REVIEW OF PARTICLE PHYSICS*

Particle Data Group

Abstract

The *Review* summarizes much of particle physics and cosmology. Using data from previous editions, plus 3,324 new measurements from 878 papers, we list, evaluate, and average measured properties of gauge bosons and the recently discovered Higgs boson, leptons, quarks, mesons, and baryons. We summarize searches for hypothetical particles such as supersymmetric particles, heavy bosons, axions, dark photons, etc. Particle properties and search limits are listed in Summary Tables. We give numerous tables, figures, formulae, and reviews of topics such as Higgs Boson Physics, Supersymmetry, Grand Unified Theories, Neutrino Mixing, Dark Energy, Dark Matter, Cosmology, Particle Detectors, Colliders, Probability and Statistics. Among the 120 reviews are many that are new or heavily revised, including a new review on High Energy Soft QCD and Diffraction and one on the Determination of CKM Angles from B Hadrons.

The *Review* is divided into two volumes. Volume 1 includes the Summary Tables and 98 review articles. Volume 2 consists of the Particle Listings and contains also 22 reviews that address specific aspects of the data presented in the Listings.

The complete *Review* (both volumes) is published online on the website of the Particle Data Group (pdg.lbl.gov) and in a journal. Volume 1 is available in print as the *PDG Book*. A *Particle Physics Booklet* with the Summary Tables and essential tables, figures, and equations from selected review articles is available in print and as a web version optimized for use on phones as well as an Android app.

The 2020 edition of the *Review of Particle Physics* should be cited as:
P.A. Zyla *et al.* (Particle Data Group), Prog. Theor. Exp. Phys. **2020**, 083C01 (2020)

DOI: 10.1093/ptep/ptaa104

For the online version see pdg.lbl.gov:

*The publication of the *Review of Particle Physics* is supported by the Director, Office of Science, Office of High Energy Physics of the U.S. Department of Energy under Contract No. DE–AC02–05CH11231; by the European Laboratory for Particle Physics (CERN); by an implementing arrangement between the governments of Japan (MEXT: Ministry of Education, Culture, Sports, Science and Technology) and the United States (DOE) on cooperative research and development; by the Italian National Institute of Nuclear Physics (INFN); and by the Physical Society of Japan (JPS). Individual collaborators receive support for their PDG activities from their respective funding agencies.

HIGHLIGHTS OF THE 2020 EDITION OF THE REVIEW OF PARTICLE PHYSICS

All PDG data and review articles are available online at **pdg.lbl.gov**.

878 new papers with 3,324 new measurements

- 411 new papers from *LHC* experiments (ATLAS, CMS and LHCb).
- Extensive up-to-date *Higgs boson* coverage from 117 new papers with 201 measurements, including latest results on mass, couplings, decay width and branching ratios, plus searches for other neutral and charged Higgs bosons.
- *Supersymmetry*: 83 new papers with major exclusions.
- *Top quark*: 36 new papers provide latest results on mass, coupling, and constraints on various models of physics beyond the Standard Model involving top-quark production and decay.
- Latest from *B-meson physics*: 85 papers and 356 measurements, including observations of new excited Λ_b baryons and new pentaquark states.
- 5 new sections including limits of cross sections in *WIMP and Dark Matter Searches* for masses in the GeV range (65 new entries, including also older results).
- *Heavy Neutral Lepton* Listings reorganized and extended.
- New *proton charge radius* measurements appear to resolve charge radius puzzle.

120 reviews (most are revised)

- New reviews on:
  - *High Energy Soft QCD and Diffraction*.
  - *Determination of CKM Angles from B Hadrons*.
- Significant update/revision to reviews on:
  - Major revision of *Physical Constants* following the 2019 redefinition of units in the International System of Units.
  - *Electroweak Model* and *CKM* reviews provide latest fits of Standard Model parameters.
  - *Structure Functions* review includes new discussion on transverse momentum dependent distributions (TMDs).
  - *Top Quark* review summarizes latest results and constraints on new physics from top quark.
  - D^0–$\overline{D}^0$ *Mixing* summarizes latest results and discusses implications of first observation of CP violation in D^0 decays.
  - Completely rewritten review on *Neutrino Masses, Mixing and Oscillations* discusses latest results from solar, atmospheric, reactor and accelerator-based neutrino experiments and provides global fit values for mixing parameters and mass spectrum.
  - *Pentaquarks* review updated based on new LHCb measurement of hidden-charm pentaquarks.
  - *Monte Carlo Neutrino Generators* includes new extensive discussion on nuclear scattering.
  - Completely rewritten review on *Dark Matter*.
  - *Experimental Tests of Gravitational Theory* revised and extended to include gravitational waves.

VOLUME 1: SUMMARY TABLES AND REVIEWS

Highlights 6
Introduction 11
History plots 19
Online particle physics information (rev.) 20

SUMMARY TABLES

Gauge and Higgs bosons 31
Leptons 34
Quarks 37
Mesons 38
Meson quick reference table 91
Baryon quick reference table 92
Baryons 93
Searches not in Other Sections 111
Tests of conservation laws 113

REVIEWS, TABLES, AND PLOTS

Constants, Units, Atomic and Nuclear Properties

VOLUME 2: PARTICLE LISTINGS (available online only)

Illustrative key and abbreviations
Illustrative key 999
Abbreviations 1000

Gauge and Higgs bosons
(γ, gluon, graviton, W, Z, Higgs, Axions) 1013

Leptons
(e, μ, τ, Heavy-charged lepton searches, Neutrino properties, Number of neutrino types Double-β decay, Neutrino mixing, Heavy-neutral lepton searches) 1101

Quarks
(u, d, s, c, b, t, b', t' (4^{th} gen.), Free quarks) 1173

Mesons
Light unflavored (π, ρ, a, b) (η, ω, f, ϕ, h) 1209
Other light unflavored 1332
Strange (K, K^*) 1337
Charmed (D, D^*) 1391
Charmed, strange (D_s, D_s^*, D_{sJ}) 1448
Bottom (B, V_{cb}/V_{ub}, B^*, B_J^*) 1465
Bottom, strange (B_s, B_s^*, B_{sJ}^*) 1640
Bottom, charmed (B_c) 1664
$c\overline{c}$ (η_c, $J/\psi(1S)$, χ_c, h_c, ψ) 1668
$b\overline{b}$ (η_b, Υ, χ_b, h_b) 1782

Baryons
N 1825
Δ 1878
Λ 1902
Σ 1927
Ξ 1959
Ω 1971
Charmed (Λ_c, Σ_c, Ξ_c, Ω_c) 1974
Doubly charmed (Ξ_{cc}) 1996
Bottom (Λ_b, Σ_b, Ξ_b, Ω_b, b-baryon admixture) 1997
Exotic baryons (P_c pentaquarks) 2014

Searches not in Other Sections
Magnetic monopole searches 2017

Introduction

1 Overview

The *Review of Particle Physics* is a comprehensive review of the field of Particle Physics and of related areas in Cosmology. It is divided into two volumes. Volume 1 includes the “Summary Tables” and “Reviews, Tables, and Plots”. Volume 2 consists of the "Particle Listings".

The *Review* is updated each year and made available on the PDG website (pdg.lbl.gov). In even-numbered years, the *Review* is also published in a journal and printed as the *PDG Book* together with an abridged *Particle Physics Booklet* containing Summary Tables and essential tables, figures, and equations from selected review articles. This edition is an updating through January 2020.

The Summary Tables give our best values and limits for particle properties such as masses, widths or lifetimes, and branching fractions, as well as an extensive summary of searches for hypothetical particles and a summary of experimental tests of conservation laws.

The 96 review articles in Reviews, Tables and Plots cover a wide variety of theoretical and experimental topics. Together with the Summary Tables they provide a quick reference for the practicing particle physicist. Two more review articles, Online Particle Physics Information and Tests of Conservation Laws, can be found in the Introduction and Summary Tables, respectively.

The Particle Listings are a compilation/evaluation of data on particle properties. They contain all the data used to get the values given in the Summary Tables. They also give information on unconfirmed particles and particle searches. In this edition, the Particle Listings include 3,324 new measurements from 878 papers, in addition to the 41,371 measurements from 11,322 papers that first appeared in previous editions [1]. 22 review articles are part of the Particle Listings and address specific aspects of the data presented in the Listings. Because of the large quantity of data, the Particle Listings are not an archive of all published data on particle properties. We refer interested readers to earlier editions for data now considered to be obsolete.

We organize the particles into six categories:

- Gauge and Higgs bosons
- Leptons
- Quarks
- Mesons
- Baryons
- Searches not in other sections

The last category only includes searches for particles that do not belong to the previous groups. For example, it includes searches for supersymmetric particles, compositeness and extra dimensions, while searches for heavy charged leptons and massive neutrinos are with the leptons.

In Sec. 2 of this Introduction, we list the main areas of responsibility of the authors of the Particle Listings. Our many consultants, without whom we would not have been able to produce this *Review*, are acknowledged in Sec. 3. In Sec. 4, we mention briefly the naming scheme for hadrons, which was extended in the previous edition [1]. In Sec. 5, we discuss our procedures for choosing among measurements of particle properties and for obtaining best values of the properties from the measurements.

The accuracy and usefulness of this *Review* depend in large part on interaction between its users and the authors. We appreciate comments, criticisms, and suggestions for improvements of any kind. Please send them to the appropriate author, according to the list of responsibilities in Sec. 2 below, or to pdg@lbl.gov.

In addition to the online publication at pdg.lbl.gov, the Review is available in different formats:

- The printed *PDG Book* includes volume 1 only, *i.e.* it contains the Summary Tables and most review articles. Since the 2016 edition [2] the detailed tables from the Particle Listings are no longer printed.
- The *Particle Physics Booklet* includes the Summary Tables plus essential tables, figures, and equations from selected review articles. Starting with the Booklets of the 2018 edition, we have excluded most text and explanations in order to revert back to a more pocket-sized format. The Booklet is available in print and as a web version optimized for use on phones as well as an Android app (see pdg.lbl.gov/booklet).
- *pdgLive* (pdgLive.lbl.gov) is a web application giving more interactive access to PDG data than the static web pages and PDF files that are also available.
- Files that can be downloaded from the PDG website include a table of masses, widths, and PDG Monte Carlo particle ID numbers; PDF files of volume 1 (PDG Book), volume 2 (Particle Listings) and Booklet; individual review articles; all figures; and an archive file containing the complete PDG website (except for pdgLive).

Copies of the *PDG Book* or the *Particle Physics Booklet* can be ordered from our website or directly at pdg.lbl.gov/order. For special requests only, please email pdg@lbl.gov in North and South America, Australia, and the Far East, and pdg-products@cern.ch in all other areas.

