51	Abstract

For the first time, this study evaluated the use of MALDI-TOF as a typing tool for *Arcobacter* butzleri. A total of 103 A. butzleri strains isolated from different sources in an artisanal dairy plant in Italy were identified and typed using MALDI-TOF and compared with their multilocus sequence typing (MLST) and pulsed field gel electrophoresis (PFGE) profiles found in previous studies. MALDI-TOF correctly identified all the isolates to species level. No clearly delineated clusters appeared on dendrograms based on either the complete spectra or the significant peaks. but nine clusters were defined using the cophenetic correlation. Interestingly, MALDI-TOF proved able to discriminate A. butzleri strains below species level, confirming its potential use for epidemiological surveys. As expected, the comparative analysis with PFGE and MLST showed that the discriminatory index was lower for MALDI-TOF but roughly comparable to sequence types and pulsotypes. MALDI-TOF appears to be a relatively low cost answer to the urgent need for more rapid, less expensive typing tools suitable for source attribution studies, readily allowing multiple typing methods to be combined. This study provides insights into MALDI-TOF as potential epidemiological tool. Its application in healthcare surveillance systems awaits further exploration to encourage interaction and convergence studies between primary care in humans and animal and food veterinary authorities as part of the One Health concept.

The genus Arcobacter is an unusual taxon within the epsilon subdivision of Proteobacteria containing both pathogenic and free-living species found in a wide range of environments (Miller et al., 2007). It has long been considered an emerging human enteric pathogen linked to gastrointestinal illnesses (Collado and Figueras, 2011; Hsu and Lee, 2015). Although several aspects of Arcobacter epidemiology and virulence are starting to be clarified, key reservoirs and mechanisms of transmission have yet to be fully determined (Collado and Figueras, 2011). Arcobacter species are ubiquitous in animals, in a variety of foods of animal and non-animal origin, and in both aquatic and food-processing environments (Collado and Figueras, 2011; Merga et al., 2013), usually showing a high genotype diversity in all these sources. Arcobacter butzleri is the best characterized of all Arcobacter species. It is probably an environmental organism (Miller et al., 2007) with some level of niche adaptation (Merga et al., 2013) and with the ability to survive in the adverse conditions imposed by food processing and storage (Collado and Figueras, 2011; Ferreira et al., 2015; Giacometti et al., 2013; Giacometti et al., 2015; Hausdorf et al., 2013; Rasmussen et al., 2013; Scarano et al., 2014; Serraino and Giacometti, 2014; Shah et al., 2013) that may cause disease through ingestion of contaminated water or food (Collado and Figueras, 2011; Miller et al., 2007). Source-attribution studies for the burden of human illness require bacterial typing to identify sources and routes of product contamination. Bacterial typing is also a prerequisite for targeted control measures (Dieckmann et al., 2016) and for source-tracking studies to determine the origin of a specific strain by grouping the sources (Santos et al., 2016). The term subtyping refers to characterization beyond the species or subspecies level, allowing the determination of clonal relationships and the phylogenetic relatedness of bacterial strains (Dieckmann et al., 2016). Nowadays, the genotyping methods most commonly used are based on DNA banding patterns, such as pulsed field gel electrophoresis (PFGE) and amplified fragment length 102 polymorphism (AFLP), PCR-restriction fragment-length polymorphism (RFLP), random 103 amplification of polymorphic DNA (RAPD), enterobacterial repetitive intergenic consensus 104 (ERIC-PCR), multiple locus variable number of tandem repeats analysis (MLVA), multilocus 105 sequence typing (MLST) and 16S rRNA gene sequencing. All these techniques possess 106 different discriminatory powers, and their use depends on the main objective to be achieved. In 107 spite of their recognized resolution, many of these approaches often lack reproducibility within 108 and among laboratories, whereas others are discriminatory and reproducible but expensive, 109 laborious and time-consuming - all undesirable factors for the identification of contamination 110 sources (Santos et al., 2016). Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry (MS) has wrought the most radical change in the diagnostic microbiology workflow in the last 113 decade (Fournier et al., 2013) and has become a routine tool for microorganism identification 114 in clinical microbiology laboratories worldwide. However, beyond microbe identification, 115 whose importance for human health care is unquestionable, MALDI-TOF MS has proved to 116 have great potential for epidemiological strain typing and antimicrobial 117 susceptibility/resistance detection (Sanguinetti and Posteraro, 2016). This phenotyping technique is based on the detection of a large number of spectral features originating from 118 119 proteins, namely highly abundant ribosomal and nucleic acid-binding proteins. Though several attempts have been made to apply MALDI-TOF MS to higher resolution microbial 121 discrimination, they have not yielded uniform success, and the limits of the taxonomic 122 resolution of MALDI-TOF MS profiling might be determined in large part by the nature of the 123 particular bacterium profiled (Ghyselinck et al., 2011; Sandrin et al., 2013). Hence, both the 124 taxonomic resolution of MALDI-TOF MS and whether MALDI-TOF MS analysis will overlap other subtyping techniques need to be evaluated individually for a particular genus or species 126 of interest. No such studies have hitherto been performed on A. butzleri isolates.

