Abstract

We present the results of an unbiased search for $\text{Ly}\alpha$ emission from continuum-selected $5.6 < z < 8.7$ galaxies. Our data set consists of 160 orbits of G102 slitless grism spectroscopy obtained with the *Hubble Space Telescope* (*HST*)/WFC3 as part of the Faint Infrared Grism Survey (FIGS; PI: Malhotra), which obtains deep slitless spectra of all sources in four fields, and was designed to minimize contamination in observations of previously identified high-redshift galaxy candidates. The FIGS data can potentially spectroscopically confirm the redshifts of galaxies, and as $\text{Ly}\alpha$ emission is resonantly scattered by neutral gas, FIGS can also constrain the ionization state of the intergalactic medium during the epoch of reionization. These data have sufficient depth to detect $\text{Ly}\alpha$ emission in this epoch, as Tilvi et al. have published the FIGS detection of previously known $\text{Ly}\alpha$ emission at $z = 7.51$. The FIGS data use five separate roll angles of *HST* to mitigate the contamination by nearby galaxies. We created a method that accounts for and removes the contamination from surrounding galaxies and also removes any dispersed continuum light from each individual spectrum. We searched for significant ($>4\sigma$) emission lines using two different automated detection methods, free of any visual inspection biases. Applying these methods on photometrically selected high-redshift candidates between $5.6 < z < 8.7$, we find two emission lines, one previously published by Tilvi et al., (2016) and a new line at $1.028 \mu\text{m}$, which we identify as $\text{Ly}\alpha$ at $z = 7.452 \pm 0.003$. This newly spectroscopically confirmed galaxy has the highest $\text{Ly}\alpha$ rest-frame equivalent width ($\text{EW}_{\text{Ly}\alpha}$) yet published at $z > 7$ ($140.3 \pm 19.0 \text{ \AA}$).

Key words: galaxies: distances and redshifts – galaxies: high-redshift – line: identification

1. Introduction

While thousands of candidate galaxies have been discovered in the epoch of reionization at $z > 6$ using photometric measurements (e.g., Bouwens et al. 2015; Bowler et al. 2015; Finkelstein et al. 2015b; McLeod et al. 2015; Ono et al. 2017), spectroscopic information is very limited. Accurate distance measures are required to improve our understanding of the evolution of galaxies, as any uncertainty in the redshift propagates through to uncertainties in key physical properties such as the luminosity, stellar mass, and star formation rate. These physical quantities are used to constrain theoretical models of galaxy formation and evolution, thus it is necessary to measure spectroscopic redshifts for a representative sample of photometrically selected galaxies, both to measure the contaminant fraction, and to calibrate the photometric redshift uncertainties.

At $z > 3$, $\text{Ly}\alpha$ emission is the dominant observed spectral feature used to search for galaxies (Kudritzki et al. 2000; Rhoads et al. 2000) because it is the emission line most accessible from ground-based observations (e.g., Finkelstein 2016; Stark 2016, and references therein). Selecting galaxies by their $\text{Ly}\alpha$ emission through narrowband surveys (e.g., Hu et al. 1998; Kudritzki et al. 2000; Rhoads et al. 2000; Steidel et al. 2000; Ouchi et al. 2003) and direct spectroscopic searches (e.g., Malhotra et al. 2005; Pirzkal et al. 2007; Rhoads et al. 2013) identifies populations that at most evolve weakly from $z \approx 3$ to $z \approx 6$, whether in $\text{Ly}\alpha$ luminosity (Dawson et al. 2007) or in UV size and surface brightness (Malhotra et al. 2012). The line strengths of $\text{Ly}\alpha$ -selected samples are large (Malhotra & Rhoads 2002) and detectably evolve from smaller equivalent widths at $z \approx 3$ to larger ones at $z \approx 6$ (Zheng & Wallace 2014). Similarly, the fraction of continuum-selected galaxies (e.g., Lyman-break galaxies) which have

detectable Ly α emission via follow-up spectroscopy rises from $\sim 30\%$ at $z = 3$ to 60% – 80% at $z = 6$ (Shapley et al. 2003; Stark et al. 2010, 2011, though see also Caruana et al. 2018). This implies that Ly α should be both a powerful and efficient means of measuring the redshifts to galaxies at $z \sim 7$ and beyond.

However, the observations at $z > 7$ tell a more complicated story. The number of Lyman-break-selected galaxies spectroscopically confirmed via Ly α at $z > 7$ is about a dozen (e.g., Fontana et al. 2010; Vanzella et al. 2011; Schenker et al. 2012; Shibuya et al. 2012; Pentericci et al. 2014; Oesch et al. 2015; Zitrin et al. 2015), with only five confirmed Ly α lines at $z > 7.5$ (Finkelstein et al. 2013; Oesch et al. 2015; Zitrin et al. 2015; Song et al. 2016; Laporte et al. 2017). This is significantly fewer than expected based on the numbers of LBG candidates observed. Narrowband surveys continue to successfully identify Ly α lines at $z \approx 7.0$ (Iye et al. 2006; Zheng et al. 2017), $z \approx 7.3$ (Shibuya et al. 2012; Konno et al. 2014), and $z \approx 7.7$ (V. Tilvi et al. 2018, in preparation), but here too the numbers are generally lower than expected based on observations of the $z < 6$ universe.