This *Review* is considered to be a single comprehensive review of particle physics and related areas. Therefore we prefer that it be cited as a whole, rather than citing *e.g.* an individual review article that is part of this *Review*. For the 2020 edition, the proper citation is:

P.A. Zyla *et al.* (Particle Data Group), Prog. Theor. Exp. Phys. **2020**, 083C01 (2020).

If you wish to refer to a specific part of the *Review*, for example to the Higgs boson review article, the following form should be used:

Status of Higgs Boson Physics in P.A. Zyla *et al.* (Particle Data Group), Prog. Theor. Exp. Phys. **2020**, 083C01 (2020).

2 Particle Listings responsibilities

* Asterisk indicates the people to contact with questions or comments about Particle Listings sections.

- Gauge and Higgs bosons

γ	A. Bettini, D.E. Groom*
Gluons	R.M. Barnett,* A.V. Manohar
Graviton	A. Bettini,* D.E. Groom
W, Z	M. Grünewald,* A. Gurtu*
Higgs bosons	S. Heinemeyer,* K. Hikasa, J. Tanaka
Heavy bosons	R.M. Barnett,* K.A. Olive, M. Tanabashi
Axions	K.A. Olive, G. Raffelt,* F. Takahashi

- Leptons

Neutrinos	M. Goodman, C.-J. Lin,* K. Nakamura, K.A. Olive, A. Piepke, P. Vogel
e, μ	A. Bettini,* C. Grab
τ	A. Lusiani, K. Mönig*

- Quarks

Quarks	R.M. Barnett,* A.V. Manohar
Top quark	R.M. Barnett,* Y. Sumino
b', t'	R.M. Barnett,* Y. Sumino
Free quark	A. Bettini,* C.-J. Lin

- Mesons

π, η	A. Bettini,* C. Grab
Unstable mesons	C. Amsler, M. Doser,* S. Eidelman,* T. Gutsche, C. Hanhart, J.J. Hernández-Rey, C. Lourenco, A. Masoni, M. Mikhasenko, R.E. Mitchell, S. Navas, C. Patrignani, S. Spanier, G. Venanzoni, V. Vorobyev
K (stable)	G. D'Ambrosio, C.-J. Lin*
D (stable, no mix.)	J. Rademacker, D. Robinson*
D^0 mixing	D.M. Asner, W.-M. Yao*
B (stable)	A. Cerri,* P. Eerola, M. Kreps, Y. Kwon, W.-M. Yao*

- Baryons

Stable baryons	C. Grab, D. Robinson*
Unstable baryons	V. Burkert, E. Klempt, U. Thoma, L. Tiator, R.L. Workman*
Charmed baryons	J. Rademacker, D. Robinson*
Bottom baryons	A. Cerri,* P. Eerola, M. Kreps, Y. Kwon, W.-M. Yao*

- Miscellanoues searches

Monopole	A. Bettini,* D. Milstead
Supersymmetry	M. D'Onofrio, H.K. Dreiner,* A. de Gouvêa, F. Moortgat K.A. Olive
Technicolor	K. Agashe,* K.A. Olive, M. Tanabashi
Compositeness	M. Tanabashi, J. Terning*
Extra Dimensions	T. Gherghetta, K.A. Olive, D. Robinson*
WIMP, DM, Other	H. Baer, A. Bettini,* W.-M. Yao*

3 Consultants

The Particle Data Group benefits greatly from the assistance of hundreds of physicists who are asked to referee review articles and verify every piece of data entered into this *Review*. Of special value is the advice of the PDG Advisory Committee, which meets biennially and thoroughly reviews all aspects of our operation. The members of the 2020 committee are:

S. Demers (Yale)
D. d'Enterria (CERN)
J. Frieman (FNAL)
L. Hall (UC Berkeley/LBNL)
T. Nakada (EPFL)
M. Yokoyama (Tokyo)
Q. Zhao (IHEP Beijing)

We have especially relied on the expertise of the following people for advice on particular topics:

- I. Abt (MPI Munich)
- M. Achasov (Budker Inst., Novosibirsk)
- M. Albrow (FNAL)
- A. Antognini (ETH Zurich)
- F. Anulli (INFN, Rome)
- E. Aprile (Columbia U.)
- G. Arduini (CERN)
- E. Armengaud (CEA Saclay, DSM/IRFU/SPP)
- M. Artuso (Syracuse U.)
- P. Azzurri (INFN, Pisa)
- H. Bachacou (IRFU, Saclay)
- K. Backes (Yale U.)
- A. Barabash (ITEP)
- E. Barberis (FNAL)
- M. Bardeen (FNAL)
- W. Barter (Imperial Coll. London)
- M. Battaglieri (U. di Genova)
- G. Bell (Siegen U.)
- V. Belyaev (ITEP)
- S. Benson (CERN)
- Z. Berezhiani (INFN, LNGS)
- F. Bernlochner (Karlsruhe U.)
- E. Berti (Johns Hopkins U.)
- V. Bertone (NIKHEF)
- M. Bettler (CERN)
- M. Beznogov (Astro. Inst. UNAM)
- M. Borsato (CERN)
- J. Bramante (Queen's U.)
- J.E. Brau (Oregon U.)
- T. Bringmann (Oslo U.)
- J. Brod (Cincinnati U.)
- G. Brooijmans (Columbia U.)
- R. Bruce (CERN)
- T. Brune (TU)
- O. Bruning (CERN)
- D.A. Bryman (TRIUMF)
- J. Butterworth (UCL)
- F. Calore (LAPTH)
- F. Canelli (Zurich U.)
- A. Canto (CERN)
- J. Cao (IHEP Beijing)
- L. Cardani (INFN, Rome)
- V. Cavaliere (BNL)
- G. Cavallero (CERN)
- M. Cepeda (CIEMAT)
- F. Cerutti (LBNL)
- M. Charles (CNRS)
- M. Chen (Queen's U.)
- K. Cheung (Tsinghua U.)
- G. Chiarelli (INFN, Pisa)
- V. Chobanova (CERN)
- J. Chou (Rutgers U.)
- S. Choudhury (Indian Inst. Tech., Mumbai)
- R. Ciesielski (Rockefeller U.)
- G. Colangelo (Bern U.)
- J.I. Collar (Chicago U.)
- G. Compère (ULB, Brussels)
- M. Crisler (FNAL)
- A. Czarnecki (Alberta U.)
- G. D'Ambrosio (INFN, Napoli)
- A. Danilov (INR, Moscow)
- M. Daum (PSI)
- I. David (Glasgow U.)
- C. Davies (Glasgow U.)
- B. Dawson (Adelaide U.)
- J. De Blas (INFN, Padua)
- P. Decowski (NIKHEF)
- G. de Lellis (INFN, Napoli)
- M. Della Morte (SDU)
- S. Demidov (INR, Moscow)
- D. Denisov (FNAL)
- D. d'Enterria (CERN)
- A.V. Derbin (Petersburg Nuclear Phys. Inst.)
- S. Derenzo (LBNL)
- S. Desai (Boston U.)
- U. De Sanctis (Rome U. Tor Vergata)
- S. Descotes-Genon (Paris-Sud U.)
- B. Dey (CERN)
- M. Diamond (Toronto U.)
- A. Di Domenica (INFN, Rome)
- F. Dordei (CERN)
- K. Dundas (Columbia U.)
- S.R. Elliott (LANL)
- K. Ellis (Durham U.)
- C. Englert (Glasgow U.)
- D. Epifanov (Budker Inst., Novosibirsk)
- M. Escudero (King's Coll. London)
- S. Esen (CERN)
- R. Essig (YITP, Stony Brook)
- P. Everaerts (MIT)

- V. Ezhov (NRC Kurchatov Inst. PNPI)
- S. Fang (IHEP Beijing)
- P. Fayet (LPTENS)
- M. Fedderke (Stanford U.)
- A. Ferrari (CERN)
- W. Fischer (BNL)
- J. Formaggio (MIT)
- J. Fortin (UC San Diego)
- T. Fujita (Kyoto U.)
- T. Gaisser (Delaware U., Bartol Inst.)
- P. Gambino (INFN, Torino)

4 Naming scheme for hadrons

We introduced in the 1986 edition [3] a new naming scheme for the hadrons. Changes from older terminology affected mainly the heavier mesons made of u, d, and s quarks. Otherwise, the only important change to known hadrons was that the $F^{\pm}$ became the $D_s^{\pm}$. None of the lightest pseudoscalar or vector mesons changed names, nor did the $c\overline{c}$ or $b\overline{b}$ mesons (we do, however, now use χ_c for the $c\overline{c}$ χ states), nor did any of the established baryons. The Summary Tables give both the new and old names whenever a change has occurred.

In the previous edition [1] the naming scheme was extended to address the naming of charmonium and bottomonium states that are commonly referred to as X, Y or Z states in the literature. The current scheme is described in "Naming Scheme for Hadrons" (p. 1) of this *Review*. A table details the correspondence between the names newly adopted by the PDG and those that have appeared in the literature.

We give here our conventions on type-setting style. Particle symbols are italic (or slanted) characters: e^-, p, Λ, π^0, K_L, D_s^+, b. Charge is indicated by a superscript: B^-, Δ^{++}. Charge is not normally indicated for p, n, or the quarks, and is optional for neutral isosinglets: η or η^0. Antiparticles and particles are distinguished by charge for charged leptons and mesons: τ^+, K^-. Otherwise, distinct antiparticles are indicated by a bar (overline): $\overline{\nu}_\mu$, $\overline{t}$, $\overline{p}$, $\overline{K}^0$, and $\overline{\Sigma}^+$ (the antiparticle of the Σ^-).

5 Procedures

5.1 *Selection and treatment of data*

The Particle Listings contain all relevant data known to us that are published in journals. With very few exceptions, we do not include results from preprints or conference reports. Nor do we include data that are of historical importance only (the Listings are not an archival record). We search every volume of 20 journals through our cutoff date for relevant data. We also include later published papers that are sent to us by the authors (or others).

In the Particle Listings, we clearly separate measurements that are used to calculate or estimate values given in the Summary Tables from measurements that are not used. We give explanatory comments in many such cases. Among the reasons a measurement might be excluded are the following:

- It is superseded by or included in later results.
- No error is given.
- It involves assumptions we question.
- It has a poor signal-to-noise ratio, low statistical significance, or is otherwise of poorer quality than other data available.
- It is clearly inconsistent with other results that appear to be more reliable. Usually we then state the criterion, which sometimes is quite subjective, for selecting "more reliable" data for averaging. See Sec. 5.4.
- It is not independent of other results.
- It is not the best limit (see below).
- It is quoted from a preprint or a conference report.

