent levee breaching
544 (see Section 5.1 and Castellarin et al., 2011b for details). For each flooded compartment, Table 6
545 reports the maximum water depth, the total overflow volume and the maximum water inundation
546 level simulated by the quasi-2D model (see also Figure 5a for a schematic representation of these
547 terms). Table 6 also reports an estimate of the overall extent of urban areas flooded in 1954 and 2008
548 under the inundation scenario Tr500, which are obtained by combining the maximum water
549 inundation levels computed in Castellarin et al. (2011b) with the Hypsometric Vulnerability Curves
550 (HVCs) proposed in this study (A_{tot} in Figure 5).

551 *Table 6*

552 Inundation occurs in 8 compartments as a consequence of just as many levee breaches; estimates
553 of the overall urban extent affected by the inundation scenario are equal to 1064 ha in 2008 and 496
554 ha in 1954.

555 According to eq. (1-3) and the MCM depth-damage curve (see Figure 4 and Figure 5), Figure 6
556 illustrates the overall losses, D [Billions of Euro], estimated for the flooded compartments by referring
557 to the average economic value of urban buildings E (€/m²) reported in Table 5. In particular,
558 considering the urban extent mapped for 1954 and the related HVCs, the overall damage associated
559 with urban buildings is equal to ~3.6 B€ (present value), with around 65% of the total losses
560 concentrated in the compartments number 8 and 20 (see Figures 1 and 6). As a consequence of the

urban expansion, the losses estimated for the 2008 urban extent rise to ~8.1 B€ (present value), more than twice the 1954 losses. Compartments 8 and 20 are responsible for ~74% of the total damage in 2008. The higher damage in these compartments can be justified by considering the high economic value of urban settlements (compartments 20 and 8 have the highest and the fourth-highest E values among those provided by AE for the residential buildings, respectively; see Table 5) and the amount of urbanized areas exposed to flood. In fact, looking at Table 6, the flooded urban areas of these compartments are larger than the others for both reference years (1954 and 2008), thus resulting in high damages. Furthermore, the striking flood-risk evolution observed in these compartments in the period 1954-2008 (see Figure 6) can also be explained by considering the spatial evolution of the urban areas, that is the location where this urban extension predominately occurred. As an example, Figure 7 reports the HVCs for urban areas of compartments 8 and 10 in the period 1954 and 2008, while the blue dashed lines in both panels represent the maximum inundation levels obtained from the quasi-2D model (see also Figure 5a). The comparison of those HVCs highlights that the urban expansion on the compartments 8 mainly occurred in the most depressed portion of the compartment, thus exacerbating the flood exposure of urban settlements (a similar land-use evolution characterized the compartment 20). On the contrary, referring to compartment 10, the urban development occurred in the highest portion of the compartment (i.e. mainly above 45 m a.s.l.; see Figure 7) with the consequence that the flood exposure did not increase significantly during the reference period.

The analysis of these different dynamics clearly emphasizes the importance of a correct land-use planning for flood-risk mitigation and highlights the suitability of HVCs as a tool for the identification of alternative flood-risk attenuation strategies (see Section 7 for a more comprehensive discussion).

Table 6 - Figure 6, Figure 7

6.2 Population dynamics

Panel a) of Figure 8 illustrates the temporal dynamics of the number of inhabitants of Emilia-Romagna and Lombardy administrative districts (grey line), where the C-Buffer is located (see Figure 1), showing a nearly constant grow rate from 1861 to 2011. Focusing on the C-Buffer, the black line on Figure 8a highlights a different evolution, with a negative population trend that started during '50s and lasted since 2001. A similar pattern can be seen looking at the panel b) of Figure 8, which compares the population density in the C-Buffer and in Emilia-Romagna and Lombardy.

Figure 9 reports the estimated number of people living in the C-Buffer that are potentially affected by the Tr500 inundation scenario. These values are estimated by combining the maximum water level simulated for one of the 8 flooded compartments with its corresponding HIC (Hypsometric Inhabitants Curve; see Section 4.2). Black and grey bars in Figure 9 represent the simulated number of people affected by the inundation scenario in 1954 and 2008, respectively. As showed in the figure, the number of inhabitants exposed to flood in 2008 (grey bars) is lower than the one estimated for 1954 for all compartments but no. 20, where the increase in the number of inhabitants is mainly due to the presence of Parma, which is a rather large city. The cumulated number of potentially affected people that can be computed moving downstream along the study reach (i.e. going from Compartment 1 to 20) is illustrated as a black line for 1954 and grey line for 2008, totalizing ~30 400 people in 1954 and ~ 29 400 people in 2008.

