Environmental catalytic processes are probably the best example for the application of structured catalysts based on activated open-cell metallic foams, and Pd on CeO<sub>2</sub> is one of the most active catalysts for different applications like three way catalysts, methane combustion and water gas shift. Here, we report the one-step deposition of Pd and CeO<sub>2</sub> on FeCrAlloy foams with very high pore densities (cell size equal to 580 and 1200 μm) by the electro-base generation method followed by calcination. The type of Pd and CeO<sub>2</sub> species, the quality of the coating and the catalytic activity in the mass transfer limited CO oxidation as a model reaction were investigated. For comparison purposes, a CeO<sub>2</sub> coating was also prepared. Reproducible and evenly distributed defective nano-CeO<sub>2</sub> coatings containing Pd<sub>0.5</sub>Ce<sub>1.5</sub>O<sub>2.5</sub> solid solution and Pd<sup>0</sup> particles were electrodeposited in 500 s regardless of the foam pore size. The structure, morphology, and adhesion of the catalytic layer, as well as the Pd distribution, were almost constant after calcination at 550 °C, only some PdO segregated. The resulting structured catalysts showed high activity and stability after 48 h time-on-stream and different thermal cycles in CO oxidation even at high GHSV values (e.g. 4 × 10<sup>6</sup> h<sup>-1</sup> referred to the total foam disk volume). High volumetric mass transfer coefficients, widely outperforming those of conventional honeycomb monoliths, were obtained, especially for the small pore (580 μm) foam. The *in situ* formation of Pd<sup>0</sup> nanoparticles and the homogeneous distribution and stability of the coating may contribute to the high catalytic performance, although these catalyst features depended on the position in the catalytic bed.

### Introduction

Pd/CeO<sub>2</sub> based catalysts on honeycomb monoliths are constitute the three-way catalysts (TWC).<sup>1</sup> These so-called structured catalysts merge the activity of the coating with the low pressure drop and enhanced mass and heat transfer of the support. Alternatives to the conventional honeycomb supports are metallic open-cell foams<sup>2</sup> and fibers,<sup>3</sup> made for instance of FeCrAlloy. In particular, open-cell metallic foams are getting increasing interest as 3D supports since they are light-weight, have a high specific mechanical strength, and large geometric surface area; moreover, their open cellular structure provides a disruptive and tortuous flow path and hence an exceptional mixing as well as supply or release of the heat to/from the surface.<sup>4</sup> Moreover, these structured catalysts

could find application in processes where the activity of Pd/CeO<sub>2</sub> has been demonstrated, such as methane combustion<sup>5-8</sup> and water gas shift.<sup>9-11</sup> In these applications, Pd/CeO<sub>2</sub> coated metallic foams have been reported to provide a unique combination of high low-temperature activity/selectivity, good catalyst stability and low conversion oscillations, low pressure drop at high-throughput operation, and enhanced heat transfer. Moreover, in methane combustion they allow for low Pd usage,<sup>12</sup> while in Water Gas Shift the redistribution of the heat over the bed allows to increase the CO conversion and the reaction rate.<sup>13</sup>

The properties of the structured catalysts based on metallic foams are related to geometric parameters, i.e. pore and strut diameter and void fraction, which can be tailored by foam producers. They not only determine the geometrical surface area for coating but also the pressure drop and gas-solid mass and heat transfer coefficients<sup>14, 15</sup> as well as the effective thermal conductivity.<sup>16</sup> The smaller the pores, the larger the surface area available to coat the catalytic layer and the better the mass and heat transfer; however, a balance between pore size and pressure drop should be considered.

Conventional washcoating is usually carried out to deposit catalytic layers on medium and large pore open-cell foam supports, i.e. 20, 40, 60 pores per inch (ppi).<sup>17-19</sup> Few works deal with the coating of small pore size foams,<sup>20</sup> probably related to pore blockage and inhomogeneous coating distribution. Other techniques, such as galvanic displacement<sup>21</sup> and hydrothermal synthesis followed by incipient wetness impregnation of the active phase<sup>22</sup> have been proposed to coat foams up to 100 ppi. former allows to deposit Pd directly onto the foam, but without co-deposition of oxide layer. In the latter, it is possible to integrate simultaneously an oxide or its precursor on the foam by a direct synthesis but the precipitation may also occur in the bulk of the solution, with the consequent loss in efficiency.

The electro-base generation method is suitable to coat 60–80 ppi metallic foams with hydroxides such as hydrotalcite-type compounds to obtain structured catalysts after thermal treatment.<sup>23, 24</sup> CeO<sub>2</sub> can be also easily synthesized by this method, although most of the published works report the coating of simple shaped supports such as foils (Ni), sheets (stainless steel), and disks (Pt, Au, platinized silicon wafer, stainless steel).<sup>25–28</sup> Coatings with tailored morphology (flaky,<sup>28, 29</sup> compact particles,<sup>28</sup> nanocubes and nanowires<sup>30</sup>) and thickness (from nanostructured films<sup>26, 29</sup> to 30 µm<sup>27</sup>) can be obtained on steel, whose main applications are the suppression of corrosion processes and in fuel cells. The deposition involves the electro-generation of a base in the electrode/electrolyte interface; when the pH suitable for the Ce<sup>3+</sup> precipitation is attained, Ce(OH)<sub>3</sub> is firstly obtained, then Ce<sup>3+</sup> is oxidized, the hydroxide dehydrated and subsequently transformed into CeO<sub>2</sub>.<sup>27</sup> This is rather easily achieved in short times after application of a constant cathodic potential or current to the working electrode dipped in either a Ce(NO<sub>3</sub>)<sub>3</sub> or CeCl<sub>3</sub> solution saturated with O<sub>2</sub> or air.<sup>26, 29</sup>