In some cases, *none* of the measurements is entirely reliable and no average is calculated. For example, the masses of many of the baryon resonances, obtained from partial-wave analyses, are quoted as estimated ranges thought to probably include the true values, rather than as averages with errors. This is discussed in the Baryon Particle Listings.

For upper limits, we normally quote in the Summary Tables the strongest limit. We do not average or combine upper limits except in a very few cases where they may be re-expressed as measured numbers with Gaussian errors.

As is customary, we assume that particle and antiparticle share the same spin, mass, and mean life. The Tests of Conservation Laws table, following the Summary Tables, lists tests of CPT as well as other conservation laws.

We use the following indicators in the Particle Listings to tell how we get values from the tabulated measurements:

- OUR AVERAGE —From a weighted average of selected data.
- OUR FIT —From a constrained or overdetermined multiparameter fit of selected data.
- OUR EVALUATION —Not from a direct measurement, but evaluated from measurements of related quantities.
- OUR ESTIMATE —Based on the observed range of the data. Not from a formal statistical procedure.
- OUR LIMIT —For special cases where the limit is evaluated by us from measured ratios or other data. Not from a direct measurement.

An experimentalist who sees indications of a particle will of course want to know what has been seen in that region in the past. Hence we include in the Particle Listings all reported states that, in our opinion, have sufficient statistical merit and that have not been disproved by more reliable data. However, we promote to the Summary Tables only those states that we feel are well established. This judgment is, of course, somewhat subjective and no precise criteria can be given. For more detailed discussions, see the minireviews in the Particle Listings.

5.2 *Averages and fits*

We divide this discussion on obtaining averages and errors into three sections: (1) treatment of errors; (2) unconstrained averaging; (3) constrained fits.

5.2.1 *Treatment of errors*

In what follows, the "error" δx means that the range $x \pm \delta x$ is intended to be a 68.3% confidence interval about the central value x. We treat this error as if it were Gaussian. Thus when the error *is* Gaussian, δx is the usual one standard deviation (1σ). Many experimenters now give statistical and systematic errors separately, in which case we usually quote both errors, with the statistical error first. For averages and fits, we then add the two errors in quadrature and use this combined error for δx.

When experimenters quote asymmetric errors $(\delta x)^+$ and $(\delta x)^-$ for a measurement x, the error that we use for that measurement in making an average or a fit with other measurements is a continuous function of these three quantities. When the resultant average or fit $\overline{x}$ is less than $x - (\delta x)^-$, we use $(\delta x)^-$; when it is greater than $x + (\delta x)^+$, we use $(\delta x)^+$. In between, the error we use is a linear function of x. Since the errors we use are functions of the result, we iterate to get the final result. Asymmetric output errors are determined from the input errors assuming a linear relation between the input and output quantities.

In fitting or averaging, we usually do not include correlations between different measurements, but we try to select data in such a way as to reduce correlations. Correlated errors are, however, treated explicitly when there are a number of results of the form $A_i \pm \sigma_i \pm \Delta$ that have identical systematic errors Δ. In this case, one can first average the $A_i \pm \sigma_i$ and then combine the resulting statistical error with Δ. One obtains, however, the same result by averaging $A_i \pm (\sigma_i^2 + \Delta_i^2)^{1/2}$, where $\Delta_i = \sigma_i \Delta [\sum (1/\sigma_j^2)]^{1/2}$. This procedure has the advantage that, with the modified systematic errors Δ_i, each measurement may be treated as independent and averaged in the usual way with other data. Therefore, when appropriate, we adopt this procedure. We tabulate Δ and invoke an automated procedure that computes Δ_i before averaging and we include a note saying that there are common systematic errors.

Another common case of correlated errors occurs when experimenters measure two quantities and then quote the two and their difference, *e.g.*, m_1, m_2, and $\Delta = m_2 - m_1$. We cannot enter all of m_1, m_2 and Δ into a constrained fit because they are not independent. In some cases, it is a good approximation to ignore the quantity with the largest error and put the other two into the fit. However, in some cases correlations are such that the errors on m_1, m_2 and Δ are comparable and none of the three values can be ignored. In this case, we put all three values into the fit and invoke an automated procedure to increase the errors prior to fitting such that the three quantities can be treated as independent measurements in the constrained fit. We include a note saying that this has been done.

5.2.2 *Unconstrained averaging*

To average data, we use a standard weighted least-squares procedure and in some cases, discussed below, increase the errors with a "scale factor." We begin by assuming that measurements of a given quantity are uncorrelated, and calculate a weighted average and error as

$$\overline{x} \pm \delta\overline{x} = \frac{\sum_i w_i\, x_i}{\sum_i w_i} \pm \left(\sum\nolimits_i w_i\right)^{-1/2} , \qquad (1)$$

where

$$w_i = 1/(\delta x_i)^2 .$$

Here x_i and δx_i are the value and error reported by the ith experiment, and the sums run over the N experiments. We then calculate $\chi^2 = \sum w_i(\overline{x} - x_i)^2$ and compare it with $N-1$, which is the expectation value of χ^2 if the measurements are from a Gaussian distribution.

If $\chi^2/(N-1)$ is less than or equal to 1, and there are no known problems with the data, we accept the results.

If $\chi^2/(N-1)$ is very large, we may choose not to use the average at all. Alternatively, we may quote the calculated average, but then make an educated guess of the error, a conservative estimate designed to take into account known problems with the data.

Finally, if $\chi^2/(N-1)$ is greater than 1, but not greatly so, we still average the data, but then also do the following:

(a) We increase our quoted error, $\delta\overline{x}$ in Eq. (1), by a scale factor S defined as

$$S = \left[\chi^2/(N-1)\right]^{1/2} . \qquad (2)$$

Our reasoning is as follows. The large value of the χ^2 is likely to be due to underestimation of errors in at least one of the experiments. Not knowing which of the errors are underestimated, we assume they are all underestimated by the same factor S. If we scale up all the input errors by this factor, the χ^2 becomes $N-1$, and of course the output error $\delta\overline{x}$ scales up by the same factor. See Ref. [4].

When combining data with widely varying errors, we modify this procedure slightly. We evaluate S using only the experiments with smaller errors. Our cutoff or ceiling on δx_i is arbitrarily chosen to be

$$\delta_0 = 3N^{1/2}\, \delta\overline{x} ,$$

where $\delta\overline{x}$ is the unscaled error of the mean of all the experiments. Our reasoning is that although the low-precision experiments have little influence on the values $\overline{x}$ and $\delta\overline{x}$, they can make significant contributions to the χ^2, and the contribution of the high-precision experiments thus tends to be obscured. Note that if each experiment has the same error δx_i, then $\delta\overline{x}$ is $\delta x_i/N^{1/2}$, so each δx_i is well below the cutoff. (More often, however, we simply exclude measurements with relatively large errors from averages and fits: new, precise data chase out old, imprecise data.)

Our scaling procedure has the property that if there are two values with comparable errors separated by much more than their stated errors (with or without a number of other values of lower accuracy), the scaled-up error $\delta\,\overline{x}$ is approximately half the interval between the two discrepant values.

We emphasize that our scaling procedure for *errors* in no way affects central values. And if you wish to recover the unscaled error $\delta\overline{x}$, simply divide the quoted error by S.

(b) If the number M of experiments with an error smaller than δ_0 is at least three, and if $\chi^2/(M-1)$ is greater than 1.25, we show in the Particle Listings an ideogram of the data. Figure 1 is an example. Sometimes one or two data points lie apart from the main body; other times the data split into two or more groups. We extract no numbers from these ideograms; they are simply visual aids, which the reader may use as he or she sees fit.

Each measurement in an ideogram is represented by a Gaussian with a central value x_i, error δx_i, and area proportional to $1/\delta x_i$. The choice of $1/\delta x_i$ for the area is somewhat arbitrary. With this choice, the center of gravity of the ideogram corresponds to an average that uses weights $1/\delta x_i$ rather than the $(1/\delta x_i)^2$ actually used in the averages. This may be appropriate when some of the experiments have seriously underestimated systematic errors. However, since for this choice of area the height of the Gaussian for each measurement is proportional to $(1/\delta\, x_i)^2$, the peak position of the ideogram will often favor the high-precision measurements at least as much as does the least-squares average. See our 1986 edition [3] for a detailed discussion of the use of ideograms.

5.2.3 *Constrained fits*

In some cases, such as branching ratios or masses and mass differences, a constrained fit may be needed to obtain the best values of a set of parameters. For example, most branching ratios and rate measurements are analyzed by making a simultaneous least-squares fit to all the data and extracting the partial decay fractions P_i, the partial widths Γ_i, the full width Γ (or mean life), and the associated error matrix.

Assume, for example, that a state has m partial decay fractions P_i, where $\sum P_i = 1$. These have been measured in N_r different ratios R_r, where, e.g., $R_1 = P_1/P_2$, $R_2 = P_1/P_3$, *etc.* [We can handle any ratio R of the form $\sum \alpha_i\, P_i / \sum \beta_i\, P_i$, where α_i and β_i are constants, usually 1 or 0. The forms $R = P_iP_j$ and $R = (P_iP_j)^{1/2}$ are also allowed.] Further assume that *each* ratio R has been measured by N_k experiments (we designate each experiment with a subscript k, e.g., R_{1k}). We then find the best values of the fractions P_i by minimizing the χ^2 as a function of the $m-1$ independent parameters:

$$\chi^2 = \sum_{r=1}^{N_r} \sum_{k=1}^{N_k} \left(\frac{R_{rk} - R_r}{\delta R_{rk}} \right)^2 , \qquad (3)$$

where the R_{rk} are the measured values and R_r are the fitted values of the branching ratios.

In addition to the fitted values $\overline{P}_i$, we calculate an error matrix $\langle \delta\overline{P}_i\ \ \delta\overline{P}_j \rangle$. We tabulate the diagonal elements of $\delta\,\overline{P}_i = \langle \delta\,\overline{P}_i\ \ \delta\,\overline{P}_i \rangle^{1/2}$ (except that some errors are scaled as discussed below). In the Particle Listings, we give the complete correlation matrix; we also calculate the fitted value of each ratio, for comparison with the input data, and list it above the relevant input, along with a simple unconstrained average of the same input.