111

112

120

The aim of the present study was to evaluate the ability of MALDI-TOF technology to characterize *A. butzleri* isolates according to their different pattern of TOF peaks, and to perform a comparative analysis of their previously obtained MLST and PFGE profiles (De Cesare *et al.*, 2015; Giacometti *et al.*, 2013).

2. Material and methods

2.1 Strains tested

A set of 103 *A. butzleri* strains, of which 102 were collected from different sources in an artisanal dairy plant in four samplings in the Emilia Romagna Region between October and December 2012, and the references strains *A. butzleri* DSM 8739^T and *A. cryaerophilus* DSM 7289^T previously characterized by pulsed-field gel electrophoresis (PFGE) (Giacometti *et al.*, 2013) and multilocus sequence typing (MLST) (De Cesare *et al.*, 2015) were selected and analysed. Overall, the strains were obtained from food samples (i.e. raw cow and buffalo milk and ricotta cheese) (N = 28); food contact surfaces (i.e. bulk tank valve, cheese vat, drainage table, milk pump and mozzarella molding roller) (N = 45) and non-food contact surfaces (i.e. floors of cooler room and floor drain) (N = 29). The strain details were previously described (Giacometti *et al.*, 2013). Extrapolating the results from the cited studies, the strains collated and used for this study showed a high diversity of 34 PFGE profiles and 21 sequence types (STs) respectively. Table 1 briefly reports the characteristics of the 102 *A. butzleri* strains included in this study and their MLST and PFGE results.

2.2 Sample preparation

Strains were cultured on nutrient agar (Oxoid, Basingstoke, United Kingdom) supplemented with 5% laked horse blood (Oxoid, Basingstoke, United Kingdom), incubated at 30°C for 24 h and subjected to ethanol-formic acid extraction according to the MALDI Biotyper protocol (Bruker Daltonics, Bremen, Germany). Briefly, nuclease-free water (200 µL) was aliquoted

into a plasticizer-free 1.5-ml Eppendorf tube, several loops of organisms from a whole plate were added, and the water and organisms were thoroughly mixed by vortexing. To this suspension of organisms, 900 µL 100% ethanol was added, and again, the organisms and the suspension were thoroughly mixed by vortexing. To deposit the biological material, the tubes were centrifuged at 20,000xg for 2 min and the supernatant was decanted. To remove the residual ethanol, the tubes were centrifuged again and the ethanol was removed by careful pipetting. Twenty microliters of 70% formic acid (Sigma) were added to the pellet, and the formic acid and pellet were well mixed by vortexing, followed by the addition of 20 µL of pure acetonitrile (Sigma-Aldrich), which was carefully mixed with the other components by pipetting up and down. Finally, the tubes were centrifuged at 20,000xg for 2 min, resulting in a supernatant ready for analysis. One microliter of sample was carefully placed on a 96-spot polished steel target (MSP 96 target, ground steel; Bruker Daltonics) with 1 µL of matrix solution, a saturated solution of α-cyano-4-hydroxycinnamic acid (HCAA) matrix (Bruker Daltonics) in 50% acetonitrile, 47.5% water and 2.5% trifluoroacetic acid (Sigma). MALDI-TOF MS was performed on the MALDI Biotyper Microflex LT controlled by FlexControl software (version 3.3; Bruker Daltonics) at the Istituto Zooprofilattico Sperimentale delle Venezie, Villorba, Treviso, Italy. Spectra were acquired using automatic mode and default settings (2,000 to 20,000 Da; linear positive method); 12 technical replicates for each of 102 strain were generated and we implemented reference A. butzleri DSM 8739^T and A. cryaerophilus DSM 7289^T for the reference spectra. The raw MALDI spectra database created was then exported and imported in BioNumerics 7.6.1 (Applied Maths NV, Sint-Martens-Latem, Belgium) for the following data analysis.