A decrease in observable Ly α lines was anticipated as a likely consequence of neutral intergalactic gas prior to reionization (Malhotra & Rhoads 2004). Reionization history remains substantially unknown, but Ly α emission serves as a powerful probe, because neutral fractions over $\sim 30\%$ will scatter enough Ly α photons out of the line-of-sight to render detections difficult. The attenuation of Ly α lines was first used as a reionization test by Malhotra & Rhoads (2004), who found that narrowband Ly α observations then available were inconsistent with a fully neutral IGM at $z \approx 6.5$. Corresponding efforts using Ly α follow-up of $z > 7$ Lyman-break-selected candidates were first published in 2011 (Pentericci et al. 2011; Ono et al. 2012; Schenker et al. 2012), and showed a significant deficit in Ly α lines. While it is possible that the lack of spectroscopic detections could indicate a flaw in the selection process, this is unlikely, as the method for selection (via the Lyman break) is identical to that used at lower redshifts, where the contamination rate has been determined to be quite low (e.g., Pentericci et al. 2011). Rather, this change in Ly α detectability is likely related to residual neutral IGM, though evolution in galaxy gas properties could also play a role (Finkelstein et al. 2012). Currently, we know that the midpoint of reionization occurred around $z = 8.8$ (Planck Collaboration et al. 2014), and is largely complete by $z \sim 6$ (e.g., Malhotra & Rhoads 2004; Fan 2006; Becker et al. 2015); but a detailed history of reionization remains substantially unknown. Searching for Ly α emission in Lyman-break galaxies at $7 < z < 9$ is a powerful way to move forward, as even non-detections of Ly α can be constraining.

The apparent paucity of Ly α detections at $z > 6.5$ has led to a number of analyses on the neutral fraction, with some studies finding an IGM neutral fraction as high as 50% – 70% at $z \sim 7$ (from \sim fully ionized at $z \sim 6$; Pentericci et al. 2011; Treu et al. 2013; Tilvi et al. 2014; Mason et al. 2017). However, there is a variety of effects that can reduce the ability of observations to make an impact. The most pressing is that at $z \sim 6$ – 8 , the photometric redshift probability distribution functions straddle the boundary between optical and near-infrared cameras, making it difficult with one instrument to probe the full wavelength range where a line may be found. This is compounded by the increasing sky brightness, and

bright telluric emission and absorption features at these and longer wavelengths, further reducing the discovery space. Both of these effects can be mitigated with space-based slitless grism spectroscopy with the *Hubble Space Telescope* (*HST*). The *HST* Wide Field Camera 3 (WFC3) G102 grism covers the range $0.8 \mu\text{m}$ – $1.15 \mu\text{m}$ at a spectral resolution of $R \sim 210$, fully covering Ly α emission at $5.6 < z < 8.7$, throughout the epoch in question, all free of telluric emission lines (though not scattered earthshine). Grism spectra have previously been used to successfully detect both Lyman-break galaxies (Malhotra et al. 2005; Rhoads et al. 2009; Oesch et al. 2015) and emission line galaxies (Malhotra et al. 2005; Pirzkal et al. 2007; Rhoads et al. 2009, 2013; Bagley et al. 2017; Schmidt et al. 2017) at high redshifts.

In this paper we report on a search for Ly α emission from galaxies in this epoch with data from the deepest *HST* grism survey yet, the Faint Infrared Grism Survey (FIGS; PI: Malhotra; Pirzkal et al. 2017). We describe FIGS in Section 2, and outline our method for data reduction and emission line discovery in Section 3. We summarize our results in Section 4, and discuss the implications in Section 5, and our conclusions in Section 6. All magnitudes are given in the AB magnitude system (Oke & Gunn 1983) and we assume $H_0 = 67.3 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_m = 0.315$ and $\Omega_\Lambda = 0.685$ (Planck Collaboration et al. 2015).

2. Data

FIGS is currently the most sensitive *HST* G102 grism survey, and targets the Cosmic Assembly Near-infrared Deep Extragalactic Legacy Survey (CANDELS; Grogin et al. 2011; Koekemoer et al. 2011) Great Observatories Origins Deep Survey (GOODS; Giavalisco et al. 2004) fields. The *HST* WFC3 grism is used for obtaining slitless spectroscopy of an entire $123'' \times 136''$ field of view. This gives us spectra for ~ 6000 galaxies across four fields, complete to $J \sim 26.5$ mag, corresponding to a comoving volume of $6.82 \times 10^4 \text{ Mpc}^3$ across our redshift range of interest ($5.6 < z < 8.7$). The unavailability of a slit leads to contamination of nearby sources as the light is spread out along the dispersion axis, and in order to remove this effect, the same field is observed at different roll angles, changing the axis of dispersion. This changes the amount of, if not completely avoiding, contamination of light from nearby sources that might fall into the dispersion pattern of a given object. The FIGS survey consists of 4 *HST* pointings, each with 40 orbits spread over 5 different position angles (PAs) in an effort to reduce the overall contamination effects from spatially nearby galaxies and foreground stars. The full description of this survey, including coordinates and PA diagrams, is available in Pirzkal et al. (2017). This data set has already proven to be successful, as Tilvi et al. (2016) detailed the FIGS detection of a previously known Ly α emitter at $z = 7.51$ (Finkelstein et al. 2013).