Figure 8, 9

7 Flood-risk evolution during the last half-century: Discussion

7.1 Flood-hazard vs. flood-exposure dynamics

Consistently with previous investigations performed for the Po river (see e.g. Montanari et al., 2012; Zanchettini et al., 2008), the results of trend detection analyses performed along the study reach point out the absence of statistically significant temporal trends, aside from a slight increase of the

610 annual variability of daily streamflows recorded at the Pontelagoscuro. Therefore the flood-hazard
611 evolution along the middle and lower portion of Po river in the last five decades does not seem to play
612 any significant control on the flood-risk dynamics over the same time span. This supports our
613 assessment of residual flood-risk changes on the basis of a 500-year inundation scenario identified
614 referring to streamflow data collected since 1917-21 along the study reach (see Castellarin et al.,
615 2011a), which we consider for representing the residual flood-hazard for the study area (i.e. the C-
616 Buffer, or dyke-protected flood prone area along the middle lower portion of the Po river).

617 We show that coupling HVCs with inundation scenarios simulated by means of a simplified
618 hydraulic model (e.g. quasi-2D) may represent a suitable and effective tool for an approximated
619 quantitative assessment of direct damages to residential settlements over large geographical areas. In
620 particular, concerning our case study we show that flood risk associated with direct economic losses to
621 private buildings doubled since 1954, mainly due to the expansion of urbanized areas in the dyke-
622 protected floodplain (i.e. C-Buffer). Figure 6 shows a significant variation of economic losses
623 associated with compartments 8 and 20 (see also Figure 1 and Figure 7), which are the most
624 urbanized compartments and are characterized by large towns. Generalized expansion of urban areas
625 notwithstanding, the number of exposed inhabitants decreased in all C-Buffer compartments but 8 and
626 20, where it remained the same (compartment 8) or increased (compartment 20) during the study
627 period (see Figure 9). This result might be a consequence of inaccuracies of land-use maps adopted in
628 this analysis, but it also might be representative of an inefficient land planning and utilization (see e.g.
629 Bhatta et al., 2010). The consequences of this phenomenon, usually known as “urban sprawl”, can be
630 seen through changes in land-use and land-cover of a specific region, increasing the built-up and paved
631 area (Sudhira and Ramachandra, 2007), without a corresponding increase of inhabitants (see also
632 Figure 8). In fact, the birth and growth of residential settlements in rural areas is a common
633 phenomenon in Northern Italy, even though expansion of metropolitan areas is definitely more
634 evident (ISTAT, 2008; Settis, 2012). ISTAT (2008) found that the urban areas mapped during the 2001
635 census covered nearly the 6.4% of the Italian territory with an increase of about 15% compared to
636 1991, whereas, in the same period, the population grew only 0.4%. Differently from metropolitans

637 area characterized by high population density, rural areas in the North-Eastern part of the country (i.e.
638 Lombardy, Veneto and Romagna) experienced an unbridled soils consumption due to a low density
639 urban development (urban sprawl; ISTAT, 2008). These new settlements represent, in some cases, the
640 outcomes of inefficient and speculative urban, and even industrial in some cases, expansion plans,
641 which did not result in economic (i.e. well-being) and social developments (see Settis, 2012). As a
642 consequence, the extent of residential areas reported in land-use maps are not always representative
643 of a higher number of inhabitants.

644

645 **7.2 Main assumptions and limitation of the proposed simplified approach for flood-**
646 **damages computation**

647 Despite the potential of the methodology, there are some limitations that have to be considered
648 given the assumptions adopted in our study. First, the spatial distribution of different building types
649 (e.g. commercial, stores, offices, etc.) over the area of interest cannot be inferred from land use maps
650 that are typically adopted for large scale analysis (e.g. Corine Land Cover). The lack of accurate
651 information concerning the location of specific building categories constrains the possibility to
652 evaluate their exposure to floods through specific HVCs (i.e. different HVCs defined for civil or
653 detached houses, garages or other buildings category such as those reported in Table 4).

654 Second, the adoption of AE estimates (see Table 5) inevitably undervalues the overall losses for
655 urban areas, and in particular for residential buildings, since a series of other direct (e.g. chattel,
656 furniture, stocks, etc.) and indirect (e.g. economic losses indirectly related to the loss of private
657 houses) costs are not considered and economically quantified. The estimate provided by AE
658 represents the present real estate market value of a given building type, that is more an expression of
659 the overall economic well-being of a specific area rather than the actual economic loss in case of a
660 flood event. This bias is expected to be more significant for the productive infrastructures (i.e.
661 industries), where a number of different variables (such as for example the type of production, the

662 technology level of the industries, the amount of stocks, the day of work interruption, etc.) strongly
663 influence the overall damages associated to inundation events.