Upon import, the background of the spectra was removed using the rolling disk method, the noise was calculated using the continuous wavelet transform (CWT) method and the spectra

were smoothed using a Kaiser window (Monchamp et al., 2007). Peaks were detected in the spectra using the CWT method with a signal-to-noise threshold of 2. The spectra of all technical replicates were summarized to create an average spectrum per isolate, replicates with a correlation to the average of less than 95% were removed and the final average spectrum was calculated with only the remaining replicates. Only peaks present in 75% of the replicates were considered a peak on the average spectrum. The resulting average spectra were used to calculate a UPGMA dendrogram using a Pearson similarity coefficient. A peak matching was performed with a position tolerance of 500ppm x m/z + 2Da. Peaks from different spectra within this tolerance were considered to belong to the same peak class. As the majority of peaks in this m/z range result from ribosomal proteins that show little variation within a species, a dendrogram was also constructed using only specific subsets of peaks. The resulting peak matching tables were used to perform Principal Component Analysis (PCA) and Linear Discriminant analysis (LDA) after average intensity-based normalization. Additional statistical analysis was done, using Kruskal-Wallis to test significant differences in peak intensities between different MLST types.

3. Results

- MALDI-TOF MS correctly identified all 103 A. butzleri strains and 1 A. cryaerphilus strain to
- species level with score values ≥1.9 using the BRUKER BIOTYPER software.
- The dendrogram of all the investigated spectra based on the complete spectra (Fig. 1.) revealed
- 198 no clearly delineated clusters. Most peaks showed no significant differences among the strains
- tested, with differences caused only by a few peaks. The following peaks were significant at
- 200 the Kruskal Wallis test (m/z 2940.78; 3753.27; 4215.49; 4349.78; 4363.08; 4413.78; 4420.53;
- 201 8698.71; 8724.88; 8827.09; 8840.86; 8866.56; 9419.41; see Fig. 2). A dendrogram based on

202 these peaks alone (see Fig. 3) showed well-delineated clusters of which nine were defined using 203 the cophenetic correlation to decide whether a cluster was well separated from the other strains. 204 In addition, in Fig. 3, a description of which significant peaks are distributed among the 205 MALDI-groups is reproduced in a heat map revealing peaks intensity and the fact that 206 significant peaks are indeed shared among groups, but each group has a specific combination 207 of peaks. 208 Interestingly, MALDI TOF was able to recognize and reflect the complex heterogeneity of the 209 food and environmental A. butzleri strains considered in this study, and the subtyping results 210 obtained appeared roughly similar to those observed with MLST and PFGE. Simpson's index 211 of diversity (DI) produces a single numerical value (from 0 to 1) to compare the abilities of 212 single or combined typing schemes to discriminate between unrelated isolates and was 0.863, 213 0.920 and 0.933 for MALDI TOF, MLST and PFGE respectively. 214 Next, PCA and LDA were applied to distinguish the overall variation among strains and among 215 the MALDI-groups. On the one hand, a PCA based on the complete peak matching table 216 showed no clearly defined groups and no separation of the subtypes obtained with MLST and 217 PFGE (data not shown), similar to the findings reported dendrogran in Fig. 1. On the other, 218 LDA using the ST as groups and only the significantly different peak classes among these STs 219 disclosed several groups (see Fig. 4). Strains from the same ST or pulsotypes (if lower) could 220 be found in the same MALDI cluster, even though some STs and pulsotypes were mixed 221 together.