3. Method

3.1. Reduction from Raw Data to 2D Spectra

The method of reduction from raw data to two-dimensional (2D) spectra for each galaxy is explained in Pirzkal et al. (2017), and follows loosely the method for the Advanced Camera for Surveys (ACS) programs Grism-ACS Program for Extragalactic Science (GRAPES; Pirzkal et al. 2004) and Probing Evolution and Reionization Spectroscopically

(PEARS: Pirzkal et al. 2009), but is discussed here briefly for completeness. These reductions relied on first being able to simulate the data, and thus Simulation Based Extractions (SBEs) were performed using the full-depth *HST* ACS and WFC3 mosaics in this field. This imaging is predominantly from the CANDELS (Grogin et al. 2011; Koekemoer et al. 2011) and GOODS (Giavalisco et al. 2004) surveys and information on how these mosaics were created can be found in Koekemoer et al. (2011). Hot and cold catalogs were created from these mosaics using a custom version of SourceExtractor (Bertin & Arnouts 1996) with elliptical Kron (Kron 1980) apertures similar to the catalogs from Finkelstein et al. (2010, 2012, 2015b). Cold catalogs were created first to find the brighter extended sources, while more aggressive hot catalogs were created for fainter, smaller sources. A final catalog was taken by adding the sources from the hot catalog to the cold catalog as long as they did not overlap a cold-catalog object’s segmentation map.

The publicly available WFC3 G102 grism calibration file (Pirzkal et al. 2016; Pirzkal & Ryan 2017) was used to simulate every single FIGS grism observation with special software that dispersed every object pixel from the mosaic into the reference frame of the FIGS observation. This allows for the calculation of the dispersion solution and creation of data cubes that were used to generate simulated dispersed images for all objects. These simulated images and data cubes were used to determine which pixels in the real observations were needed to produce 2D spectra for each object. In this way it was possible to determine the dispersed flux in each pixel from nearby sources in the field and get a measure of contamination for each object.

The combination of all this information was used to create a 2D, wavelength-rectified image for each object, by binning the data for each galaxy in 25 Å bins based on the properties of the G102 filter. The error values are computed as the rms of the multiple (~ 32) measurements used in creating the 2D spectrum. Having five roll angle observations and subsequent simulations of the dispersion solutions for all objects in the field allowed for the creation of five 2D, contamination-subtracted spectra for every galaxy. This process also created 2D models of where each galaxy was expected to be spatially (z -direction) dispersed by combining the SourceExtractor footprint with the broadband photometry. 2D weighted maps were created for each galaxy using these models. We do not combine the five 2D maps because the object profile in the dispersion direction defines the resolution of each spectrum and these are different across PAs. They also each have different background residuals and contamination effects, so we analyze them separately, or after these effects are corrected for as in the following reduction steps. An example of the five 2D spectra for the most robust detection of a $z > 7$ galaxy (FIGS ID: GS2_1406) is shown in Figure 1. For more details on this process, see Pirzkal et al. (2017).

3.2. Reduction from 2D to 1D Spectra

The extraction from 2D spectra to one-dimensional (1D) spectra is done using the optimal extraction technique from Horne (1986). This method applies non-uniform weights to pixels in the spatial direction based on the photometric shape of the object to achieve better spectrophotometric accuracy. In the reduction process done by Pirzkal et al. (2017) several 2D products are created for each galaxy for each PA of the telescope: the contamination-subtracted spectrum (S), a spatial

profile of the object in the 2D spectrum (W), and an error (E). We extract the 2D spectrum into a 1D one by spatially (z -direction) summing per wavelength pixel using a simplified version of the optimal extraction equation from Horne (1986):

$$f_{\text{opt}} = \frac{\sum_z (SW)/E^2}{\sum_z W^2/E^2},$$

which gives us an inverse-variance weighted optimal flux (f_{opt}) value at each wavelength pixel. We then take this 1D spectrum, apply the sensitivity curve of the G102 grism, and use this final spectrum for all following work (see Figure 1 for 1D optimally extracted spectra for the $z = 7.452$ object). This process is also illustrated in Pirzkal et al. (2017).

3.3. Line-fitting Routine

As we are looking for Ly α emission from high-redshift galaxies, we focused on a subset of galaxies in the FIGS data that were previously classified with CANDELS photometry to be at $z > 5.5$ (Finkelstein et al. 2015b). This sample consists of 154 galaxies in our 4 fields, 24 of which are brighter than $J = 26.5$, and could potentially be detected in our data. We restrict our analysis to the section of each spectra between 8500 and 11,200 Å, as the sensitivity curve of the G102 instrument drops off significantly outside this range, substantially increasing the noise.

Rather than relying on uncertain and arbitrary visual inspection of 2D spectra to identify plausible emission lines, we utilize a Monte Carlo Markov Chain (MCMC) routine (R. Ryan et. al 2018, in preparation) to search for significant emission lines in the 1D spectra. While we know Ly α has an asymmetric profile, at this spectral resolution ($R \sim 210$) we do not expect to resolve this asymmetry and a Gaussian function is an appropriate fit to this data. As such, our fitting routine fits a Gaussian + constant function that takes in four parameters: the spectroscopic continuum level constant, central wavelength, FWHM, and integrated line flux. We use an IDL implementation of the affine-invariant sampler (Goodman & Weare 2010) to sample the *posterior*, which is similar to the *emcee* package (Foreman-Mackey et al. 2013). We run the MCMC code with 500,000 iterations and 100 walkers at each pixel (significantly past the convergence point), stepping through wavelength space. This allows for a mostly unbiased search, as we are fitting a Gaussian centered at every wavelength pixel across the spectrum, instead of giving an expected location for our emission line based on the photometric redshift information from Finkelstein et al. (2015b). A comparison to photometric redshifts for detected lines is discussed in Section 5.1. Fitting parameters for the initial run are shown in Table 1.

3.3.1. Removal of Residual Contamination

While the data reduction process takes into account much of the contamination and residual emission from nearby sources, there is often an overall zeroth order continuum shape to each spectrum. This is likely due to residual contamination that is missed during these reduction steps. Galaxies at these redshifts should have very faint continuum emission, and by removing any residual continuum shape to the spectrum, we are not significantly affecting emission line results, but are accounting for imperfect noise and contamination corrections done in earlier steps. Searches for real continuum breaks in these data are discussed in Tilvi et al. (2016).