The electrodeposition is more challenging when performed on complex shaped supports and in presence of a highly reducible cation in the electrolytic solution, such as the case of the electrodeposition of Pd-CeO<sub>2</sub> catalysts on metallic foams. To achieve a highly active structured catalyst, for instance in the mass transfer limited CO oxidation, the coating thickness, distribution and adhesion to the metallic support are of paramount importance,<sup>31</sup> but also the Pd oxidation state,<sup>32, 33</sup> particle size<sup>33–35</sup> and interaction with the CeO<sub>2</sub> (forming a Pd<sub>x</sub>Ce<sub>1-x</sub>O<sub>2-δ</sub> solid solution).<sup>36, 37</sup> Catalysts with such tailored properties are prepared by coprecipitation with a base,<sup>35, 38–41</sup> namely by the same process that should occur during the electro-base generation method. However, the electrodeposition conditions may provoke the uncontrolled deposition of large metallic particles and thin coatings, such as recently reported during the electrodeposition of Pt-CeO<sub>2</sub> on FeCrAlloy foams.<sup>42</sup>

The aim of this work was to electrodeposit in one-step Pd-CeO<sub>2</sub> for the first time on high or medium density cell FeCrAlloy foams (with a nominal cell diameter equal to 580 and 1200 µm, which according to visual inspection of foam micrographs roughly correspond to 100 and 60 ppi, respectively). After calcination at 550 °C, the activity of the samples was evaluated in the mass transfer limited CO oxidation, as a model reaction. The samples were fully characterized after electrodeposition, calcination and catalytic tests to investigate the type of Pd and CeO<sub>2</sub> and the quality and adhesion of the coating. For comparison purposes on the coating properties, a foam was also coated with only CeO<sub>2</sub>.

## Experimental

### Catalysts preparation

9 mm disks of FeCrAlloy open-cell foams with a nominal cell size equal to 580 and 1200 µm and thickness of 1.9 and 3.1 mm, respectively were cut from commercial panels from Alantum GmbH and used as structured supports. Prior to use, the foams were washed in acetone, water and then dried at 40 °C for 24 h.

The electrolyte was an aqueous solution of PdCl<sub>2</sub> (> 99%, Sigma-Aldrich) and Ce(NO<sub>3</sub>)<sub>3</sub> (> 98%, Sigma-Aldrich), 0.15 M total concentration, and atomic ratio (a.r.) Pd/Ce = 3/97 to give a Pd nominal loading of 2 wt.% in the final catalyst. A given amount of PdCl<sub>2</sub>, calculated for 250 mL electrolyte, was firstly dissolved in 10 mL of distilled water with the addition of 0.1 g concentrated of HCl (37%) and kept under stirring and heating at 50 °C. When the solution became transparent orange colour, the rest of water and Ce(NO<sub>3</sub>)<sub>3</sub> were added to obtain the electrolyte. The final pH of the solution before the synthesis was approximately 2.5–2.7. For comparison purposes, samples containing only CeO<sub>2</sub> were synthesized from a 0.15 M Ce(NO<sub>3</sub>)<sub>3</sub> electrolyte.

Electrodepositions were performed in a homemade double-compartment flow electrochemical cell by FAVS Gnudi, using a potentiostat (Autolab, PGSTAT128N, Eco Chemie) with GPES software. A Pt coil (0.4 mm diameter and 40 cm in length) and a saturated calomel electrode (SCE) were used as counter and reference electrode (C.E. and R.E.), respectively. The working electrode (W.E.) was the FeCrAlloy foam disk and it was assembled by a two-pronged Pt electrical contact. The working and counter electrode compartments were separated by a glass frit tube to avoid the mixture of the electrochemical reaction products. The R.E. was in electrolytic contact with the main compartment *via* a Luggin capillary placed 1 mm close to the surface of the foam cylinder. All potentials were reported with respect to SCE. The electrodepositions were performed at -1.2 V vs SCE for 500 s with circulation of the electrolyte at a flow rate of 2 mL min<sup>-1</sup> as described elsewhere.<sup>43</sup> It should be noted that in these electrolytes, the set-up reached a low uncompensated resistance (*R<sub>u</sub>*) ca. 1–2 Ω in all of experiments. After electrodeposition, the coated foams were thoroughly washed with distilled water and dried at 120 °C for 24 h. The samples were then calcined at 550 °C for 10 h with a heating rate of 10 °C min<sup>-1</sup>.

### Characterization techniques

Scanning electron microscopy (SEM) coupled with energy dispersive spectrometry (EDS) was performed by using an EP EVO 50 Series Instrument (EVO ZEISS) equipped with an INCA X-act Penta FET® Precision EDS microanalysis and INCA Microanalysis Suite Software (Oxford Instruments Analytical) to provide images of the spatial variation of elements in a sample. The accelerating voltage was 20 kV and the spectra were collected for 60 s. As-prepared, calcined and spent coated foams were analysed in 3–4 regions of interest. The average Pd/Ce a.r. ratio values were estimated for 5 different foams. The thickness of the coated layers was estimated from images where the solid developed cracks.

During SEM/EDS analysis, Micro-Raman spectra were *in situ* recorded by a Renishaw Raman SCA (*Structural and Chemical Analyser for SEM*) probe linked by optical fiber to a Renishaw Raman Invia spectrometer. The electron and laser beam (Ar<sup>+</sup> laser source λ = 514.5 nm, P<sub>out</sub> = 30 mW considering the decrease in power due to the plasma filter) are confocal. By this way, it was possible to analyse different locations of the where the compositions were identified by EDS. In each measurement, the laser power was set by 10% of the source and the signal was accumulated by four individual spectra with a 30 s acquisition time.