4. Discussion

Microbiological monitoring of food products and the efficiency of early warning systems and outbreak investigations depend on the rapid identification and strain characterization of pathogens posing risks to the health and safety of consumers (Dieckmann *et al.*, 2016).

Although pathogen detection is the first stage of identifying problem areas in a food processing environment or health care system, strain level subtyping is crucial to highlight genotypic differences among strains with particular niches and to trace the sources of contamination in a food processing plant during an outbreak or extended epidemiological investigations, or to track foodborne pathogens throughout production to determine where they enter into the system. Specifically, accurate identification of A. butzleri transmission pathways among animals and environmental sources and accurate source tracking studies remain scant. In addition, A. butzleri biology is not closely associated with any particular host or hosts (Miller et al., 2007). Nor does it possess species-wide pathogenicity, suggesting that A. butzleri is an environmental microorganism demanding rapid identification of the contamination source to understand the epidemiology of a disease and the relative contribution of reservoirs, pathways, exposure and risk factors. To obtain these data, a more extensive and rigorous application of high throughput subtyping methods is a priority. Since, MALDI TOF is a rapid low-cost epidemiological method, this study tested its use for the first time as a typing tool for A. butzleri. Contrary to species-level identification, strain-level discrimination using MALDI-TOF MS is expected to be influenced by minor changes in the mass spectra (Kern et al., 2014). Therefore, the same culture conditions, namely culture media, culturing time and conditions, were applied to all the investigated samples to avoid the differences observed in the literature (Jadhav et al., 2015; Sandrin et al., 2013). Overall, MALDI TOF was able to discriminate the investigated A. butzleri strains below species level, confirming its potential use for epidemiological surveys. As expected, the comparison analysis with PFGE and MLST showed the DI was lower for MALDI TOF but, at the same time, roughly comparable to ST types and pulsotypes indicating a fair concordance among the typing method results. MALDI TOF was able to trace a possible transmission route from environment to product, or vice versa, within an artisanal dairy plant, reflecting similar results and typing ability previously observed by both MLST and PFGE.

249

250

PFGE is generally regarded as "the gold standard" for subspecies classification of microorganisms, and obviously a similar strain-level discrimination and demarcation between food and environmental isolates is difficult to obtain with MALDI TOF. A well-reported but important consideration is that genotypic and phenotyic typing techniques measure completely different cellular properties (Jadhav et al., 2015): MALDI TOF detects mainly conserved ribosomal proteins and, to a lesser extent, nucleic acid binding proteins that exhibit only limited strain specificity (Dieckmann et al., 2016). At the same time, the same set of genetic events relevant for PFGE will give rise to changes in the mobility of proteins during MS and a variable peak number/PFGE restriction fragment number ratio could be tolerated to define related types by MALDI TOF typing (Spinali et al., 2015). MLST is based on allelic nucleic acid variants among housekeeping genes located in the genome of the tested microorganism and has a high discriminatory power with the advantage of providing data readily transportable from one laboratory to another and suitable for global and long-term or evolutionary studies rather than local epidemiology (Dieckmann et al., 2016). On the contrary, an added advantage of MALDI TOF is that the peak intensities which indirectly convey the extent of protein expression are also used to discriminate the isolates, whereas most genotypic methods test only the presence or absence of particular genes (Taneja et al., 2016). Moreover, identification and typing can both be done simultaneously using MALDI TOF with the direct colony plating method (Taneja et al., 2016). Finally, both these conventional typing methods (MLST and PFGE) remain either very labor intensive or very expensive, whereas MALDI TOF provides a low cost per sample analysis and rapid results despite the high initial acquisition costs. Obviously MALDI TOF has some limitations, namely those linked to different sample preparation and culture conditions which can influence the reproducibility of the method. In addition, MALDI TOF is based on the expression of intrinsic proteins which are conserved and do not show a high degree of evolution, meaning that evolutionary changes may not be