Three comments on the example above:

(1) There was no connection assumed between measurements of the full width and the branching ratios. But often we also have information on partial widths Γ_i as well as the total width Γ. In this case we must introduce Γ as a parameter in the fit, along

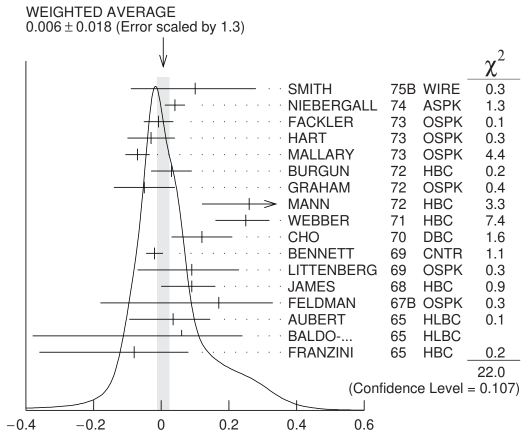

Figure 1: A typical ideogram. The arrow at the top shows the position of the weighted average, while the width of the shaded pattern shows the error in the average after scaling by the factor S. The column on the right gives the χ^2 contribution of each of the experiments. Note that the next-to-last experiment, denoted by the incomplete error flag ($\perp$), is not used in the calculation of S (see the text).

with the P_i, and we give correlation matrices for the widths in the Particle Listings.

(2) We try to pick those ratios and widths that are as independent and as close to the original data as possible. When one experiment measures all the branching fractions and constrains their sum to be one, we leave one of them (usually the least well-determined one) out of the fit to make the set of input data more nearly independent. We now do allow for correlations between input data.

(3) We calculate scale factors for both the R_r and P_i when the measurements for any R give a larger-than-expected contribution to the χ^2. According to Eq. (3), the double sum for χ^2 is first summed over experiments $k = 1$ to N_k, leaving a single sum over ratios $\chi^2 = \sum \chi_r^2$. One is tempted to define a scale factor for the ratio r as $S_r^2 = \chi_r^2 / \langle \chi_r^2 \rangle$. However, since $\langle \chi_r^2 \rangle$ is not a fixed quantity (it is somewhere between N_k and N_{k-1}), we do not know how to evaluate this expression. Instead we define

$$S_r^2 = \frac{1}{N_k} \sum_{k=1}^{N_k} \frac{\left(R_{rk} - \overline{R}_r\right)^2}{\langle (R_{rk} - \overline{R}_r)^2 \rangle}. \tag{4}$$

With this definition the expected value of S_r^2 is one. We can show that

$$\langle (R_{rk} - \overline{R}_r)^2 \rangle = \langle (\delta R_{rk})^2 \rangle - (\delta \overline{R}_r)^2, \tag{5}$$

where $\delta \overline{R}_r$ is the fitted error for ratio r.

The fit is redone using errors for the branching ratios that are scaled by the larger of S_r and unity, from which new and often larger errors $\delta \overline{P}_i'$ are obtained. The scale factors we finally list in such cases are defined by $S_i = \delta \overline{P}_i' / \delta \overline{P}_i$. However, in line with our policy of not letting S affect the central values, we give the values of $\overline{P}_i$ obtained from the original (unscaled) fit.

There is one special case in which the errors that are obtained by the preceding procedure may be changed. When a fitted branching ratio (or rate) $\overline{P}_i$ turns out to be less than three standard deviations ($\delta \overline{P}_i'$) from zero, a new smaller error $(\delta \overline{P}_i'')^-$ is calculated on the low side by requiring the area under the Gaussian between $\overline{P}_i - (\delta \overline{P}_i'')^-$ and $\overline{P}_i$ to be 68.3% of the area between zero and $\overline{P}_i$. A similar correction is made for branching fractions that are within three standard deviations of one. This keeps the quoted errors from overlapping the boundary of the physical region.

5.3 *Rounding*

While the results shown in the Particle Listings are usually exactly those published by the experiments, the numbers that appear in the Summary Tables (means, averages and limits) are subject to a set of rounding rules.

The basic rule states that if the three highest order digits of the error lie between 100 and 354, we round to two significant digits. If they lie between 355 and 949, we round to one significant digit. Finally, if they lie between 950 and 999, we round up to 1000 and keep two significant digits. In all cases, the central value is given with a precision that matches that of the error. So, for example, the result (coming from an average) 0.827 ± 0.119 would appear as 0.83 ± 0.12, while 0.827 ± 0.367 would turn into 0.8 ± 0.4.

Rounding is not performed if a result in a Summary Table comes from a single measurement, without any averaging. In that case, the number of digits published in the original paper is kept, unless we feel it inappropriate. Note that, even for a single measurement, when we combine statistical and systematic errors in quadrature, rounding rules apply to the result of the combination. It should be noted also that most of the limits in the Summary Tables come from a single source (the best limit) and, therefore, are not subject to rounding.

Finally, we should point out that in several instances, when a group of results come from a single fit to a set of data, we have chosen to keep two significant digits for all the results. This happens, for instance, for several properties of the W and Z bosons and the τ lepton.

5.4 *Discussion*

The problem of averaging data containing discrepant values is nicely discussed by Taylor in Ref. [5]. He considers a number of algorithms that attempt to incorporate inconsistent data into a meaningful average. However, it is difficult to develop a procedure that handles simultaneously in a reasonable way two basic types of situations: (a) data that lie apart from the main body of the data are incorrect (contain unreported errors); and (b) the opposite—it is the main body of data that is incorrect. Unfortunately, as Taylor shows, case (b) is not infrequent. He concludes that the choice of procedure is less significant than the initial choice of data to include or exclude.

We place much emphasis on this choice of data. Often we solicit the help of outside experts (consultants). Sometimes, however, it is simply impossible to determine which of a set of discrepant measurements are correct. Our scale-factor technique is an attempt to address this ignorance by increasing the error. In effect, we are saying that present experiments do not allow a precise determination of this quantity because of unresolvable discrepancies, and one must await further measurements. The reader is warned of this situation by the size of the scale factor, and if he or she desires can go back to the literature (via the Particle Listings) and redo the average with a different choice of data.

Our situation is less severe than most of the cases Taylor considers, such as estimates of the fundamental constants like $\hbar$, *etc.* Most of the errors in his case are dominated by systematic effects. For our data, statistical errors are often at least as large as systematic errors, and statistical errors are usually easier to estimate. A notable exception occurs in partial-wave analyses, where different techniques applied to the same data yield different results. In this case, as stated earlier, we often do not make an average but just quote a range of values.

A brief history of early Particle Data Group averages is given in Ref. [4]. On the following page, our History Plots show the time evolution of some of our values of a few particle properties. Sometimes large changes occur. These usually reflect the introduction of significant new data or the discarding of older data. Older data are discarded in favor of newer data when it is felt that the newer data have smaller systematic errors, or have more checks on systematic errors, or have made corrections unknown at the time of the older experiments, or simply have much smaller errors. Sometimes, the scale factor becomes large near the time at which a large jump takes place, reflecting the uncertainty introduced by the new and inconsistent data. By and large, however, a full scan of our history plots shows a dull progression toward greater precision at central values quite consistent with the first data points shown.

We conclude that the reliability of the combination of experimental data and our averaging procedures is usually good, but it is important to be aware that fluctuations outside of the quoted errors can and do occur.

ACKNOWLEDGMENTS

The publication of the *Review of Particle Physics* is supported by the Director, Office of Science, Office of High Energy Physics of the U.S. Department of Energy under Contract No. DE–AC02–05CH11231; by the European Laboratory for Particle Physics (CERN); by an implementing arrangement between the governments of Japan (MEXT: Ministry of Education, Culture, Sports, Science and Technology) and the United States (DOE) on cooperative research and development; by the Italian National Institute of Nuclear Physics (INFN); and by the Physical Society of Japan (JPS). Individual collaborators receive support for their PDG activities from their respective funding agencies.

We thank all those who have assisted in the many phases of preparing this *Review.* We particularly thank the many who have responded to our requests for verification of data entered in the Listings, and those who have made suggestions or pointed out errors.

We are grateful to the staff at CERN, IHEP Beijing, KEK, and LBNL who take care of the mailing and distribution of our products.

This work used resources of the National Energy Research Scientific Computing Center, a DOE Office of Science User Facility supported by the Office of Science of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231.

Revised August 2019 by M. Moskovic (CERN).

1 Introduction

The collection of online information resources in particle physics and related areas presented in this chapter is of necessity incomplete. An expanded and regularly updated online version can be found at:

`http://library.cern/particle_physics_information`

Suggestions for additions and updates are very welcome.[1]

2 Particle Data Group (PDG) resources

- **Review of Particle Physics (RPP):** A comprehensive report on the fields of particle physics and related areas of cosmology and astrophysics, including both review articles and a compilation/evaluation of data on particle properties. The review section includes articles, tables and plots on a wide variety of theoretical and experimental topics of interest to particle physicists and astrophysicists. The particle properties section provides tables of published measurements as well as the Particle Data Group's best values and limits for particle properties such as masses, widths, lifetimes, and branching fractions, as well as an extensive summary of searches for hypothetical particles. RPP is published as a large book every two years, with partial updates made available once each year on the web.

  All the contents of the book version of RPP are available online:

  `http://pdg.lbl.gov`

  The printed book can be ordered:

  `http://pdg.lbl.gov/2019/html/receive_our_products.html`

  Of historical interest is the complete RPP collection which can be found online:

  `http://pdg.lbl.gov/rpp-archive/`

  `http://library.cern/PDG_publications/review_particle_physics`
- **Particle Physics booklet:** An abridged version of the Review of Particle Physics, available as a pocket-sized 250-page booklet. It is one of the most useful summaries of physics data. The booklet contains an abbreviated set of reviews and the summary tables from the most recent edition of the Review of Particle Physics.

  The PDF file of the booklet can be downloaded:

  `http://pdg.lbl.gov/current/booklet.pdf`

  The printed booklet can be ordered:

  `http://pdg.lbl.gov/2019/html/receive_our_products.html`
- **PDGLive:** A web application for browsing the contents of the PDG database that contains the information published in the Review of Particle Physics. It allows one to navigate to a particle of interest, see a summary of the information available, and then proceed to the detailed information published in the Review of Particle Physics. Data entries are directly linked to the corresponding bibliographic information in INSPIRE.

  `http://pdglive.lbl.gov`
- **Computer-readable files:** Data files that can be downloaded from the PDG include tables of particle masses and widths, PDG Monte Carlo particle numbers, and cross-section data. The files are updated with each new edition of the Review of Particle Physics.