Figure 1. 2D and 1D contamination-subtracted spectra of GS2_1406 in the FIGS data set. The top 5 plots are 2D/1D spectra from individual PAs, and the bottom plot is a weighted combination of all 5 PAs, all after the reductions from Pirzkal et al. (2017). This galaxy exhibits a strong emission line near $1.03 \mu\text{m}$ that appears as a bright spot in the right half of each 2D spectrum, and that is marked by a vertical line in each 1D spectrum.

Table 1

Fitting Parameters for the MCMC Chain That Fits a Constant + Gaussian Function at Each Wavelength Pixel

Fitting Parameters	
“Continuum” Constant	$-1 \times 10^{-18} < C < 1 \times 10^{-18} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ \AA}^{-1}$
Peak Wavelength	$\lambda_{\text{pixel}} \pm 12 \text{ \AA}$
Gaussian FWHM	$25 \text{ \AA} < \text{FWHM} < 68 \text{ \AA}$
Line Flux	$10^{-20} < \text{Flux} < 10^{-15} \text{ erg s}^{-1} \text{ cm}^{-2}$

Note. These parameters are used in the first fit to each PA spectrum. Once residual contamination is removed (Section 3.3.1), the continuum constant is fixed to 0.

The first step of this process is to use our MCMC routine to fit a Gaussian function + a constant centered at each pixel of the wavelength array. At this step we let the constant vary between $\pm 1 \times 10^{-18} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ \AA}^{-1}$, which are much

larger values than the 1σ noise level and are much higher than the typical continuum values for our high-redshift sources. We also restrict the peak wavelength to be the wavelength at that pixel $\pm 12 \text{ \AA}$, such that we fit a Gaussian within each pixel. We limit the FWHM to between 25 \AA , which is half the instrumental resolution, and the FWHM, which would correspond to 2000 km s^{-1} ($\sim 68 \text{ \AA}$) as calculated by $\text{FWHM}_{\text{max}} = 2000 \text{ km s}^{-1} \frac{\lambda_{\text{peak}}}{c}$ (where c is the speed of light). We force the line flux value to be greater than 10^{-20} and less than $10^{-15} \text{ erg s}^{-1} \text{ cm}^{-2}$, which does not put strong restrictions on the MCMC chain, but keeps the chain from spending time in unlikely regions of parameter space. These parameters are listed in Table 1.

To measure our line fluxes we use the median value of the last 100,000 steps of our MCMC chain, well after it has sufficiently converged. We use the “robust sigma” calculation to measure our error, using the median absolute deviation as the

Figure 2. Top: example of a residual contamination (“continuum”) fit to one PA spectrum. The blue line shows the original spectrum, while the black portion shows the region 3 pixels on either side of the peak of a line identified in the first pass (indicated by the vertical line). The pink line is our residual, which is calculated by 12-pixel boxcar smoothing of the blue line that interpolates across the potential emission line. Bottom: the final “flattened” spectrum after this residual is subtracted.

initial estimate, then weighting points using Tukey’s Biweight (Equation (9) from Beers et al. 1990). We calculate the signal-to-noise ratio (S/N) of the emission line as the median line flux divided by the line flux error. We count the fit as a potential emission line if it has an S/N > 4 and also has the lowest χ^2 of the surrounding two pixels ($\pm 25 \text{ \AA}$) on each side (accounting for a single line being detected in multiple pixels).

To remove this residual contamination, we mask out any detected emission lines from our first pass (those with S/N > 4) and a region around them (± 3 pixels on either side) and then interpolate over these regions. Here, we use a larger region than the expected FWHM of the emission line to ensure we are not smoothing out the wings of the line profile. We then fit a boxcar smoothing function with a width of 12 pixels to the entire spectrum to average over the noise and identify a smooth residual component (see Figure 2). It is possible that this results in a slight over or under subtracting of the residual contamination, but this effect is minimal in the search for an emission line. Once we have measured this residual we subtract

it from the original spectrum to produce our final spectrum (see the bottom panel of Figure 2).

3.3.2. Line Detection Steps

We then search for emission lines in these fully reduced 1D spectra using two different and independent methods. First, we look for matching lines in more than one PA for the same galaxy. Second, we simultaneously fit all five PA spectra and use a combined χ^2 estimate to find emission lines. Each method is described in the following sections but they both follow the same general steps. We use our MCMC routine to fit a Gaussian at each wavelength pixel, using the same restrictions as in Table 1, except we now fix the constant to 0 for both, as we expect there to be no remaining continuum emission after our steps in Section 3.3.1.

3.3.3. Method 1: Matching Lines from Individual PAs

In this method we run our line-finding code on each of the five spectra separately, searching for $>4\sigma$ detections in individual PAs. In order for an emission line to be selected as a potential real emission line in this method, an object must have a line detected at $>4\sigma$ significance in two or more PAs at the same wavelength ± 2 pixels ($\pm 50 \text{ \AA}$). Finding a significant line in only one PA could just be indicative of a noise spike or neighboring contamination, and setting the detection threshold at 4σ removes the detection of potentially correlated noise, as the lines span several pixels. If the emission line is real, the rotation of the telescope will not affect the wavelength at which the emission line is found, therefore searching for lines at matching wavelengths in more than one PA provides further evidence of real detections. Here, we assume that the emission line source is not offset from the assumed center of the object. This method finds two candidate emission line galaxies in all four of the FIGS fields. An example of a successful fit to four PAs of GS2_1406 can be found in the left panel of Figure 3.