Field emission scanning electron microscopy (FE-SEM) analyses were conducted on a Zeiss LEO Gemini 1530 equipped with an Everhart-Thornley (E-T) secondary electron detector and a

Scintillator BSE detector – KE Developments CENTAURUS. The accelerating voltages were 5 or 10 kV.

Disk samples (before and after electrodeposition) were scanned using a microfocussed X-ray tomographic system (MICRO XCT-400 Xradia, Zeiss), at 80 kV and 125  $\mu$ A. For each sample, 1500 projection images were recorded with an exposure time of 22 sec. The volume was reconstructed with the instrument software and was then exported to CTAn (SkyScan, Bruker) for further 3D image analysis. Voxel size was the same for all samples (5 $\times$ 5 $\times$ 5  $\mu$ m). Porosity was calculated by simple voxel counting in the 3D binary image after segmentation; the error in the measurements below is 0.1%, derived from image processing and scan resolution. Thickness of the struts and nodes, named solid structure thickness, was calculated using a model independent sphere filling technique,<sup>44</sup> it corresponds to the mean diameter of the spheres that could fill the solid structure. The mean pore size is the average pore volume of equivalent sphere diameter. To obtain direct comparison, the CT scans were performed firstly on the bare foam and then on the same locations of this foam but after being coated with Pd-CeO<sub>2</sub> by the electrodeposition. The image registration process was achieved using the DataViewer 3D Registration Tool (SkyScan, Bruker).

The X-ray diffraction (XRD) analysis of the film grown on the foam was carried out using a PANalytical X'Pert diffractometer equipped with a copper anode ( $\lambda_{\text{mean}} = 0.15418$  nm) and a fast X'Celerator detector. Wide-angle diffractograms were collected over  $2\theta$  range from 20 to 70° with a step size of 0.07° and counting time 600 s. The cell parameters of the detected phases could not be obtained since the surface of the analysed samples was not planar. Small modifications in the reflection positions could be related to differences in the radiation paths rather than the incorporation of Pd<sup>2+</sup> into the CeO<sub>2</sub> lattice.

Chemical composition of the Pd-CeO<sub>2</sub> coatings was analysed by ICP-OES measurements using an instrument ICP Thermo Elemental IRIS Intrepid (Thermo Scientific). The foam catalysts were mineralized with a mixture of HNO<sub>3</sub>/HClO<sub>4</sub> and then diluted with UPP-water to obtain suitable concentrations for a sufficient detection of each element. Concentrations of Pd and Ce were obtained by quantification of the peak areas at 324.27 and 413.38 nm, respectively.

N<sub>2</sub> adsorption-desorption isotherms were measured at -196 °C using a Micromeritics ASAP 2020 instrument. Prior each measurement, the coated foams were degassed via two steps: at 150 °C for 30 min under a pressure of 30  $\mu$ mHg and then 250 °C for 30 min (150 °C for not calcined samples). The specific surface area ( $S_{\text{BET}}$ ) was calculated using the Brunauer-Emmett-Teller (BET) multiple-point method in the relative 0.05 to 0.3 pressure range  $p/p_0$ .

High resolution transmission electron microscopy (HRTEM) characterization was carried out by a TEM/STEM FEI TECNAI F20 microscope, equipped with an EDS analyser. Powder catalysts were collected by scratching the foam surface and then suspended in ethanol under ultrasounds for 20 min. The suspension was subsequently deposited on a Cu grid with lacey quanti-foil carbon film and dried at 100 °C before doing the measurement. Selected Area Electron Diffraction (SAED) and Fast Fourier Transformation (FFT) were used to determine the interplanar spacing of the crystals. Particle size distribution was processed considering around 150 particles in three different zones for each sample.

X-Ray photoelectron spectra (XPS) studies were carried on a Physical Electronics spectrometer (PHI Versa Probe II Scanning XPS Microprobe) with monochromatic X-ray Al K $\alpha$  radiation (100  $\mu$ m, 100 W, 20 kV, 1486.6 eV) and a dual beam charge neutralizer. Charge referencing was measured against adventitious carbon (C 1s at 284.8 eV). A PHI ACCESS ESCA-V6.0 F software package was used for acquisition and data analysis. A Shirley-type background was subtracted from the signals. Recorded spectra were always fitted using Gaussian–Lorentzian curves in order to determine the binding energies of the different element core levels more accurately.

Temperature programmed reduction by H<sub>2</sub> (H<sub>2</sub>-TPR) was performed in an AutoChem II (Chemisorption analyzer, Micromeritics) with one coated foam. The catalyst was firstly outgassed at 150 °C under 30 mL min<sup>-1</sup> of He for 30 min. After cooling to -10 °C by vapor of liquid N<sub>2</sub>, the carrier gas was switched to 5 % H<sub>2</sub>/Ar (v/v) at 30 mL min<sup>-1</sup>. When the baseline was stable, the temperature was increased to 900 °C with a ramp of 10 °C min<sup>-1</sup>, while the amount of H<sub>2</sub> consumed was measured by means of a thermal conductivity detector (TCD).

### Catalytic tests

Evaluation of the catalytic activity of electrodeposited samples was performed running CO catalytic oxidation. This reaction is considered a model reaction for environmental applications and it is usually adopted for the analysis of mass transfer performances since it is active at low temperature and does not produce intermediates.