664 Finally, using an averaged economic value for all urban assets within a given compartment may
665 introduce biases in the economic assessment of the flood impacts. The expansion and development of
666 urban areas at higher elevations in the compartment (and thus in “safer” locations) may increase the
667 overall economic value use of urban settlements within the compartment. Consequently, averaging the
668 economic value over all residential areas in the compartment would increase the economic value also
669 of rural residential areas situated in the lowland portion of the compartment, with the paradox that a
670 correct land-use development policy may increase the risk in the flood-prone areas. This limitation can
671 be easily overcome by constructing different HVCs for different municipalities (or economically
672 different residential areas) within each compartment and by using them in parallel. Furthermore,
673 when using a single HVC for all urban settlements within a given compartment, as in this study, bias
674 can be effectively reduced by referring to a single economic value, as we did (i.e. 2014), for all
675 considered historical land-use scenarios (i.e. 1954 and 2008 in this study). Under this hypothesis, the
676 analysis of the urban development over the period of interest is considered exclusively in terms of
677 elevation, that is considering in which part of the compartment the urban area expanded (i.e. in areas
678 that are more or less prone-to-floods), without considering its economic development during the last
679 half century.

680 Despite these limitations, the proposed methodology appears appropriate for the purpose of the
681 analysis, that is not aimed at providing a comprehensive and exhaustive quantification of the flood risk
682 or of the overall flood losses expected in case of an extreme flood event, but rather to propose a tool
683 which enables the inferring of factors that mainly driven the evolution of the residual flood risk in a
684 specific area, or for investigating alternative flood-risk mitigation strategies at basin scale (see Section
685 7 for more details).

686

687 7.3 The “levee paradox” along the Po river

688 Following the concept of the “levee effect” (see e.g., Tobin, 1995), the feeling of safety ensured by
689 levee systems may encourage the economic and social growth on the floodplain areas, leading to the
690 potential condition for a faster development of human settlements. However, considering our study
691 area, we already stated that while during the last fifty years we observe an increase of the total
692 economic losses associated with a given inundation scenario (see Figure 6), the “levee effect”
693 paradigm is not supported by the associate population dynamics. Considering Figure 8, the population
694 growth on the area closer to the river appears comparable with the one measured in the remaining
695 part of the basin (i.e. Emilia-Romagna and Lombardy) until 1950. Starting from the 50's, people moved
696 from the floodplains toward the major cities and settled far away from the main river, causing a
697 significant decrease of number of people exposed to floods. The “shock” induced by the flood disaster
698 occurred in the 1951 to the floodplain socioeconomic system (see e.g., Amadio et al., 2013; Di
699 Baldassarre et al., 2013) is clearly visible in Figure 8. Together with an increased flood-risk awareness
700 resulted from the 1951 inundation event, the rapid industrial and economic growth that characterized
701 the aftermath of the II World War is undoubtedly another important driver that attracted people from
702 rural areas towards richer and more industrialized areas, such as large cities.

703 Figure 10 further investigates the levee paradox in the study area. Panel a), in particular,
704 compares the growth rate of the urban settlements in the C-Buffer with the one observed in the Emilia-
705 Romagna and Lombardy districts during the last half-century. Urban extent in the C-Buffer doubled in
706 the last fifty years (increase of about 180%), while the growth rate observed in Emilia-Romagna and
707 Lombardy districts is higher than or equal to 230%. Even though the urban development in the flood-
708 prone area is evident and representative of a levee-effect, it appears to be less pronounced than in
709 other parts of the basin. These findings seem to support the idea that the expansion of residential
710 areas is related mainly to social and economic drivers, than to the proximity to the water, that no
711 longer represents a peculiarity of favorable development conditions in developed society (Di
712 Baldassarre et al., 2013). A different behavior could otherwise be expected considering the industrial
713 sector, where the availability of a large amount of fresh water still represents a key element for

developing productive activities. Panel b) of Figure 10 confirms these considerations for the study area. Referring to the results of a preliminary investigation, panel b) of Figure 10 compares the extent and growth rate of industries in the C-Buffer and in the Emilia-Romagna and Lombardy districts, showing an opposite trend relative to what can be observed for residential areas. Even though industrial areas grew over 712% in Emilia-Romagna and Lombardy, the industrial activities experienced a higher grow-rate (1350%) in the areas closer to the river (i.e. C-Buffer). The presence of a levee system, together with the proximity to abundance of fresh water, is evidently an incentive to the development of industries, which is also encouraged by the lower costs of formerly rural areas. The dynamic of the industrial asset strongly impacts the evolution of the residual flood risk and will be the objective of specific future analyses.