  `http://pdg.lbl.gov/current/html/computer_read.html`

3 Particle Physics Information Platforms

- **INSPIRE:** INSPIRE serves as a one-stop information platform for the particle physics community, comprising 8 interlinked databases on literature, conferences, institutions, journals, researchers, experiments, jobs and data. Run in collaboration by CERN, DESY, Fermilab, IHEP, IN2P3, and SLAC, it has been serving the scientific community for almost 50 years. Previously known as SPIRES, it was the first website outside Europe and the first database on the web. Close interaction with the user community and with arXiv, ADS, HEPData, ORCID, PDG and publishers is the backbone of INSPIRE's evolution.

  `http://inspirehep.net/`

  In 2019, INSPIRE launched INSPIRE beta, featuring all-new literature search, author profiles and job postings. INSPIRE beta is running in parallel with the current platform and it will fully replace it in the future. The INSPIRE beta site is available at:

  `http://beta.inspirehep.net`

  – Blog: `http://blog.inspirehep.net/`
  – Twitter: `@inspirehep`

4 Literature Databases

- **ADS:** The SAO/NASA Astrophysics Data System is a Digital Library portal offering access to 13 million bibliographic records in Astronomy and Physics. The ADS search engine also indexes the full-text for approximately four million publications in this collection and tracks citations, which now amount to over 80 million links. The system also provides access and links to a wealth of external resources, including electronic articles hosted by publishers and arXiv, data catalogs and a variety of data products hosted by the astronomy archives worldwide. The ADS can be accessed at:

  `http://ads.harvard.edu/`
- **arXiv.org:** A repository of full-text articles in physics, astronomy, mathematics, computer science, statistics, nonlinear sciences, quantitative finance, quantitative biology, electrical engineering and systems science, and economics. Papers are submitted by registered authors to arXiv, often as preprints in advance of submission to a journal for publication; includes postprints, working papers, and other relevant material. Established in 1991, the repository is interlinked

[1] Please send comments and corrections to micha.moshe.moskovic@cern.ch

with ADS and INSPIRE, among others. Readers can browse subject categories or search by author, title, abstract, date, and other fields. Receive daily update alerts for subfields by email or RSS.

`https://arXiv.org`

- Blog: `https://blogs.cornell.edu/arXiv`
- Twitter: `@arxiv`

- **CDS:** The CERN Document Server contains records of about 700,000 CERN and non-CERN articles, preprints, theses. It includes records for internal and technical notes, official CERN committee documents, and multimedia objects. CDS is planning to focus on its role as an institutional repository covering all CERN material from the early 50s and reflecting the holdings of the CERN library. Non-CERN particle and accelerator physics content is in the process of being exported to INSPIRE.

  `http://cds.cern.ch`
- **INSPIRE HEP:** The HEP collection, the flagship of the INSPIRE suite, serves more than 1.3 million bibliographic records with a growing number of full-text articles attached and metadata including author affiliations, abstracts, references, experiments, keywords as well as links to arXiv, ADS, PDG, HEPData, publisher platforms and other servers. It provides fast metadata and full-text searches, plots extracted from full text, author disambiguation, author profile pages and citation analysis and is expanding its content to, e.g., experimental notes.

  `http://inspirehep.net`
- **JACoW:** The Joint Accelerator Conference Website publishes the proceedings of several accelerator conferences held around the world. A custom interface allows searching based on keywords, titles, authors, and in the full text.

  `http://www.jacow.org/`
- **KEK Library Preprints and Reports Database:** This database contains bibliographic records of preprints and technical reports held in the KEK library, with links to the full-text images of more than 100,000 papers scanned from their worldwide preprint collection. Particularly useful for older scanned preprints. Links to it are included in INSPIRE HEP.

  `https://www.i-repository.net/il/meta_pub/engG0000128Lib`
- **MathSciNet:** This database of almost 3 million items provides reviews, abstracts and bibliographic information for much of the mathematical sciences literature. Over 100,000 new items, most of them classified according to the Mathematics Subject Classification, and more than 80,000 reviews of the current published literature are added each year. Author identification allows users to search for publications by author and citation data allows users to track the history and influence of research publications.

  `http://www.ams.org/mathscinet`
- **OSTI.GOV:** A portal to free, publicly available DOE-sponsored R&D results including technical reports, bibliographic citations, journal articles, conference papers, books, multimedia and data information. It consolidates OSTI's home page and the now-retired primary search tool SciTech Connect. It contains over 3 million records, including citations to 1.5 million journal articles, 1 million of which have digital object identifiers (DOIs) linking to full-text articles on publishers' websites.

  `https://www.osti.gov`

5 Particle Physics Journals and Conference Proceedings Series

- **CERN Journal List:** This list of journals and conference series publishing particle physics content provides information on Open Access, copyright policies and terms of use.

  `http://library.cern/oa/where-publish`
- **INSPIRE Journals:** The database contains over 3,600 journals publishing HEP-related articles.

  `http://inspirehep.net/collection/journals`

6 Conference Databases

- **INSPIRE Conferences:** The database of more than 23,000 past, present, and future conferences, schools, and meetings relevant to high-energy physics and related fields is searchable by title, acronym, series, date and location. Included are information about published proceedings, links to conference contributions in the INSPIRE HEP database, and links to the conference website when available. New conferences can be submitted from the entry page.

  `http://inspirehep.net/conferences`

7 Research Institutions

- **INSPIRE Institutions:** INSPIRE Institutions contains over 11,500 institutes, laboratories, and universities, where research on particle physics and astrophysics is led. Every record includes, whenever possible, as detailed information, such as address, web links, experiments, and links to INSPIRE papers authored by people affiliated to that institution. One can search for a particular institution by name, acronym, and location.

  `http://inspirehep.net/institutions`

8 People

- **INSPIRE HEPNames:** Searchable worldwide database of over 125,000 active, departed, retired, and deceased people associated with particle physics and related fields. The affiliation history of these researchers, their e-mail addresses, ORCIDs, web pages, experiments they participated in, PhD advisor, information on their graduate students and links to their papers in the INSPIRE HEP, arXiv and ADS databases are provided, as well as a user interface to update this information.

  `http://inspirehep.net/hepnames`
- **ORCID**: Registry providing persistent digital identifiers allowing to unambiguously identify researchers. Through integration in key research workflows such as manuscript and grant submission, it supports automated linkages between scientists and their professional activities ensuring that their work is recognized.

  `https://orcid.org`

9 Experiments

- **INSPIRE Experiments:** Contains more than 3,500 past, present, and future experiments in particle physics. Lists both accelerator and non-accelerator experiments. Includes official experiment name and number, location, and collaboration lists. Simple searches by participant, title, experiment number, institution, date approved, accelerator, or detector, return a description of the experiment, including a complete list of authors, title, overview of the experiment's goals and methods, and a link to the experiment's web page if available. Recently, it has expanded its scope to include particle accelerators besides experiments and to link them together.

  `http://inspirehep.net/Experiments`
- **Cosmic ray/Gamma ray/Neutrino and similar experiments:** This extensive collection of experiment websites is organized by focus of study and by location. Additional sections link to educational materials, organizations, and other useful resources. The site is maintained at the Max Planck Institute for Nuclear Physics, Heidelberg.

  `http://www.mpi-hd.mpg.de/hfm/CosmicRay/CosmicRaySites.html`

10 Jobs

- **AAS Job Register:** The American Astronomical Society publishes once a month graduate, postgraduate, faculty and other positions mainly in astronomy and astrophysics.

  `http://jobregister.aas.org/`
- **Academic Jobs Online**: A full-service online recruiting site for academic institutions worldwide in all disciplines and areas.

  `https://academicjobsonline.org/ajo`

- **APS Careers:** A gateway for physicists, students, and physics enthusiasts to information about physics jobs and careers. It contains Physics job listings, career advice, upcoming workshops and meetings, and career and job-related resources provided by the American Physical Society.
  `http://www.aps.org/careers/employment`
- **brightrecruits.com:** A recruitment service run by IOP Publishing that connects employers from different industry sectors with jobseekers who have a background in physics and engineering.
  `http://brightrecruits.com/`
- **IOP Careers:** Career information and resources primarily aimed at university students are provided by the UK Institute of Physics.
  `http://www.iop.org/careers/`
- **INSPIRE HEPJobs:** Lists academic and research jobs in high energy physics, nuclear physics, accelerator physics and astrophysics with the option to post a job or to receive email notices of new job listings. About 500 jobs are currently listed.
  `http://inspirehep.net/jobs`
- **Physics Today Jobs:** Online recruitment advertising website for Physics Today magazine, published by the American Institute of Physics. Physics Today Jobs is the managing partner of the AIP Career Network, an online job board network for the physical science, engineering, and computing disciplines. Over 6,000 resumes are currently available, and nearly 5,000 jobs were posted in 2018.
  `http://www.physicstoday.org/jobs`

11 Software Packages and Repositories

Most relevant software is hosted by general-purpose repositories like GitHub, GitLab or BitBucket, but here are a few specific repositories focused on astrophysics or HEP. ## Repositories

- **ASCL:** The Astrophysics Source Code Library (ASCL) is a free online registry for source codes of interest to astronomers and astrophysicists. It lists codes that have been used in research that has appeared in, or been submitted to, peer-reviewed publications.
  `http://ascl.net`
- **GenSer:** The Generator Services project collaborates with Monte Carlo (MC) generator authors and with LHC experiments in order to prepare validated LCG compliant code for both theoretical and experimental communities at the LHC, sharing the user support duties, providing assistance for the development of the new object-oriented generators, and guaranteeing the maintenance of the older packages on the LCG supported platforms. The project consists of the generators repository, validation, HepMC record and MCDB event databases.
  `http://ep-dep-sft.web.cern.ch/project/generator-service-project-genser`
- **Hepforge:** A development environment for high-energy physics software projects, in particular housing many event-generator related projects, that offers a ready-made, easy-to-use set of web-based tools, including shell account with up-to-date development tools, web page hosting, subversion, git and Mercurial code management systems, mailing lists, bug tracker and wiki system.
  `http://www.hepforge.org/`