A schematic view of the reactor used for the catalytic tests is reported in Fig. 1. The samples with a diameter equal to 9 mm were loaded in a pipe with internal diameter of 9 mm and external diameter of 11 mm. This pipe was then inserted in a threaded tubular reactor fixed with a screw and placed in an oven. At the top and at the bottom of the catalytic samples, additional bare foams were added in order to increase the bed length and avoid inlet effects acting as flow distributors: in particular, for 1200  $\mu$ m foams, other two non-activated samples with same morphological features were used in the inlet and outlet section, while for 580  $\mu$ m foam the inlet bed was composed by two 1200  $\mu$ m foams and a single 580  $\mu$ m foam disk maintaining the same downstream configuration. Two K-type thermocouples were inserted in the reactor to measure the temperature upstream and downstream the catalytic bed (Thermocouple 1 and 2, respectively in Fig. 1). Carbon monoxide and air provided by SAPIO® were fed through stainless steel lines and regulated with BROOKS mass flow controllers; gases were mixed and preheated in a coil up to 175 °C before entering in the reaction zone.

Fig. 1. Layout of the reactor.

Effects of the flow rates on the CO combustion were assessed investigating different flow rates in the range 1000–9000 cm<sup>3</sup> min<sup>-1</sup> at STP (1 – 9 SLM). In order to observe the effect of CO concentration on light-off curves and on the conversion at diffusive regime, for some of the flow rates, the inlet CO concentration was varied from 2 to 3% (v/v) in air. During each test the oven temperature was increased stepwise in order to change the inlet temperature, after reaching steady state conditions for the temperatures, the conversion of CO was determined by the analysis of the reaction products; the overall errors detected in carbon balances were in the range 1-3%. Only analyses before the proper ignition point or in the plateau regime when the reaction is almost under complete diffusive control were performed, due to the problematic control of the temperature in the kinetically-limited regime. Due to the exothermic character of the reaction, temperature differences up to 120 °C across the foam bed were observed in the achieved mass transfer regime.

Before performing the catalytic tests, blank tests with non-active foams were performed in order to confirm the absence of homogeneous reaction and avoid any effect in the conversion induced by the setup or the bare supports - conversions lower than 4% were observed up to 450 °C.

Tests at low flow rate - 1000 cm<sup>3</sup> min<sup>-1</sup> at STP (1 SLM) – were performed to exclude any preferential flow path inside the reactor; in these tests, almost complete conversion was observed ensuring adequate activity of the catalyst and allowing to exclude the presence of a significant bypass.

## Results and Discussion

### Characterization of as-deposited foams

Open-cell foams were easily and quickly coated, regardless of the pore size, by a sole cerium-containing 5 µm film of graded morphology (Fig. 2a-a3). Platelet-like particles with their planes oriented perpendicular to the foam surface (Fig. 2a1, a2), giving rise to a highly porous coating characteristic of electrodeposited CeO<sub>2</sub>,<sup>28</sup> and a very compact layer laying on it (Fig. 2a1, a3) precipitated during the cathodic pulse. A graded morphology was previously reported for electrodeposited CeO<sub>2</sub>,<sup>45</sup> however, in that case the outer layers showed a needle-like morphology and the inner layers were more compact. Solid loadings of ca. 11-12 wt.% were estimated on both types of foams.

**Fig. 2.** Characterization of coatings on 580 µm foams. CeO<sub>2</sub>: SEM images (a, a1, a2, a3), Raman spectrum (a4); Pd-CeO<sub>2</sub>: SEM images, EDS spectra (b, b1, b2, b3), Raman spectrum (b4); calcined Pd-CeO<sub>2</sub>: (c, c1, c2) SEM, FESEM images, EDS spectra, (c3) Raman spectra, also CeO<sub>2</sub> calcined.

The structural characterization of the films by XRD confirmed the formation of the cubic fluorite  $\text{CeO}_2$  phase (Fig. 3). In the Raman spectra (Fig. 2a4), the coexistence of the  $F_{2g}$  mode of  $\text{CeO}_2$  at ca.  $460\text{ cm}^{-1}$  and a shoulder at ca.  $610\text{ cm}^{-1}$  evidenced that the ceria contained structural defects such as oxygen vacancies. The band at ca.  $1050\text{ cm}^{-1}$  confirmed the entrapment of nitrates into the  $\text{CeO}_2$  structure during the electrodeposition.<sup>46, 47</sup>

**Fig. 3.** XRD patterns of  $\text{CeO}_2$  and  $\text{Pd-CeO}_2$  electrodeposited on  $580\text{ }\mu\text{m}$  foams.

Good and reproducible coatings made by porous and compact layers were also achieved with  $\text{Pd-CeO}_2$  (Fig. 2b-b3, Fig. S1a-a3), nonetheless a larger amount of material than for  $\text{CeO}_2$  deposited,  $25.6 \pm 1.2$  and  $22.6 \pm 1.3\text{ wt.}\%$  for  $580$  and  $1200\text{ }\mu\text{m}$  foams, respectively. Excluding some regions where palladium clusters were clearly identified (Fig. 2b3),  $\text{Pd}$ -containing species were well dispersed on the coating (Fig. 2b1, 2b2), i.e.  $\text{Pd}$  signal was detected by EDS but there were no  $\text{Pd}$  particles observed. Average  $\text{Pd/Ce}$  a.r. ratio values in these regions were around  $3/97$ , corresponding to the nominal value in the electrolytic solution ( $2\text{ }\%$  w/w). However, ICP analysis of the detached coatings gave a  $5/95$  atomic ratio for both types of foams, i.e.  $3\text{ wt.}\%$   $\text{Pd}$  loading in the electrodeposited catalysts, since it measured  $\text{Pd}$  well dispersed and present in clusters. The total  $\text{Pd}$  loading in the structured catalyst considering the foam weight was around  $0.54\text{ wt.}\%$ . The surface area values for the coated foams were  $11.3$  and  $10.8\text{ m}^2\text{ g}^{-1}$  for  $1200$  and  $580\text{ }\mu\text{m}$ , respectively (Table 1), which normalized to the solid loading corresponded to  $52.3 - 40.6\text{ m}^2\text{ g}^{-1}$ . The isotherms obtained were characteristics of macroporous or non-porous materials with interparticle pores (Fig. S2).<sup>48</sup>