3.3.4. Method 2: Fit to all Five PAs Simultaneously

For this method we fit all five PAs simultaneously, using the same fitting parameters as before, except now we are using the combined χ^2 value of the same Gaussian fit to all five PAs as the goodness-of-fit statistic. Real lines might not be detected in all PAs but these PAs will have larger uncertainties and will thus be down-weighted in this method. An example of a fit to GS2_1406 using this method is shown in the right panel of Figure 3. This method finds 5 emission lines. This method is also the one we use for our final fit values for significant emission lines, as it includes all the available spectra and more accurately accounts for potential noise amplification from one PA.

3.4. Method Validation

In an effort to rule out the possibility that any of our detections were spurious, we used both of these methods to fit a sample of spectra from 47 objects from the FIGS data set in the GS1 field that are highly unlikely to have real emission lines, as these objects are extremely faint ($m \sim 29$). Using both methods, with the same fitting criteria as above, we recovered *no emission lines* and therefore conclude that the likely contamination rate of spurious noise being misidentified as a significant emission line in our sample is negligible. It is likely

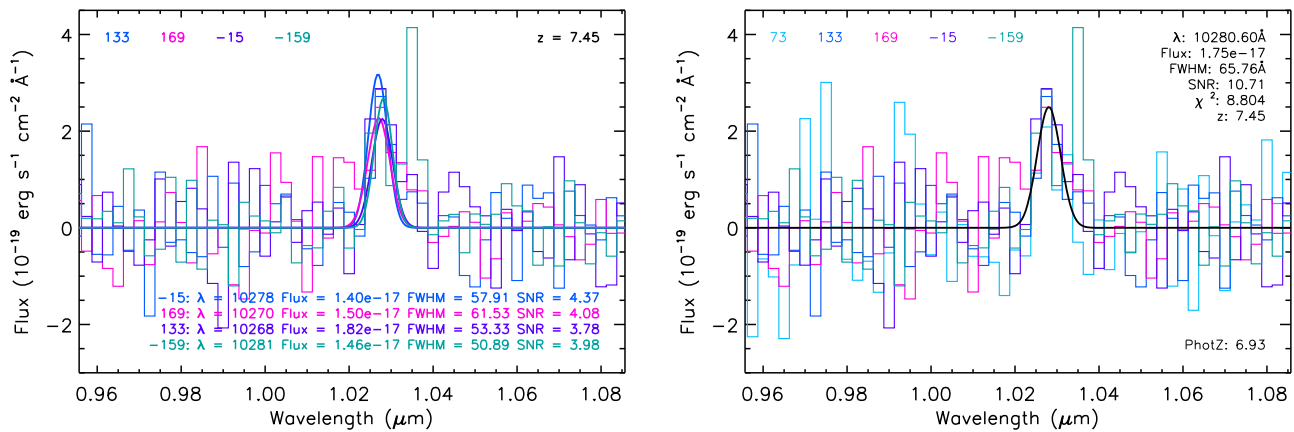

Figure 3. Method 1 (left): example of an emission line found in four position-angle spectra (colored) individually for GS2_1406 in the FIGS data. Individual PA fit results are printed, as well as their corresponding S/N measurements. Note that our S/N cut for this method is $>4\sigma$, but we are showing all detections above 3σ in this plot to further illustrate the significance of this emission line. Method 2 (right): example of an emission line fit (black) to all five position-angle spectra (colored) simultaneously for GS2_1406. This emission line has a flux of $(1.75 \pm 0.16) \times 10^{-17} \text{ erg s}^{-1} \text{ cm}^{-2}$ and gives a redshift for the galaxy of $z = 7.452 \pm 0.003$. We use this measurement as the reported line flux information, as it uses all the available spectra and more accurately accounts for potential noise amplification from one PA.

that some of our individual detected emission lines are in fact noise, but by invoking the criteria that they are found at the same wavelength in multiple PAs (Method 1) or that they are found in a simultaneous fit to all five PAs (Method 2) we are not including them in our results. The EM2D method (Pirzkal et al. 2013; N. Pirzkal et al. 2017, in preparation) also uses a combination of two methods to identify emission line galaxies using the 2D spectra for this reason.

We also tested both methods on low-redshift lines to determine the likelihood that a significant emission line exists in our data and we do not recover it. To do this we used a sample of known emission lines in the FIGS data set from lower-redshift galaxies but with roughly the same fluxes we expect Ly α to have in our high-redshift sample. These emission lines are identified as either H α or [O III] and are discussed in an upcoming paper by N. Pirzkal et al. (2017, in preparation). Of the 8 objects in this sample we recover a significant emission line using both methods in 7 of them. The 8th object has a brighter emission line than we included in our parameter space ($>3.5 \times 10^{-16}$) and as such our method does not accurately fit this data. This one emission line is ~ 30 times brighter than the brightest line we find, and would expect to find, in our high-redshift sample and we thus exclude this from our test measures and determine that our code is accurately recovering significant emission lines in our data set.

4. Emission Line Results

We find five emission line galaxies in at least one method, and two galaxies in both methods. One of these galaxies detected by both methods is the known Ly α emission line at $z = 7.51$ from Finkelstein et al. (2013) and Tilvi et al. (2016) (FIGS ID: GN1_1292), which is found in our two methods at $>5\sigma$ significance: it is found in the two PAs as reported by Tilvi et al. (2016) and it is also found by fitting all five PAs simultaneously. Our measured line flux for this line is $(1.10 \pm 0.17) \times 10^{-17} \text{ erg s}^{-1} \text{ cm}^{-2}$, which is consistent with the measured value from Tilvi et al. (2016), $(1.06 \pm 0.12) \times 10^{-17} \text{ erg s}^{-1} \text{ cm}^{-2}$, using this same data set. As this line was originally identified as Ly α from ground-based Keck MOS-FIRE spectra by Finkelstein et al. (2013), this in part validates our line identification procedure.