11.1 *Particle Physics Software*

- **FastJet:** This is a software package for jet finding in pp and e^+e^- collisions. It includes fast native implementations of many sequential recombination clustering algorithms, plugins for access to a range of cone jet finders and tools for advanced jet manipulation.
  `http://fastjet.fr/`
- **GAMBIT:** A global fitting code for generic Beyond the Standard Model theories, designed to allow fast and easy definition of new models, observables, likelihoods, scanners and backend physics codes.
  `http://gambit.hepforge.org`
- **Geant4:** This is a toolkit for the simulation of the passage of particles through matter. Its areas of application include high energy, nuclear and accelerator physics, as well as studies in medical and space science.
  `http://geant4.web.cern.ch/geant4/`
- **LHAPDF:** HEP community standard library for parton distribution function interpolation, including official collection of PDF data sets.
  `http://lhapdf.hepforge.org/`
- **QUDA:** Library for performing calculations in lattice QCD on GPUs using NVIDIA's CUDA platform. The current release includes optimized solvers for Wilson, Clover-improved Wilson,Twisted mass, Staggered, Improved staggered, Domain wall and Mobius fermion actions.
  `http://lattice.github.io/quda/`
- **Rivet:** The Rivet toolkit, a system for validation of Monte Carlo event generators, provides a large set of experimental analyses useful for MC generator development, validation, and tuning.
  `http://rivet.hepforge.org/`
- **ROOT:** This framework for data processing in high-energy physics, born at CERN, offers applications to store, access, process, analyze and represent data or perform simulations.
  `http://root.cern.ch`
- **Scikit-HEP:** This is a community-driven and community-oriented project with the aim of providing Particle Physics at large with an ecosystem for data analysis in Python. The project started in Autumn 2016 and is under active development. It focuses on providing core and common tools for the community but also on improving the interoperability between HEP tools and the scientific ecosystem in Python as well as the discoverability of utility packages and projects.
  `http://scikit-hep.org`
- **tmLQCD:** This freely available software suite provides a set of tools to be used in lattice QCD simulations, mainly a HMC implementation for Wilson and Wilson twisted mass fermions and inverter for different versions of the Dirac operator.
  `https://github.com/etmc/tmLQCD`
- **USQCD:** The software suite enables lattice QCD computations to be performed with high performance across a variety of architectures. The page contains links to the project web pages of the individual software modules, as well as to complete lattice QCD application packages which use them.
  `http://usqcd-software.github.io`
- **Software lists:** A list of Monte Carlo generators may be found at:
  `http://cmsdoc.cern.ch/cms/PRS/gentools/www/geners/collection/`
  The homepage of the SUSY Les Houches Accord contains links to codes relevant for supersymmetry calculations and phenomenology.
  `http://skands.physics.monash.edu/slha/`
  A variety of codes and algorithmic tools for analysing supersymmetric phenomenology is described in
  `http://arxiv.org/abs/0805.2088`
  G. Cowan's list provides links to HEP software, general statistics and data analysis links.
  `http://www.pp.rhul.ac.uk/~cowan/sda/statlinks.html`
  An extended list of more specialized HEP-related software can be found in the online version of this review:
  `http://library.cern/particle_physics_information#sof`

11.2 *Astrophysics Software*

- **Astropy:** The Astropy Project is a community effort to develop a single core package for Astronomy in Python and foster interoperability between Python astronomy packages.
  `http://www.astropy.org`
- **Starlink:** Starlink was a UK Project supporting astronomi-

cal data processing. It was shut down in 2005 but its open-source software continued to be developed at the Joint Astronomy Centre until March 2015. It is currently maintained by the East Asian Observatory. The open-source software products are a collection of applications and libraries, usually focused on a specific aspect of data reduction or analysis.

`http://starlink.eao.hawaii.edu/starlink`

- Links to a large number of astronomy software archives are listed at:

  `http://heasarc.nasa.gov/docs/heasarc/astro-update/`

11.3 *Web Apps*

- **APFEL Web:** This online parton density function plotter allows to compare predictions for different PDF fits.

  `https://apfel.mi.infn.it/`
- **ColliderReach:** A tool to give a simple estimate of the relation between the mass reaches of different proton-proton collider configurations.

  `http://collider-reach.web.cern.ch/`
- **TMDplotter:** Allows to plot TMDs and PDFs as a function of different variables.

  `http://tmdplotter.desy.de/`

11.4 *Mobile Apps*

- **arXiv eXplorer:** Android app for browsing and searching arXiv.org, and for reading, saving and sharing articles.

  `https://play.google.com/store/apps/details?id=com.gbeatty.arxiv`
- **Collider:** This mobile app allows users to see data from the ATLAS experiment at the LHC.

  `http://collider.physics.ox.ac.uk/`
- **LHSee:** This smartphone app allows users to see collisions from the Large Hadron Collider.

  `http://www2.physics.ox.ac.uk/about-us/outreach/public/lhsee`
- **The Particles:** App for Apple iPad, Windows 8 and Microsoft Surface. Allows users to browse a wealth of real "event" images and videos, read popular "biographies" of each of the particles and explore the A-Z of particle physics with its details and definitions of key concepts, laboratories and physicists. Developed by Science Photo Library in partnership with Prof. Frank Close.

  `http://www.sciencephoto.com/apps/particles.html`

12 Data repositories

Data is increasingly deposited in general-purpose repositories like Zenodo (https://zenodo.org/), figshare (https://figshare.com/) or the Open Science Framework (https://osf.io/), but here are a few specific repositories focused on physics.

12.1 *Particle Physics*

- **HEPData:** The HEPData project, funded by the STFC (UK) and based at Durham University, has been built up over the past four decades as a unique repository for scattering data from experimental particle physics papers. It currently comprises the data points from plots and tables related to several thousand publications including those from the LHC. The data from HEPData can also be accessed through INSPIRE. A new enhanced service was recently developed in collaboration with CERN.

  `https://hepdata.net`
- **CERN Open Data:** The CERN Open Data portal provides data from real collision events, as well as simulated and simplified datasets, produced by the experiments at the LHC, virtual machines to reproduce the analysis environment, and software to process the data. It serves over 2 PB of data in total and encourages their use for both educational and research purposes.

  `http://opendata.cern.ch`
- **HepSim:** A repository with Monte Carlo simulations for particle-collision experiments. It contains predictions from parton shower models and includes Monte Carlo events after fast and full detector simulations and event reconstruction.

  `http://atlaswww.hep.anl.gov/hepsim/`
- **ILDG:** The International Lattice Data Grid is an international organization which provides standards, services, methods and tools that facilitate the sharing and interchange of lattice QCD gauge configurations among scientific collaborations by uniting their regional data grids. It offers semantic access with local tools to worldwide distributed data.

  `http://www.usqcd.org/ildg/`
- **MCDB - Monte Carlo Database:** This central database of MC events aims to facilitate communication between Monte-Carlo experts and users of event samples in LHC collaborations. Having these events stored in a public place along with the corresponding documentation allows for direct cross checks of the performances on reference samples.

  `http://mcdb.cern.ch/`
- **MCPLOTS:** MCPLOTS is a repository of Monte Carlo plots comparing High Energy Physics event generators to a wide variety of available experimental data. The website is supported by the LHC Physics Centre at CERN.

  `http://mcplots.cern.ch/`

12.2 *Astrophysics*

- **CfA Dataverse:** This astronomy data repository at Harvard is open to all scientific data from astronomical institutions worldwide.

  `https://dataverse.harvard.edu/dataverse/cfa`
- **NASA's HEASARC:** The High Energy Astrophysics Science Archive Research Center (HEASARC) is the primary archive for NASA's (and other space agencies') missions dealing with electromagnetic radiation from extremely energetic phenomena ranging from black holes to the Big Bang.

  `http://heasarc.gsfc.nasa.gov/`
- **NASA archives:** The NASA archives provide access to raw and processed datasets from numerous NASA missions.

  Mikulski Archive for Space Telescopes (MAST): Hubble telescope, other missions (UV, optical):

  `http://archive.stsci.edu/`

  NASA/IPAC Infrared Science Archive: Spitzer, Herschel, Planck telescope, other missions:

  `http://irsa.ipac.caltech.edu/`
- **NASA/IPAC Extragalactic Database (NED):** An astronomical database that collates and cross-correlates information on extragalactic objects. It contains their positions, basic data, and names as well as bibliographic references to published papers, and notes from catalogs and other publications. NED supports searches for objects and references, and offers browsing capabilities for abstracts of articles of extragalactic interest.

  `http://ned.ipac.caltech.edu/`
- **SIMBAD:** The SIMBAD astronomical database provides basic data, cross-identifications, bibliography and measurements for astronomical objects outside the solar system. It can be queried by object name, coordinates and various criteria. Lists of objects and scripts can be submitted.

  `http://simbad.u-strasbg.fr/simbad/`
- **VizieR:** VizieR provides access to the most complete library of published astronomical catalogues and data tables, available online organized in a self-documented database. Query tools allow users to select relevant data tables and extract and format records matching given criteria. Currently, more than 19,000 catalogues are available.

  `http://vizier.u-strasbg.fr/`

12.3 *General Physics*

- **NIST Physical Measurement Laboratory:** The National Institute of Standards and Technology provides access to physical reference data (physical constants, atomic spectroscopy data, x-ray and gamma-ray data, radiation dosimetry data, nuclear physics data and more) and measurements and calibrations data (dimensional and electromagnetic measurements).

https://www.nist.gov/pml/

- **Springer Materials - The Landolt-Börnstein Database:** Landolt-Börnstein is a data collection covering all areas of physical sciences and engineering, such as particle physics, electronic structure and transport, magnetism, superconductivity. International experts scan the primary literature in more than 8,000 peer-reviewed journals and evaluate and select the most valid information to be included in the database. It includes more than 130,000 online documents, 1,2 million references, and covers 250,000 chemical substances. SpringerMaterials Interactive allows to visualise and analyse data. The search functionality is freely accessible and the search results are displayed in their context, whereas the full text is secured to subscribers.

  http://materials.springer.com

13 Data preservation activities

13.1 *Particle Physics*

- **CERN Analysis Preservation:** CERN Analysis Preservation is a platform for preserving knowledge and assets of individual physics analyses in LHC collaborations. Its aim is to capture and document all the elements needed to understand and rerun an analysis even several years later: data, software, environment, workflow, context, and documentation. This platform is currently in a pilot stage. It is accessible by LHC experimental groups (standard collaboration access restrictions are applied).

  https://analysispreservation.cern.ch
- **DASPOS:** A collective effort to explore the realisation of a viable data, software and algorithm preservation architecture in High Energy Physics

  https://daspos.crc.nd.edu
- **DPHEP:** DPHEP coordinates the efforts to define and implement Data Preservation and Long Term Analysis in HEP. DPHEP, which was initiated as a study group in 2008-2009, includes all major HEP experiments and labs. In 2014, it has become a Collaboration through the signature of a Collaboration Agreement by a number of large funding agencies. The group is endorsed by the International Committee for Future Accelerators (ICFA).