reproduced using this technique (Taneja et al., 2016). Further, rigorous statistical analysis is 277 278 inevitably required to analyse MALDI TOF profiles. 279 Our findings suggest that MALDI TOF may allow multiple typing methods to be combined 280 when certain strains are associated in an outbreak or for epidemiological studies of emergent 281 pathogens like A. butzleri that present prohibitive sampling, isolation and genotyping costs if 282 the bacterium is not already integrated in existing surveillance or monitoring programs. For this 283 aspect, typing is likely restricted to relative small cohorts of isolates in either clinical 284 diagnostics or a healthcare setting (Sanguinetti and Posteraro, 2016) and MALDI TOF appears 285 to be a relatively low cost answer to the urgent need for more rapid, less expensive typing tools 286 suitable for source attribution. In addition, faster methods are more realistic than prolonged 287 genotypic methods in an outbreak setting (Taneja et al., 2016), and a standardized MALDI TOF 288 scheme could serve to generate a preliminary cluster of isolates for a result-based isolate 289 selection (Jadhav et al., 2015) to decide if further and more appropriate typing methods are 290 necessary. Similar promising findings were reported for emetic and non-emetic *Bacillus cereus* 291 group members (Sato et al., 2017; Fiedoruk et al., 2016) and for Escherichia coli (Tagg et al., 292 2015; Christner et al., 2014) confirming that the use of MALDI TOF as an automated tool for 293 large-scale populations analyses or for targeted screening seems to be effective. 294 In the case of outbreaks, clinical microbiology laboratories can detect the emergence of 295 unknown species, particular pathotypes or antibiotic resistance patterns, and therefore play an 296 important part in warning the medical authorities, which can corroborate the results across a 297 particular region, country or continent (Fournier et al., 2013). In this context, the potential of 298 MALDI TOF in the field of healthcare surveillance systems merits further exploration and 299 validation. 300 The acquisition of MALDI TOF MS is recommended for leading microbiological laboratories 301 where its daily use for bacterial identification and a systematic elaboration of MS peaks for

302 epidemiological strain typing and antimicrobial susceptibility/resistance detection would be 303 useful to create a shared database for strains of interest. The exchange of data between human 304 and animal/food care surveillance systems could serve to organize a standardized central 305 warning system and reflects the need for convergence of these domains under the One Health 306 concept. 307 308 **Conflict of Interest** 309 Katleen Vranckx and Katrien De Bruyne are employees of Applied Maths NV. 310 **Acknowledgments.** This research did not receive specific grant from any funding agencies in 311 312 the public, commercial, or not-for-profit sectors. 420	Fig. 1. MSP dendrogram of all the 102 A. butzleri strains based on the complete spectra
421	compared with their MLST and PFGE types. Different colored squares represent MLST and
422	PFGE types.
423	Fig. 2. Two representative A. butzleri mass-spectral profiles showing MALDI TOF peaks
424	differing significantly between different MLST profiles, at m/z 4413.8, m/z 4420.5 and at m/z
425	8827.1, m/z 8840.9 and m/z 8866.5; x-axis contains $m(Da)/z$, y-axis intensity with left the
426	absolute intensity in arbitrary units and right the relative intensity compared to the most intense
427	peak in the profile.
428	Fig. 3. MSP dendrogram of the A. butzleri strains based on the peaks significantly different STs
429	compared with their MLST and PFGE types with the MALDI-group marked on the right. Peak
430	intensity is represented using different colors ranges from blue (low intensity) to green and
431	yellow (medium intensity) and red (high intensity).
432	Fig. 4. Linear discriminant analysis with isolates coloured according to their sequence type
433	shows the majority of isolates fall into the same group with isolates of the same ST, though
434	several STs cannot be separated from each other. The data is visualized with the three
435	components containing the highest discrimination between the STs, the x-axis contributes to
436	43.9 % of discrimination, the y-axis for 22.3% and the z-axis for 18.2%.