For the remainder of this paper we focus on the second emission line selected via both methods, which has not been previously published. This line is found in FIGS ID: GS2_1406 (ID z7_PAR2_2909 in Finkelstein et al. 2015b), at a position of $\alpha = 53.288090$, $\delta = -27.865408$. This galaxy has a detected emission line at $10280.60 \pm 3.94 \text{ \AA}$ with a line flux of $(1.75 \pm 0.16) \times 10^{-17} \text{ erg s}^{-1} \text{ cm}^{-2}$, a FWHM of $65.76 \pm 2.73 \text{ \AA}$ (consistent with an unresolved line), and a line flux signal-to-noise of 10.71 (see the fitting results from Method 2 and Figure 3). A summary of the properties of this emission line can be found in Table 3. The remaining lines that have been detected in only one of our two methods (Method 2), or both methods at a lower significance, require further data to confirm their robustness, thus we are pursuing ground-based spectroscopic follow-up to be discussed in a future paper.

Due to the nature of slitless spectroscopy, the measured line width is convolved with the shape of the source, and as these galaxies are not point sources in our data, the line gets spread out due to the spatial extent of the source and small astrometry misalignment between the different PAs.

5. Discussion

5.1. Line Identification

As our data set is derived from the high-redshift-selected galaxies from the CANDELS-GOODS fields we have ample photometry measurements in these fields from Finkelstein et al. (2015b). Our emission line galaxy, GS2_1406, falls in the Hubble Ultra Deep Field (HUDF) second parallel field, referred to as the HUDF09-02 (Bouwens et al. 2011). This field has deep WFC3 imaging from the HUDF09 survey (PI Illingworth; e.g., Bouwens et al. 2010; Oesch et al. 2010) and also has optical imaging with ACS (Beckwith et al. 2006) from the UDF05 survey (PI: Stiavelli, Oesch et al. 2007).

This field has imaging in the V_{606} , i_{775} , z_{850} , Y_{105} , J_{125} , and H_{160} bands, and was also observed with the *Spitzer Space Telescope* Infrared Array Camera (IRAC; Fazio et al. 2004) program 70145 (the IRAC Ultra Deep Field; Labbé et al. 2013) at 3.6 and 4.5 μm . Postage stamp images of this galaxy are shown in Figure 4 with the *HST* images being $3''7 \times 3''7$ (61×61 pixels), while *Spitzer* images are $7''8 \times 7''8$

Figure 4. Images of GS2_1406 (circled in purple) from the CANDELS survey showing it to be a clear z -band dropout. *HST* images are $3''7 \times 3''7$ (61×61 pixels), while *Spitzer* images are $7''8 \times 7''8$ (13×13 pixels).

Figure 5. Filled circles denote our measured photometry, removing the emission line contribution from the z_{850} and Y_{105} bands (the flux values prior to this subtraction are shown by the open black circles). Horizontal error bars show the width of each filter through which 90% of the flux is transmitted. The pink line shows the EAZY template at the best-fit photometric redshift of $z = 6.94$, which is higher than the original CANDELS photo- z , as we use the line-subtracted photometry values (we note this best-fit template does include weak $\text{Ly}\alpha$ emission). The purple and cyan lines show the best-fitting spectral energy distribution (SED) models at the spectroscopic redshift ($z = 7.452$) and the potential lower-redshift photo- z solution ($z = 1.33$), where these models come from full SED fitting the $\text{Ly}\alpha$ -subtracted photometry (using models with no $\text{Ly}\alpha$ emission). The colored diamonds are the corresponding SED flux for each filter. Inset: the PDF from our fiducial photometric redshift fit (pink), where the possible low-redshift solution is the second minimum in the chi-squared distribution, shown as the cyan dashed line. The spectroscopic redshift is indicated by the purple vertical line.

(13×13 pixels). The galaxy is marked by a purple circle to show it being a clear z -band dropout.

We used non PSF-matched catalogs for re-measuring the photometry values in elliptical Kron apertures, using the H_{160} band as the detection image. We used an identical process as that done in Finkelstein et al. (2015b), measuring object colors in smaller apertures (PHOT_AUTOPARAMS = 1.2, 1.7), and then applying an aperture correction, based on the ratio between the default Kron aperture (PHOT_AUTOPARAMS = 2.5, 3.5) and that in our smaller aperture in the H -band. For the two bands impacted by our emission line at $1.03 \mu\text{m}$, the z_{850} and Y_{105} bands, we subtract the contribution of the observed emission line from the measured photometry (see the open circles in Figure 5 for original photometry values). While the aperture measurement in the z -band shows a $\sim 2.5\sigma$ significance measurement before subtraction of the $\text{Ly}\alpha$ line flux, visual inspection of this region shows no significant connected pixels, implying that this measurement is likely dominated by random noise (as well as a $\sim 40\%$ flux contribution from our detected emission line). Prior to this subtraction, the $Y - J$ color from original photometry shows clear emission line contribution to the flux in that filter. We note that if we use smaller apertures, the $z - Y$ color becomes even redder, as these smaller apertures exclude noisy z -band

pixels, increasing the best-fitting photometric redshift to $z = 7.26$.