**Table 1.** Specific surface area ( $S_{\text{BET}}$ ) values and normalized to the solid loading of the coated  $580\text{ }\mu\text{m}$  and  $1200\text{ }\mu\text{m}$  foams (fresh and calcined)

Sample	$S_{\text{BET}}\text{ (m}^2\text{ g}^{-1}\text{)}$			
	Fresh	Fresh coating	Calcined	Calcined Coating
$\text{Pd-CeO}_2 - 1200\text{ }\mu\text{m}$	11.3	52.3	11.1	64.5
$\text{Pd-CeO}_2 - 580\text{ }\mu\text{m}$	10.8	40.6	11.9	54.1

XRD patterns showed the reflections of cubic  $\text{CeO}_2$  and neither  $\text{Pd}^0$  nor  $\text{PdO}$  phases were identified (Fig. 3). In comparison to the  $\text{CeO}_2$  sample, the broadening of the  $F_{2g}$  mode and the increase in the defect band intensity in Fig. 2b4 suggested the incorporation of  $\text{Pd}^{2+}$  in the  $\text{CeO}_2$  matrix.<sup>32, 40</sup> The  $\text{Pd } 3d$  core level XPS spectra

showed two doublets at binding energies (BE)  $335.5\text{--}340.7\text{ eV}$  and  $337.9\text{--}343.2\text{ eV}$  (Fig. 4), confirming the presence of two types of  $\text{Pd}$  species on the coating surface. The contribution at  $335.5\text{ eV}$  was related to  $\text{Pd}^0$ , while the one at  $337.9\text{ eV}$  was attributed to the formation of the  $\text{Pd}_x\text{Ce}_{1-x}\text{O}_{2-δ}$  solid solution.<sup>36, 40, 49, 50</sup> The  $\text{Pd}$  content determined by XPS was  $2.49\text{ wt.}\%$ . Concerning to  $\text{Ce } 3d$  core level spectra (Fig. S3), in all cases four spin-orbit doublets denoted as  $v$  and  $u$  can be observed. Three doublets were ascribed to the presence of  $\text{Ce}^{4+}$ :  $v$  ( $\sim 882.3\text{ eV}$ ) and  $u$  ( $\sim 901.0\text{ eV}$ );  $v''$  ( $\sim 888.7\text{ eV}$ ) and  $u''$  ( $\sim 907.3\text{ eV}$ );  $v'''$  ( $\sim 898.5\text{ eV}$ ),  $u'''$  ( $\sim 917.0\text{ eV}$ ). Meanwhile, a doublet  $v'$  ( $\sim 885.3\text{ eV}$ ) and  $u'$  ( $\sim 903.7\text{ eV}$ ), assigned to  $\text{Ce}^{3+}$ , presented a weak intensity due to the low proportion of  $\text{Ce}^{3+}$ .<sup>51</sup> Both  $\text{Ce}^{4+}$  and  $\text{Ce}^{3+}$  were therefore present in the electrodeposited solids, but with a major presence of  $\text{Ce}^{4+}$ .

**Fig. 4.** XPS spectra of  $\text{Pd}$  core  $3d$  in  $\text{Pd-CeO}_2$  coated on  $580\text{ }\mu\text{m}$  foams: (a) electrodeposited and (b) calcined sample.

In conclusion, the increase of the pH due to nitrate reduction provoked the easy and homogeneous precipitation of  $\text{CeO}_2$  on the foam surface. Moreover, the local pH increase allowed the incorporation of  $\text{Pd}^{2+}$  into the  $\text{CeO}_2$  structure forming the solid solution, as per conventionally coprecipitated samples.<sup>40</sup> The massive deposition of large  $\text{Pd}$  metallic particles was decreased, but not completely avoided, probably because of the use of palladium chloride precursors.<sup>52</sup> The electrochemical reduction of  $\text{Pd}^{2+}$ , but also to the interfacial reduction reaction between  $\text{Pd}^{2+}$  and  $\text{Ce}^{3+}$ , reported after mixing  $\text{Ce}^{3+}$  precursor with  $\text{Pd}^{2+}$  and ammonia,<sup>53</sup> could contribute to the formation of  $\text{Pd}^0$  particles.

#### Characterization of calcined coated foams

To obtain the final catalysts, deposited foams were calcined at  $550\text{ }^\circ\text{C}$  for  $10\text{ h}$ . SEM images of the samples are shown in Fig. 2c-c2 and Fig. S1b-b3. During calcination the nitrates and water were removed, and an oxide scale developed (see below), consequently a ca.  $5\%$  weight loss occurred; however, some mechanical loss of the coating could not be discarded. Solid shrinking during weight loss and shearing stresses developed some more cracks in the layers. These phenomena were more important in compact coatings, leading to partial detachment in some localized regions. However, the calcination did not modify the morphology and size of the particles in the coating. Likewise, in electrodeposited samples, locally aggregated and well dispersed  $\text{Pd}$ -containing particles coexisted. For instance, even at the high resolution of FE-SEM (Fig. 2c2), although  $\text{Pd}$  signal was detected in the EDS spectra, there were not  $\text{Pd}$  particles identified.