  DPHEP regularly organizes workshops, creates status reports, and maintains links with similar activities in other disciplines. Details of the organizational structure, the objectives, workshops and publications can be found on the website.

  http://dphep.org
- **REANA:** REANA (REusable ANAlyses) is a system for instantiating research data analyses on the cloud using container-based solutions. It complements CERN Analysis Preservation permitting the reuse and revalidation of preserved analyses. It is being developed in close collaboration with DASPOS and RECAST.

  http://reanahub.io/
- **RECAST:** Building on analysis preservation and re-use infrastructure of the LHC experiments, RECAST acts as a science gateway allowing theorists to suggest new reinterpretations of archived analyses of the LHC dataset. Experiments review suggestions and, if approved, simulate the proposed models and re-run the archived analysis to determine their viability. Such reinterpretation results are then appended to the records of the original publication in the relevant digital archives.

  https://recast.cern.ch

13.2 *Astrophysics*

More formal and advanced data preservation activity is ongoing in the field of Experimental Astrophysics, including:

- Fermi Data

  https://fermi.gsfc.nasa.gov/ssc/data
- IVOA (International Virtual Observatory Alliance)

  http://www.ivoa.net/astronomers/applications.html
- GWOSC (Gravitational Wave Open Science Center)

  https://www.gw-openscience.org/about/
- PLA (Planck Legacy Archive)

  http://pla.esac.esa.int/pla/
- SDSS (Sloan Digital Sky Survey)

  http://sdss.org

14 Particle Physics Education and Outreach Sites

A useful list of resources can also be found at

http://www.stfc.ac.uk/research/particle-physics-and-particle-astrophysics/particle-physics-resources/

14.1 *Science Educators' Networks*

- **IPPOG:** The International Particle Physics Outreach Group is a network of scientists, science educators and communication specialists working across the globe in informal science education and outreach for particle physics. The IPPOG collaboration comprises 30 members: 24 countries, 5 experiments and CERN as an international laboratory.

  http://ippog.web.cern.ch
- **Interactions.org:** Designed to serve as a central resource for communicators of particle physics. The daily updated website provides links to current particle physics news from the world's press, high-resolution photos and graphics from the particle physics laboratories of the world; links to education and outreach programs; information about science policy and funding; a glossary; and links to many educational sites.

  http://www.interactions.org
- **QuarkNet:** The QuarkNet Collaboration is a national program that partners high school science teachers with particle physicists working in experiments at CERN or Fermilab. The network consists of over 50 centers at research groups in universities and labs across the United States. About 100,000 students from 500+ U.S. high schools learn fundamental physics as they participate in inquiry-oriented investigations and analyze authentic data online. QuarkNet is supported in part by the National Science Foundation and Fermilab.

  https://quarknet.org/
- **Netzwerk Teilchenwelt:** Behind the project are about 200 researchers from 30 institutes and universities doing research in particle physics, astroparticle physics and hadron and nuclear physics in Germany. Exciting young scientists throughout Germany for particle physics and accompanying them from school to top-level particle physics research—that's what they have set their sights on. https://www.teilchenwelt.de

14.2 *Physics Courses*

- **MIT OpenCourseWare - Physics:** These MIT course materials reflect almost all the undergraduate and graduate subjects taught at MIT. In addition to physics courses, supplementary educational resources are also available.

  http://ocw.mit.edu/courses/physics/
- **OnlineCourses.com:** A collection of online tests, video lectures, and related course materials from mostly prestigious universities around the world.

  http://www.onlinecourses.com/physics/

14.3 *Masterclasses*

- **Cosmic Ray Studies:** There are more than 12 projects around the world that address young people and teachers giving them an opportunity to explore cosmic particles, collecting, uploading and analyzing data and sharing results. Two annual events include International Cosmic Day and International Muon Week.

  https://icd.desy.de

  https://quarknet.org/content/international-muon-week

- **Hands-On Universe:** This program enables students to investigate the Universe while applying tools and concepts from science, math and technology.
  `http://handsonuniverse.org/`
- **HYPATIA:** HYPATIA (Hybrid Pupil's Analysis Tool for Interactions in ATLAS) is a tool for high school students to inspect the graphic visualization of particle collision products in the ATLAS detector at CERN.
  `http://hypatia.phys.uoa.gr/`
- **International Masterclasses:** Each year about 13,000 high school students in 55 countries come to one of about 225 nearby universities or research centres for a day to unravel the mysteries of particle physics. Lectures from active scientists give insight in topics and methods of basic research enabling the students to perform measurements on real data from one of seven experiments. At the end of the day, like an international research collaboration, participants join a video conference for discussion and combination of results. The program is coordinated from Institut fur Kern- und Teilchenphysik at TU Dresden and the Notre Dame University QuarkNet Center within the framework of the International Particle Physics Outreach Group (IPPOG). CERN, Fermilab and TRIUMF support videoconferences.
  `https://physicsmasterclasses.org`
  World Wide Data Day is an annual event.
  `https://quarknet.org/content/world-wide-data-day`
- **LHC physics Masterclasses:** Lectures from active scientists give insight into methods of basic research, enabling the students to perform measurements on real data from LHC experiments. Like in a real research collaboration, the participants then discuss their results and compare with expectations.
  `http://cms.web.cern.ch/content/cms-physics-masterclass`
  `http://lhcb-public.web.cern.ch/lhcb-public/en/LHCb-outreach/masterclasses/en`
  `http://alice.physicsmasterclasses.org/MasterClassWebpage.html`
  `http://atlas-minerva.web.cern.ch/atlas-minerva`
- **IceCube Masterclass:** The program is inspired by the International Masterclasses program started by IPPOG and is coordinated by the Wisconsin IceCube Particle Astrophysics Center with support from QuarkNet. https://masterclass.icecube.wisc.edu/

14.4 *General Sites*

- **Contemporary Physics Education Project (CPEP):** Provides charts, brochures, Web links, and classroom activities. Online interactive courses include: Fundamental Particles and Interactions; Plasma Physics and Fusion; History and Fate of the Universe; and Nuclear Science.
  `http://www.cpepweb.org/`
- **PhysicsCentral:** This site maintained by the American Physical Society provides information about current research and people in physics, experiments that can be performed at home or at school and the possibility to get physics questions answered by physicists.
  `http://www.physicscentral.com`

14.5 *General Physics Activities*

- **HyperPhysics:** An exploration environment for concepts in physics employing concept maps and other linking strategies and providing opportunities for numerical exploration.
  `http://hyperphysics.phy-astr.gsu.edu/hbase/hph.html`
- **PhET Interactive Simulations:** Founded in 2002 by Nobel Laureate Carl Wieman, the PhET Interactive Simulations project at the University of Colorado Boulder creates free interactive math and science simulations. PhET sims are based on extensive education research and engage students through an intuitive, game-like environment where students learn through exploration and discovery.
  `https://phet.colorado.edu/en/simulations/category/physics`

14.6 *Particle Physics Activities*

Citizen Science

- **Higgs Hunters:** A web-based citizen science project to help search for unknown exotic particles in the LHC data.
  `http://HiggsHunters.org`
- **LHC @ home:** Volunteer computing platform to help physicists compare theory with experiment, in the search for new fundamental particles and answers to questions about the Universe.
  `http://lhcathome.web.cern.ch`

Classroom Activities Collections

- **Contemporary Physics Education Project - Fundamental particle and interactions:**
  `http://www.cpepphysics.org/particles.html`
- **Fermilab Physical Science/Physics Resources:**
  `https://ed.fnal.gov/home/educators1000-physics.shtml`
- **IceCube Activities:**
  `https://icecube.wisc.edu/outreach/activities`
- **IPPOG Resources:**
  `http://ippog.org/resources`
- **Jefferson Lab Teacher Resources:**
  `https://education.jlab.org/indexpages/teachers.html`
- **LIGO Classroom Activities:**
  `https://www.ligo.caltech.edu/page/classroom-activities`
- **MINERvA Neutrinos in the Classroom:**
  `https://neutrino-classroom.org`
- **Perimeter Institute Educational Resources:**
  `https://resources.perimeterinstitute.ca`
- **Quarked Lesson Plans:**
  `http://www.quarked.org/parents/lessonplans.html`
- **QuarkNet Data Activities Portfolio:**
  `https://quarknet.org/data-portfolio`
- **Sanford Lab curriculum materials:**
  `https://sanfordlab.org/educators/curriculum-modules`

Interactive Sites

- **CAMELIA:** CAMELIA (Cross-platform Atlas Multimedia Educational Lab for Interactive Analysis) is a discovery tool for the general public, based on computer gaming technology.
  `https://www.atlasexperiment.org/camelia.html`
- **CERNland:** With a range of games, multimedia applications and films CERNland is a virtual theme park developed to bring the excitement of CERN's research to a young audience aged between 7 and 12. CERNland is designed to show children what is being done at CERN and inspire them with some physics.
  `http://www.cernland.net/`
- **In particular:** Podcast and more about physics and the process of discovering physics at the ATLAS experiment.
  `https://inparticular.web.cern.ch/`
- **Lancaster Particle Physics:** Suitable for 16+ students, this site offers a number of simulations and explanations of particle physics, including a section on the LHC.
  `http://www.lppp.lancs.ac.uk/`
- **Quarked!** - Adventures in the Subatomic Universe: This project, targeted to kids aged 7-12 (and their families), brings subatomic physics to life through a multimedia project including an interactive website, a facilitated program for museums and schools, and an educational outreach program.
  `http://www.quarked.org/`

Planetarium Show

- **Phantom of the Universe:** A planetarium show about dark matter that covers astrophysics, an underground experiment, and the LHC. It is distributed to planetariums for free.
  `http://phantomoftheuniverse.com/`

Video/Film

- **Angels and Demons:** With the aim of looking at the myth versus reality of antimatter and science at CERN this site describes the science behind the story including a set of videos.
  `http://angelsanddemons.web.cern.ch/`
- **CollidingParticles:** A series of films following a team of physicists involved in research at the LHC.
  `http://www.collidingparticles.com/`
- **Rewarding Learning videos about CERN:** The three videos based on interviews with scientists and engineers at CERN introduce pupils to CERN and the type of research and work undertaken there and are accompanied by teachers' notes.
  `http://www.nicurriculum.org.uk/STEMWorks/resources/cern/index.asp`
- **Videos by Don Lincoln:** Short YouTube videos on basic particle physics and cosmology.
  `https://www.youtube.com/playlist?list=PLCfRa7MXBEsoJuAM8s6D8oKDPyBepBosS`

Websites * **Cambridge Relativity and Cosmology:** Materials for the greater public to learn about the Origins of the Universe, including information on black holes, string theory, M-thoery, the cosmic microwave background and the structure of the Universe.
`http://www.damtp.cam.ac.uk/research/gr/public/index.html`
* **Imagine the Universe:** This site is for students age 14 and up and for anyone interested in learning about the Universe.
`http://imagine.gsfc.nasa.gov/home.html`
* **Particle Adventure:** An interactive tour of quarks, neutrinos, antimatter, extra dimensions, dark matter, accelerators and particle detectors from the Particle Data Group of Lawrence Berkeley National Laboratory. Simple elegant graphics and translations into 16 languages.
`http://particleadventure.org/`