Spitzer IRAC photometry fluxes were originally deblended with T-PHOT (Merlin et al. 2015) as measured by Finkelstein et al. (2015b) and Song et al. (2016), with a $>2\sigma$ measurement in the $3.6 \mu\text{m}$ band. However, this source is blended by two nearby sources. To obtain the most robust measure of the flux at the position of our source in the IRAC images, we performed a dedicated, deblended photometric measurement to the IRAC data by modeling the bright sources nearby using the GALFIT software (Peng et al. 2002) and subtracted them from our image following a similar procedure as Finkelstein et al. (2015a). We then used a $1''9$ circular aperture to measure the flux at the position of our object at the residual image. We used the photometric uncertainties from the T-PHOT catalog, as these accurately contain the uncertainty due to the residuals after subtracting the neighbor sources, and are conservatively larger than other uncertainty measures. With these uncertainty values, we do not measure significant flux in the IRAC bands, consistent with visual inspection of the residual images. We note that many $z > 7$ $\text{Ly}\alpha$ emitters (e.g., Stark et al. 2017) show significant IRAC emission due to a large photoionization rates (corresponding to strong $[\text{O,III}]$). The error bars on the IRAC measurements for this source are large due to

Table 2
Photometric Measurements for GS2_1406 in nJy, with the Ly α Line-flux-subtracted Values for the z_{850} , Y_{105} Bands

GS2_1406 Photometric Measurements (in nJy)								
	V_{606}	i_{775}	z_{850}	Y_{105}	J_{125}	H_{160}	3.6 μm	4.5 μm
Measured Photometry	-7.78 ± 3.6	0.49 ± 4.3	12.98 ± 5.2	60.46 ± 4.4	48.57 ± 3.4	52.38 ± 4.1	35.44 ± 49.4	42.89 ± 42.4
Line-flux-subtracted Values	7.66 ± 5.2	39.48 ± 4.4

deblending, so we cannot make this distinction with this data. All photometric measurements for this galaxy can be found in Table 2.

We use these *HST*/ACS, *HST*/WFC3, and *Spitzer*/IRAC photometric measurements to measure the photometric redshift using the EAZY photometric redshift fitting code (Brammer et al. 2008). EAZY measures a best-fit photometric redshift of $z = 6.94$ with a secondary, low-redshift solution of $z = 1.33$ obtained from the second χ^2 minimum (see the inset of Figure 5). Exclusion of the low-significance IRAC photometry points produces an equivalent photometric redshift solution; as such they are ultimately included in our calculations. SEDs of best-fit galaxy templates at these redshifts are plotted in Figure 5. The fiducial photometric redshift in pink is EAZY’s best-fit solution, while the spectroscopic redshift (purple) and low-redshift solution (blue) are best-fit templates at those redshifts. If the low-redshift solutions were correct, the observed emission line could be instead [O II] at $z = 1.30$. However, as shown in Figure 5, a galaxy at this redshift would be expected to have emission significantly higher than the observed limits in the optical bands with no significant spectral break, and a much redder SED in the detected bands, thus we consider the low-redshift solution to be ruled out.

Our interpretation is thus that the detected line is Ly α at a spectroscopic redshift of $z = 7.452 \pm 0.003$. This deviates from the photometric redshift best-fit solution of $z = 6.94$ at the $\sim 2\sigma$ level. To see if this difference is due to the EAZY template set and/or fitting method, we verify this result using the Bayesian Photo-Z estimation (BPZ; Benítez 2000), and get a similar photometric redshift measure of $z = 6.8$. This discrepancy is not necessarily a problem, as photometric redshifts have not been spectroscopically calibrated at high redshifts, and even so, 2σ deviations are expected $\sim 5\%$ of the time. Clearly a larger number of spectroscopic redshifts is needed to validate photometric redshift probability density functions (PDFs) as photometric redshifts are fundamentally not right for single objects since they primarily rely on templates. As no two galaxies are truly identical, it is not surprising that photometric redshifts work well for looking at properties of many galaxies but can fail in individual cases. If significant outliers like these are found to be commonplace, it would imply that our photometric redshift uncertainties are higher than expected, resulting in increased uncertainties in luminosity functions and galactic properties. This issue is discussed in more detail in Pirzkal et al. (2017).

To derive relevant galaxy physical properties, we performed galaxy SED fitting with the line-subtracted *HST*/ACS and WFC3 and *Spitzer*/IRAC fluxes, thus the models do not have Ly α emission. Our SED fitting is based on an MCMC algorithm and uses the Bruzual & Charlot (2003) stellar population synthesis model, and the details of the SED fitting are described in Jung et al. (2017). We find that the 68% confidence measurements of this object give a stellar mass of $\log(M/M_{\odot}) = 8.79$ to 8.99, and a dust-corrected UV star

Table 3

Final Emission Line Results for New $z = 7.452$ Ly α Detection in GS2_1406 (CANDELS ID: z7_PAR2_2909)

GS2_1406 Emission Line Values	
Coordinates	(53.288090, -27.865408)
Peak Wavelength	$10280.60 \pm 3.94 \text{ \AA}$
Gaussian FWHM	$65.76 \text{ \AA} \pm 2.73 \text{ \AA}$
Line Flux	$(1.75 \pm 0.16) \times 10^{-17} \text{ erg s}^{-1} \text{ cm}^{-2}$
$L_{\text{Ly}\alpha}$	$1.15 \times 10^{43} \text{ erg s}^{-1}$
Signal-to-noise	10.71
$\text{EW}_{\text{Ly}\alpha}$	$140.3 \pm 19.0 \text{ \AA}$

formation rate of $7.77\text{--}8.32 M_{\odot} \text{ yr}^{-1}$. The SED is also fairly blue, thus the model fitting unsurprisingly prefers little dust with an $(E[B - V] = 0.007 \text{ to } 0.057)$.