Figure 9

8 Conclusions

Our study considers the middle-lower portion of the Po river and analyzes the evolution of the residual flood-risk during the last half century for residential areas in the Pianura Padana, a large and socio-economically very important dyke-protected flood-prone area located in Northern Italy, by investigating changes in flood frequency (i.e. flood hazard) and exposure to floods.

Consistently with previous analyses (see e.g. Montanari, 2013; Zanchettini et al., 2008) our trend detection analysis, which we carried out on long historical series observed for the Po river, does not detect any evidence of a statistically significant change in the flood hazard along the Po river and supports the stationarity of the hydrological series during the period of interest (i.e. last five decades).

Changes in the residual flood risk, if any, could be mainly ascribed to an evolution of the exposure to floods. Therefore, we analyzed the possible alteration of exposure to floods in the study area, looking in particular at number of inhabitants and extension of residential areas. We propose the use of simplified graphical tools (i.e. Hypsometric Vulnerability Curves-HVCs and Hypsometric Inhabitants Curve-HICs) for a quantitative, yet approximate, large-scale assessment of the direct tangible

economic losses to private residential buildings and of the number of people affected by a given inundation scenario. HVCs and HICs can be constructed using a minimal set of information (i.e. a digital elevation model, land-use map, census data) for any given flood-prone compartment represented in a quasi two-dimensional numerical schematization as a storage area. Despite the usefulness and ease of the proposed methodology it is worth noting that its application in our study relies on a number of simplifying assumptions that need to be acknowledged in order not to misinterpret the results (see also Section 5.2):

a) the flood-hazard assessment is performed by means of a simplified quasi-2D model (see Castellarin et al., 2001b) in which the flood-prone compartments are reproduced as storage areas regulated by means of volume-water level defined on a DEM with a resolution of 10 m (see Section 5.1);

b) aggregation classes adopted by land-use maps (see Table 3) do not enable the identification of specific building typology, such as for example detached house, garages, office, stores, etc. (see Table 4); as a result, the economic estimates consider a single (average) building typology for each compartment.

c) the economic estimates provided by AE represent the market value of the urban buildings in a given municipality and are not representative of the actual potential damages expected in case of inundations (e.g. damages to furniture are not considered);

d) the population density adopted for the HICs is assumed to be uniform within a given municipality neglecting differences between rural and central urban areas.

These limitations notwithstanding, our preliminary application demonstrates the usefulness of HVCs and HICs and their potential for flood-vulnerability and flood-risk assessment. The accuracy of the proposed methodology can be easily increased by referring to more accurate data (e.g. finer land-use discretization, advanced economic estimate; etc.), different HVCs defined for each municipality or land use type, or to detailed simulation of the inundation characteristics (e.g. flood dynamics simulated by means of 2D hydraulic models).

765 The analysis points out a significant growth of the extension of residential areas over the study
766 region, with a consequent increase in the expected damage that is almost doubled relative to the
767 considered inundation scenario (recurrence interval ~ 500 years). On the contrary, the number of
768 exposed inhabitants showed only marginal modifications during the study period. These findings offer
769 important elements to further the discussion on the existence and importance of the “levee effect” (or
770 call-effect, Tobin, 1995) along the middle-lower portion of the Po river. The study outcome also foster
771 some general considerations on the arguable applicability of the call-effect for developed and
772 technologically advanced countries, where the physical proximity to fresh water may not represent
773 the predominant factor for the development of residential settlements (Di Baldassarre et al., 2013).
774 Despite our study focused on the development of urban settlements only, different evidences seem to
775 arise from preliminary analysis performed relative to the industrial asset, from which we have noticed
776 in the C-Buffer a greater growth rate than the one occurred in the rest of Emilia-Romagna and
777 Lombardy districts. However, further investigations are needed addressing this specific point for
778 getting a more definite answer concerning the existence and entity of a call-effect relative to industrial
779 activities in the study area during the last fifty years. Further analyses are also required to enable the
780 assessment of flood-losses that are potentially expected in commercial and industrial areas, for which
781 the economic values provided by the Italian Revenue Agency (AE) appear far from being useful as
782 indicators of the expected losses (see also Section 5.2).