**Fig. 5.** Micro-computed tomography 2D slices and 3D reconstructions of 1200  $\mu\text{m}$  foams before (a, c) and after coating with Pd-CeO<sub>2</sub> (b, d).

3D micro-computed tomography measurements of the whole foam disks before and after coating were recorded to have a larger samples overview (Fig. 5, Table 2). The presence of hollow struts with internal voids were clearly observed in Fig. 5a and 5b. From the solid structure thickness data (i.e. thickness of the hollow strut wall plus thickness of the coating), summarized in Table 2, a 5  $\mu\text{m}$  average coating thickness was estimated, which is in the limit of the tomography resolution. The surface of the foam within the voids could also be coated by a thin layer, as identified in our previous

work by a higher resolution nano-XRF/XRD tomography.<sup>43</sup> The coating layers only slightly reduced the total porosity of the foams and the mean pore sizes (values reported in Table 2 are actually an average of pore and cell sizes); rough surfaces and cellular structures were not largely altered. In Fig. 5d, it seemed that the coating was well-distributed in the triangular struts, and no accumulation in the valleys was observed. Thus, structured catalysts keep the low pressure drop and transport phenomena of the original bare foam.<sup>54</sup>

**Table 2.** Change in geometrical parameters of the foams before and after coating obtained by 3D micro-computed tomography measurements

Sample	Porosity* (%)	Mean pore size ( $\mu\text{m}$ )	Solid structure thickness ( $\mu\text{m}$ )
580 $\mu\text{m}$ bare	89.3	511 $\pm$ 60	35 $\pm$ 8
580 $\mu\text{m}$ coated	87.7	501 $\pm$ 59	41 $\pm$ 10
1200 $\mu\text{m}$ bare	92.7	1058 $\pm$ 130	37 $\pm$ 11
1200 $\mu\text{m}$ coated	91.1	1037 $\pm$ 136	42 $\pm$ 11

To further investigate the coatings at a higher magnification, HRTEM images of powders scratched away from the foam surfaces were collected (Fig. 6). CeO<sub>2</sub> nanoparticles with an ill-defined shape and average sizes of 5 – 15 and 3 – 10 nm were identified for CeO<sub>2</sub> and Pd-CeO<sub>2</sub>, respectively (Fig. 6a, b). The combined analysis of HAADF images and EDS spectra again evidenced well dispersed palladium species (Fig. 6b3, b4, b5), there were no Pd-containing particles despite EDS Pd signal. They were related to Pd<sup>2+</sup> inside the CeO<sub>2</sub> matrix in agreement with the signal at BE 337.9 eV in the Pd 3d core level in the XPS spectrum of the calcined (Fig. 4), which coexisted with Pd<sup>0</sup> (335.5 eV).

**Fig. 6.** Characterization of powders scratched from 580  $\mu\text{m}$  coated foams. CeO<sub>2</sub>: (a, a1) HRTEM images, (a2) SAED; Pd-CeO<sub>2</sub>: (b) HRTEM images, (b1, b2) SAED, (b3) STEM-HAADF image, (b4, b5) EDS spectra from b3.

The presence of the solid solution may decrease the cubic fluorite sintering during calcination. Indeed, less crystalline nanoparticles (corresponding to more diffuse SAED diffraction rings) (Fig. 6a2, b1), and a broader  $F_{2g}$  mode in the Raman spectra (Fig. 2c3) were observed for Pd-CeO<sub>2</sub> than for CeO<sub>2</sub> samples after calcination. The specific surface areas of the Pd-CeO<sub>2</sub> calcined catalysts were 11.1 and 11.9 m<sup>2</sup> g<sup>-1</sup>, corresponding to 64.5 and 54.1 m<sup>2</sup> g<sup>-1</sup> for the solid (Table 1). The increase in the surface area, in comparison to the fresh samples suggested the increase of the porosity, which might be related to the gases evolving during calcination. However, it should be considered that coating  $S_{BET}$  values may deviate from real ones since the catalytic loading could not be precisely obtained because of the modification of the metallic foam or loss of some coating as above commented. During calcination the foam was oxidized; in the Raman spectra of a calcined bare foam bands due to Fe<sub>2</sub>O<sub>3</sub><sup>55</sup> or Fe<sup>3+</sup> partially substituted by Al<sup>3+</sup> in the Fe<sub>2</sub>O<sub>3</sub> lattice<sup>56</sup> were recorded (Fig. S4).

The Raman spectra of calcined CeO<sub>2</sub> (Fig. 2c3) developed a small band at 250 cm<sup>-1</sup> attributed to the normal Raman inactive (IR active) second-order transverse acoustic (2TA) mode,<sup>57-59</sup> which was previously reported in spectrum of electrodeposited CeO<sub>2</sub>.<sup>30</sup> On the other hand, two new bands were registered at 196 and 651 cm<sup>-1</sup> for Pd-CeO<sub>2</sub> (Fig. 2c3). The latter was attributed to the B<sub>1g</sub> vibrational mode of square planar [PdO<sub>4</sub>] subunits in the PdO structure,<sup>60</sup> which could be formed in regions of the coating with a high Pd/Ce ratio,<sup>61</sup> but that were not identified by XPS (PdO at BE ca. 336.9 eV).<sup>62</sup> The small peak at 196 cm<sup>-1</sup> could also be related to the E<sub>u1</sub> forbidden mode of PdO<sub>4</sub>,<sup>60</sup> however, it was shifted from the 165 cm<sup>-1</sup> value expected value in PdO, and its intensity did not follow the same trend than the B<sub>1g</sub> mode. Hence, it was ascribed to PdO<sub>4</sub> in the ceria lattice as previously reported by Gulyaev and co-workers.<sup>40</sup> It should be remarked that XRD patterns of the coated foams did not show any Pd<sup>0</sup> and PdO crystalline phase, suggesting either a low amount or poor crystallinity.