5.2. Ly α Equivalent Width

Ly α rest-frame equivalent width ($\text{EW}_{\text{Ly}\alpha}$) measurements are much lower at $z > 7$, possibly due to an increase in the neutral fraction of the IGM (Forero-Romero et al. 2012; Tilvi et al. 2014). However, recent observations by Hu et al. (2017) and Zheng et al. (2017) have found luminous Ly α emitters at $z > 7$. The $\text{EW}_{\text{Ly}\alpha}$ measurement for GS2_1406 is taken by comparing the grism-measured line flux to the best-fit SED template at the spectroscopic redshift ($z = 7.452$) immediately redward of the Ly α line (average of $1220\text{--}1320 \text{ \AA}$ rest-frame) as the continuum value. The continuum flux is $1.25 \times 10^{-19} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ \AA}^{-1}$, giving GS2_1406 a $\text{EW}_{\text{Ly}\alpha} = 140.3 \pm 19.0 \text{ \AA}$, much higher than any previously spectroscopically confirmed galaxy at $z > 7$, as shown in Figure 6. All line-fit results can be found in Table 3. While robust statements about the ionization state of the IGM cannot be made from one galaxy, either internal galaxy kinematics or ionized bubbles must conspire to allow for the presence of such bright Ly α in this galaxy.

5.3. Ly α Luminosity

The measured line luminosity of Ly α for this source (GS2_1406) is $1.15 \times 10^{43} \text{ erg s}^{-1}$, and for the previously known source (GN1_1292), is $7.42 \times 10^{42} \text{ erg s}^{-1}$. This gives us a number density in the whole FIGS survey volume for $\log_{10} L_{\text{Ly}\alpha} \sim 43$ galaxies of $2.93 \times 10^{-5} \text{ Mpc}^{-3}$ (± 1.14 Poisson uncertainty). This number density is very similar to that found at $z = 7.3$ and 6.6 by Zheng et al. (2017) and Matthee et al. (2015), respectively, though it is lower than the recent results at $z = 5.8$ by Sobral et al. (2018).

6. Summary

Using the deepest *HST* Grism data available we have built an automated detection method to find emission lines from CANDELS-GOODS continuum-selected $z > 5.5$ galaxies. These data include five separate roll angles to reduce the

Figure 6. This shows the redshift evolution of rest-frame Ly α equivalent width ($EW_{Ly\alpha}$) for galaxies with high spectroscopic confidence (Iye et al. 2006; Ouchi et al. 2010; Vanzella et al. 2011; Ono et al. 2012; Rhoads et al. 2012; Schenker et al. 2012; Finkelstein et al. 2013; Pentericci et al. 2014; Hu et al. 2017). There was a missing population of high- $EW_{Ly\alpha}$ galaxies at $z > 7$ prior to the detection of this GS2_1406 (red square), which falls squarely in the high- $EW_{Ly\alpha}$, high-redshift range with an $EW_{Ly\alpha} = 140.3 \pm 19.0 \text{ \AA}$. This figure is adapted from Tilvi et al. (2014).

impact of contamination, and we then perform additional reduction to remove any residual contamination in our spectra. We searched for $>4\sigma$ emission lines using two different methods. In the first method, we compare the results for each galaxy across all roll angles and identify significant lines like those that are detected at the same wavelength in more than one roll angle. This method finds two emission line galaxies. In the second method, we perform a fit to all five roll angles simultaneously, using a combined χ^2 value, which finds five emission line galaxies. Of these two, one is a previously measured Ly α line (Finkelstein et al. 2013), already extensively studied in this data set by Tilvi et al. (2016), and our routine recovers the same line flux as previously reported. The other is a first-time detection in GS2_1406, discovered photometrically as z7_PAR2_2909 by Finkelstein et al. (2015b).

GS2_1406 has a detected emission line at $\sim 1.03 \mu\text{m}$, a line flux of $(1.75 \pm 0.16) \times 10^{-17} \text{ erg s}^{-1} \text{ cm}^{-2}$, and a line flux signal-to-noise of 10.71. We compare this result with broadband photometric measurements of this galaxy, and interpret this line to be Ly α at a redshift of $z = 7.452$. This spectroscopic redshift is a 2σ outlier from the photometric redshift ($z = 6.94$) illustrating the caveats of simple photometric redshift determinations for single sources. If further follow-up on other emission line galaxies in this data set show a similar offset, this could have strong implications on the accuracy of photometric redshift fitting.

This galaxy also has the highest Ly α rest-frame equivalent width ($EW_{Ly\alpha}$) at $z > 7$: $140.3 \pm 19.0 \text{ \AA}$. It is expected that $EW_{Ly\alpha}$ should decrease with z , paralleling an increase in the neutral fraction of the IGM during the epoch of reionization. The consequence of finding a high-redshift, high- $EW_{Ly\alpha}$ galaxy could mean there is a highly ionized line-of-sight to this galaxy, or that the kinematics in this galaxy result in Ly α being emitted significantly redward of the systemic redshift. These scenarios, as well as a higher confidence in the line identification, can be obtained with higher-resolution follow-up

of the Ly α line and measurement of another emission line such as rest-UV C III] or rest-FIR [C II].

This work is based on observations made with the NASA/ESA *Hubble Space Telescope*, obtained [from the Data Archive] at the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5-26555.