783 Over the past two decades the flood-risk management experienced a shift from a hazard-driven
784 view to a risk-based perspective, in which the risk management policies are increasingly identified and
785 evaluated in the light of system susceptibility and resilience, thus focusing on the capacity of the
786 system to coexist with, and recover from, inundations (see e.g. Merz et al., 2010). The European Flood
787 Directive 2007/60 further promotes this process requiring the Member States to identify flood-risk
788 mitigation plans in order to reduce the adverse consequences (e.g. number of people affected,
789 damages, etc.) of a given inundation event. In this context, keeping in mind all the assumptions that
790 were previously highlighted, the combination of HVCs (and HICs) with inundation scenarios computed
791 through simplified hydraulic models can be a viable strategy for quantitative large-scale assessments

792 of the residual flood risk. The proposed methodology may be useful for decision-makers in charge of
793 the definition of large scale flood-risk mitigation strategies, as the resort to HVCs can provide
794 stakeholders with a preliminary estimation of the impact of a given inundation event and enables
795 them to easily compare the effectiveness of alternative flood risk mitigation strategies (e.g. controlled
796 flooding vs. strengthening of the existing levee system, see e.g. Vis et al., 2003; Merz et al., 2010;
797 Castellarin et al., 2011a).

994 **TABLE**

995 **Table 1.** Characteristics of the long daily streamflow series available along the main stretch of the Po river
996 (observation period, mean (μ), standard deviation (σ) and range of variation of the daily discharge data series),
997 along with the catchment area (A) at the specific gauging location.

<i>Gauging station</i>	<i>Period</i>	μ [m ³ /s]	σ [m ³ /s]	<i>min-max</i> [m ³ /s]	<i>A</i> [km ²]
<i>Moncalieri</i>	1942-1984	80	89	3 - 2 170	4 885
<i>Piacenza</i>	1924-2009	959	773	52 - 12 600	42 030
<i>Pontelagoscuro</i>	1920-2009	1 490	1 007	168 - 9 780	71 000

998

Table 2. Results of the Mann-Kendall statistical trend detection tests for AMS, MEAN and SD data series at the gauges section of Moncalieri, Piacenza and Pontelagoscuro (see also Table 1): test significance p -value, Sen's slope (β) and variation (Δ) over the period of available data.

	<i>Moncalieri</i>			<i>Piacenza</i>			<i>Pontelagoscuro</i>		
	<i>p-value</i>	β [m ³ /s/year]	Δ [m ³ /s]	<i>p-value</i>	β [m ³ /s/year]	Δ [m ³ /s]	<i>p-value</i>	β [m ³ /s/year]	Δ [m ³ /s]
AMS	0.753	2.09	87.8	0.822	2.02	172.5	0.106	13.2	1178
MEAN	0.397	0.31	13.41	0.770	-0.28	-24.17	0.450	1.27	113
SD	1	-0.02	-0.90	0.796	0.07	5.95	0.043	2.53	225

Table 3. Aggregated land-use classes adopted for the characterization of urban settlements in different time periods [x indicates all sub-categories considered by finer land-use classifications].

CORINE (2006)		G.A.I - WWS (1954)		AGEA-2008	
<i>Cod.</i>	<i>Class description</i>	<i>Cod.</i>	<i>Class description.</i>	<i>Cod.</i>	<i>Class description</i>
111	Continuous urban fabric	1a	Continuous and discontinuous urban fabric	111x	Continuous and sparse urban fabric
112	Discontinuous urban fabric	1g	Green urban and sport areas	112x	Discontinuous and isolated residential fabric
14x	Green urban and sport areas			142x	Farmstead, gardens, parks and campground

Table 4. Example of economic values ($E[\text{€/m}^2]$) provided by AE in relation to buildings typology in a given municipality (values and buildings typologies may vary from different municipalities).

Category	Building typology	Economic value $E [\text{€/m}^2]$
Residential	Civil houses	1 975
	Garage, cellar, etc.	850
	Detached houses	2 400
Commercial	Stores	1 750
	Warehouses	925
Tertiary	Offices	1 550
Manufacturing	Productive plant	850

Table 5. Average economic values of civil buildings provided by the Italian Revenue Agency (AE) in the C-Buffer compartments flooded in case of the Tr500 event.

Compartment	Average value E [€/m ²]
1	~ 840
2	~ 970
3	~ 865
6	~ 870
8	~ 935
10	~ 850
18	~ 1 105
20	~ 1 245