**Fig. 7.** H<sub>2</sub>-TPR profiles of CeO<sub>2</sub> and Pd-CeO<sub>2</sub> coated on 580 μm foams.

The reducibility of coated foams during H<sub>2</sub>-TPR profiles, shown in Fig. 7, was related to the above commented textural and structural features. The H<sub>2</sub> consumption profile of the CeO<sub>2</sub> showed the reduction steps of surface (520 °C) and bulk ceria (755 °C).<sup>63</sup> In Pd-CeO<sub>2</sub> sample, two peaks were recorded at ca 70 and 150 °C attributed to the reduction of PdO and well dispersed Pd-containing

species interacting with the support, respectively.<sup>32, 64-66</sup> The reduction of CeO<sub>2</sub> could be overlapped in the second peak since palladium promoted its reduction; this promotion was also observed by the shift of the CeO<sub>2</sub> surface reduction towards lower temperatures and the decrease of the surface to bulk areas ratio. Despite Pd<sup>0</sup> particles were in the catalyst, the typical decomposition of palladium hydrides was not observed,<sup>67</sup> probably because of overlapped with the reduction peak of well dispersed Pd species and surface ceria in tight contact with Pd.

#### Catalytic activity in the CO oxidation

The samples coated by electrodeposition were finally tested in the CO oxidation reaction. As well documented in literature,<sup>14</sup> such a reaction shows significant activity even at low temperatures in presence of noble-metal catalysts, it does not produce intermediates and it is usually chosen as a model reaction for many environmental applications. Fig. 8 shows the CO ignition curves obtained with 1200 μm and 580 μm foams, respectively, changing the CO inlet concentration from 2% to 3%. From data collected on 1200 μm foam it is evident the effect of the CO concentration. The curve at 3% shows a higher light-off temperature, in agreement with literature studies that assume a negative reaction order of the CO;<sup>68</sup> this aspect is less evident on 580 μm foam. A second relevant aspect that can be noted for both samples is the null effect of the CO inlet concentration on the conversion at plateau, a typical feature of the physical regime.

**Fig. 8.** CO ignition curves at 3 SLM tests in different CO concentrations for 580 μm foam (a) and for 1200 μm foam (b).

Fig. 9 shows the effect of the flow rate on the conversion at diffusive regime for both foams. In all the cases, significantly high CO conversions were obtained despite very low residence times ( $5.10^{-4} - 8.10^{-3}$  s). The very high geometrical surface of the foams enhances gas/solid interaction between the gas and the catalyst leading to very high volumetric mass transfer coefficients, calculated assuming an ideal plug flow reactor from the measured CO conversion as reported in Equation 1

$$k_v = k_c S_v = - \frac{\ln(1-\eta) \cdot Q}{V} \quad (1)$$

where  $k_v$  is the volumetric mass transfer coefficient [ $s^{-1}$ ],  $k_c$  is the mass transfer coefficient [ $m\ s^{-1}$ ],  $S_v$  is the geometric surface area [ $m^{-1}$ ],  $\eta$  is the CO conversion,  $Q$  is the actual flow rate [ $m^3\ s^{-1}$ ] and  $V$  is the reactor volume [ $m^3$ ].

**Fig. 9.** Effect of the flow rate on the CO conversion over 580  $\mu m$  foams and 1200  $\mu m$  foams.

Calculated volumetric mass transfer coefficients for both foams are reported in Fig. 10. Values of volumetric mass transfer coefficients up to 1200  $s^{-1}$  were measured in these conditions for 1200  $\mu m$  foam and values up to 3600  $s^{-1}$  for 580  $\mu m$  foams, high cell density foams, which widely outperform state of the art 900 CPSI honeycombs, i.e.  $k_v = 950\ s^{-1}$  as calculated by Tronconi and Forzatti.<sup>69</sup> This aspect is central for the design of compact exhaust after-treatment systems where, due to the needs of more stringent environmental regulations, higher requirements on pollutant emissions will be necessary.

**Fig. 10.** Calculated volumetric mass transfer coefficients against actual flow velocity.

Tests at 3 SLM were repeated after some days of continuative operations of the rig in order to evaluate the stability of the coating under harsh conditions in terms of temperature gradients. In these specific conditions, both the number of thermal cycles and the hours of operation may influence the coating stability. Tests were performed after 24 h of operation and 6 thermal cycles and 48 h of operation and 12 thermal cycles for 1200  $\mu m$  foam and only after 48 h of operation after 12 thermal cycles for 580  $\mu m$  foams. Results reported in Fig. 11 evidence that 1200  $\mu m$  foams shows no decay of performances after 3 days and a decrease of just 1% of CO conversion after one week respect to the conversion curve obtained with fresh catalyst. 580  $\mu m$  foam, instead, shows no decay of performances after one week suggesting a good quality and stability of the catalyst coating. Thus, the coating and Pd-containing species were characterized after the long-term catalytic tests.

**Fig. 11.** Evaluation of the decay of performances of the catalyst over 1200  $\mu m$  and 580  $\mu m$  foams – diamonds: fresh catalyst, triangles: after 24 h and 6 thermal cycles, squares: after 48 h and 12 cycles.

### Spent catalysts

In the characterization of the spent catalysts, special attention was paid to analyse different regions of the foam disks since axial temperature gradients generated during reaction conditions, i.e. 100-120  $^{\circ}C$  difference between the inlet and outlet of the bed.

The coating on the top of the foam disk, i.e. at the inlet of the catalytic bed, was less stable than the one at the bottom, being partially detached (Fig. 12a1, a2, Fig. S5). Conversely, the morphology of the  $CeO_2$  particles was not modified at the inlet of the bed and well dispersed Pd species were found (Fig. 12a2). While the sintering of both the support and Pd occurred at the outlet, where spherical Pd particles, of around 25 nm were identified by FE-SEM (Fig. 12b2).

HRTEM images shown in Fig. 13 confirmed that the coating placed at the inlet of the bed was made by  $CeO_2$  nanoparticles with dispersed Pd-containing species and Pd particles in the 2-7 nm range ( $4.1 \pm 1.3$  nm) (Fig. 13a-a2). On the other hand, both large  $CeO_2$  (up to 100 nm) and Pd ( $14.9 \pm 8.6$  nm) particles were identified at the outlet of the bed, the latter being distributed both on the surface and in the bulk of ceria particles (Fig. 13b-b2). SAED analyses confirmed the presence of Pd<sup>0</sup> particles.

**Fig. 12.** SEM images of spent Pd-CeO<sub>2</sub> 580 μm foam catalyst: (a, a1, a2) top catalytic bed; (b, b1, b2) bottom catalytic bed, b2 is a FESEM image.

The modifications in the catalytic coating depending on the position in the bed were confirmed by XRD and Raman. Diffraction patterns in Fig. 14a and Raman spectra in Fig. 14b showed narrower CeO<sub>2</sub> reflections and F<sub>2g</sub> modes, respectively, in spent than in calcined sample and in the bottom than in the top of the bed, due to ceria sintering. From SEM and HRTEM it would appear that the sintering did not modify the particle size at the top but it did at the bottom of the foam. Pd-containing species features also changed under reaction conditions. The Pd<sup>0</sup> (111) reflection, not observed in calcined catalysts, was recorded in the pattern of the spent catalysts, being more intense at the bottom of the bed. While in Raman spectra the band at 650 cm<sup>-1</sup> due to PdO also become narrower at the outlet of the bed, but it was not visible at the inlet.

From these characterization results, it could be stated that the catalytic coating was rather stable in terms of adhesion, while CeO<sub>2</sub> sintered and Pd species were modified with time-on-stream due to the high flow rates, temperature and interaction with CO. In the

fresh catalyst both Pd<sup>0</sup>, PdO and Pd<sup>2+</sup> in the solid solution were identified. Pd<sup>0</sup> is reported to have an increased activity in CO conversion<sup>32, 33, 70, 71</sup> and Pd<sup>2+</sup> into CeO<sub>2</sub> generates oxygen vacancies responsible of activation of O<sub>2</sub>.<sup>72</sup> Under reaction conditions, Pd<sup>2+</sup> was reduced by CO to Pd<sup>0</sup> nanoparticles with a narrow size distribution at the inlet of the bed,<sup>70, 72, 73</sup> generating more active sites. At the outlet of the bed, the highest temperatures provoked the sintering of Pd<sup>0</sup> and PdO, which might be facilitated by the CeO<sub>2</sub> sintering. The coalescence of particles was observed in Fig. 13b, b1, however, the Ostwald ripening could also occur.<sup>74</sup> Furthermore, the less reducing atmosphere (lower CO concentration) decreased the reduction degree of the catalyst, indeed some PdO peaks were still observed in the Raman spectra. Thus, during the CO oxidation test, the active sites were modified by simultaneous transformations, namely generation of new Pd<sup>0</sup> sites and their loss due to the partial sintering, this behaviour, together with the fact that tests were performed under diffusive controlled regime, may explain the absence of differences in the activity with the number of cycles.

## Conclusions

This study demonstrated that the electrodeposition is a promising one-step method to coat high pore density open-cell foams with active and stable Pd-CeO<sub>2</sub> catalysts for mass transfer controlled reactions, such as CO oxidation and many other environmental catalytic processes.

A cubic fluorite nano-CeO<sub>2</sub> with defects was homogeneously deposited on the foam surface by the electrobase generation method forming a coating with vertically orientated platelets and compact particles; the process being independent on the pore size. During the synthesis procedure, Pd<sup>2+</sup> was incorporated into CeO<sub>2</sub> forming a Pd<sub>x</sub>Ce<sub>1-x</sub>O<sub>2-δ</sub> solid solution. The massive Pd<sup>2+</sup> to Pd<sup>0</sup> reduction did not occur, but the formation of Pd<sup>0</sup> particles could not be completely avoided because the direct electrochemical reduction or interfacial reduction reaction between Pd<sup>2+</sup> and Ce<sup>3+</sup>, which was also observed in conventional coprecipitation.

The porous coating with perpendicularly orientated particles may better withstand shrinking and shearing stresses than compact layers enhancing the stability during calcination and reaction conditions. While the conservation of the solid Pd<sub>x</sub>Ce<sub>1-x</sub>O<sub>2-δ</sub> solution may help to decrease the CeO<sub>2</sub> sintering. These highly dispersed Pd<sup>2+</sup> species in the solid solution

generated small Pd<sup>0</sup> nanoparticles that were also stable against sintering at the inlet of the bed, 4.1 ± 1.3 nm, but sensible to coalescence or Ostwald ripening when high temperatures were reached at the outlet.

The stable coating with dispersed Pd species all over the foam surface provided both high activities and stabilities in the CO oxidation operating at very high GHSV. While the very high geometrical specific surface of the foams enhanced gas/solid interaction leading to volumetric mass transfer coefficients larger than their honeycomb state of the art counterparts. Consequently, electrodeposited Pd-CeO<sub>2</sub> catalysts are promising for compact exhaust after-treatment systems.