14.7 *Lab Education Offices*

- **Argonne National Laboratory (ANL) Educational Programs:** Connecting today's world-class research to tomorrow's STEM problem solvers.
  `http://www.anl.gov/education/`
- **Brookhaven National Laboratory (BNL) Educational Programs:** The Office of Educational Programs mission is to design, develop, implement, and facilitate workforce development and education initiatives that support the scientific mission at Brookhaven National Laboratory and the Department of Energy.
  `http://www.bnl.gov/education/`
- **CERN's education programmes:** CERN's education and outreach programmes cover all ages from high-school students to university students. Specifically, CERN offers the tailor-made High-School Students Internship Programme several times per year and the Beamline for Schools Competition, challenging high-school students from around the world to propose an experiment to carry out at a real research laboratory. The Laboratory also runs residential programmes for high-school teachers from around the world and a summer programme for undergraduate students.
  `https://home.cern/about/what-we-do/our-educational-programmes`
- **DESY Education:** DESY Hamburg offers a regular series of public lectures and the DESY Science Café for young and old alike.
  `https://fortbildung.desy.de/index_eng.html`
- **DESY Zeuthen Outreach:** Posters, photos, lectures, videos and blogs. Projects for teachers and students include School Labs, Cosmic@Web, Teilchenwelt and International Cosmic Day.
  `https://astro.desy.de/outreach`
- **Fermilab Office of Education and Public Outreach:** Provides education resources and information about activities for 's, physicists, students and visitors to the Lab. In addition to information about 25 programs, the website provides online data-based investigations for high school students, online versions of exhibits in the Lederman Science Center, links to particle physics discovery resources, web-based instructional resources, tips for education and outreach, and links to the Lederman Science Center and the Teacher Resource Center.
  `http://ed.fnal.gov/`
- **Perimeter Institute Outreach:** Perimeter Institute shares ideas with students, teachers, and like-minded people through programs and resources that communicate the power, joy, and mystery of science. Perimeter's award-winning Outreach team brings science to life and raises scientific literacy through classroom resources, public lectures, teacher workshops, an educator network, and a summer school where students interact with Perimeter researchers.
  `https://www.perimeterinstitute.ca/outreach`
- **Science Education at Jefferson Lab:** Jefferson Lab's long-term commitment to science education continues to focus on increasing the number of teachers with a substantial background in math and science, strengthening the motivation and preparation of all students, especially minorities and females, and addressing the serious under representation of minorities and females in science, math, engineering and technology careers.
  `http://education.jlab.org/`
- **Joint Institute for Nuclear Research Education (JINR):** The JINR educational portal has resources, programs for teachers and school students and lab tours.
  `http://www.jinr.ru/schoolstudents-teachers-en/`
- **Laboratori Nazionali di Frescati Educational (INFN):** INFN educational programs are addressed to students, teachers and general audiences of every age, from Italy and abroad. Insights and education about the INFN-LNF research are offered thanks to the organization of guided tours and open days, stages for students, refresher courses for teachers, seminars and divulgation events. The aim is to create a constant exchange between the research world and society, thanks to direct contact and via the internet and other social media.
  `http://edu.lnf.infn.it/about/?lang=en`
- **Laboratori Nazionali del Gran Sasso Outreach Activities:** The Lab offers pupils the opportunity to approach the fascinating world of Physics and Science in general through stages, summer schools and training camps. It makes young researchers' skills and competences available to people both in public events, such as the Open Day and the European Researchers' Night, and in guided tours to visit the underground experimental halls.
  `https://www.lngs.infn.it/en/outreach-activities`
- **Lawrence Berkeley National Laboratory (LBNL) Workforce Development and Education:** Working with our partners both within and outside Berkeley Lab, LBNL promotes equal access to scientific and technical careers for students from all backgrounds, supports STEM teachers, and build sscientific literacy through innovative education programs. The lab also supports educational outreach efforts from Berkeley Lab's divisions by providing program development assistance, materials, funding, volunteers, project management, marketing, and administrative support.
  `https://education.lbl.gov/`
- **Sanford Underground Research Facility Education and Outreach:** Leveraging research being conducted underground at Sanford Lab, staff provide training, teaching

tools and materials for teachers so they can inspire and challenge students.

`https://sanfordlab.org/educators`

- **SNOLAB Outreach:** The goal at SNOLAB is to develop new educational material that fosters an appreciation of the field of astroparticle physics. The education team endeavours to facilitate an exchange of knowledge with the public and scientists from around the world to better understand our solar system. The desired outcome of the educational work is to have a network of healthy and resilient community partners with informed and active citizens better equipped to understand the goals here at SNOLAB now and in the future.

  `https://www.snolab.ca/outreach`
- **TRIUMF High School Programs:** TRIUMF offers outreach programs for high-school students, teachers, and the general public with a mission of promoting science and research in the public arena. TRIUMF's outreach activities are also designed to tell Canadian students, teachers, and the public about the excitement of curiosity-driven research and about how a laboratory like TRIUMF adds value to Canada in new technologies, medical applications, and highly qualified people.

  `https://www.triumf.ca/for-public/high-school-programs`
- **LBL Workforce Development and Education:** This group carries out Berkeley Lab's mission to inspire and prepare the next generation of scientists, engineers, and technicians.

  `https://education.lbl.gov/`

14.8 *Educational Programs of Experiments*

- **ATLAS Education:** The ATLAS Experiment has a wide range of educational resources available for students and teachers. Categories include primary and secondary school students, university students, teachers, citizen science, and multimedia and resources.

  `https://atlas.cern/resources/education`
- **CMS Education and Outreach Resources:** Access to 110 resources from Activities and Artworks to Visualizations.

  `https://cds.cern.ch/collection/CMS%20Education%20and%20Outreach%20Resources?ln=en`
- **HiSPARC at UCU:** HiSPARC is an outreach, educational and research experiment on cosmic rays detection, which was initiated in the Netherlands in 2004. It brings together secondary school students and teachers, undergraduate students and university researchers in the quest to understand the origin of the most energetic particles in our universe. HSPARC has stations in the Netherlands, the United Kingdom, Denmark and Namibia.

  `https://www.uu.nl/en/organisation/university-college-utrecht/hisparc-at-ucu`
- **IceCube Education and Outreach:** IceCube is committed to bringing science to a wider audience. Learning opportunities for high school students, research experiences for teachers and undergraduates, learning activities for the classroom or at home, and wecasts.

  `https://icecube.wisc.edu/outreach`
- **KASCADE and KASCADE-Grande KDKC:** The aim of the project KCDC (KASCADE Cosmic Ray Data Centre) is the installation and establishment of a public data centre for high-energy astroparticle physics based on the data of the KASCADE experiment.

  `https://kcdc.ikp.kit.edu`
- **LIGO Education Resources:** Something fun and educational for K-12 educators, parents and interested students.

  `https://www.ligo.caltech.edu/page/educational-resources`
- **MINERvA Neutrinos in the Classroom:** Information and educational materials provide high school physics students with an in-depth hands-on interactive experience with real high-energy particle physics. The materials should be suitable for a 1-2 weeks module on particle physics as it's done by professional scientists.

  `https://neutrino-classroom.org`
- **VIRGO Educational Resources:** Useful resources (websites, texts, videos) for teachers and students related to gravitational waves and the interferometers like Virgo.

  `http://public.virgo-gw.eu/educational-resources/`
- **Pierre Auger Observatory's Educational Pages:** The site offers information about cosmic rays and their detection, and provides material for students and teachers.

  `https://www.auger.org/index.php/edu-outreach`

14.9 *News*

- **Asimmetrie:** Bimonthly magazine about particle physics published by INFN, the Istituto Nazionale di Fisica Nucleare (in Italian).

  `http://www.asimmetrie.it/`
- **CERN Courier:**
  - Website: `https://cernocurier.com`
  - Twitter: `@cerncourier`
- **DESY inForm:**
  - Website: `http://www.desy.de/news/desy_inform/index_eng.html`
  - Twitter: `@desy`
- **Fermilab News:**
  - Website: `https://news.fnal.gov`
  - Twitter: `@Fermilab`
- **LC Newsline:** The newsletter of the Linear Collider community.

  `http://newsline.linearcollider.org/`
  - Twitter: `@LCnewsline`
- **IOP News:**

  `http://www.iop.org/news/`
- **JINR News:**

  `http://www1.jinr.ru/News/Jinrnews_index.html`
- **News at Interactions.org:** The Interactions site provides news and press releases on particle physics.

  `http://www.interactions.org/news-center`
  - Twitter: `@particlenews`
- **Perimeter Institute News:**
  - Website: `https://www.perimeterinstitute.ca/news`
  - Twitter: `@perimeter`
- **Sandford News and Events:**
  - Website: `https://sanfordlab.org/news-and-events`
  - Twitter: `@SanforLab`
- **SLAC Signals:** This email newsletter reports about cutting-edge science, major SLAC milestones and other lab information. It has replaced SLAC Today in November 2013. Its signup page can be found at

  `http://eepurl.com/IqPl1`
- **SNOLAB News and Headline:**

  `https://www.snolab.ca/news`
- **Symmetry:** This magazine about particle physics and its connections to other aspects of life and science, from interdisciplinary collaborations to policy to culture is published 6 times per year by Fermilab and SLAC.

  `http://www.symmetrymagazine.org/`
  - Twitter: `@symmetrymag`
- **TRIUMF on NewsWise:**

  `https://www.newswise.com/institutions/newsroom/19528`

14.10 *Art in Physics*

- **Arts@CERN - When Art Meets Science:** Arts at CERN is the leading art and science programme promoting the dialog between artists and particle physicists. Programmes include Art Commissions and Exhibitions, Collide, Accelerate and Guest Artists.

  `https://arts.cern`

  The Collide@CERN residency programme aims to develop expert knowledge in the arts through the connection with fundamental science. Since 2011 the COLLIDE award calls to artists to win a fully funded residency for up to 3 months.

  `https://arts.cern/programme/collide`

  Accelerate@CERN is a country specific one-month research award for artists who have never spent time at a science lab before.

  `https://arts.cern/programme/accelerate`

- **Art of Physics Competition:** The Canadian Association of Physicists organizes this competition, the first was launched in 1992, with the aim of stimulating interest, especially among non-scientists, in some of the captivating imagery associated with physics. The challenge is to capture photographically a beautiful or unusual physics phenomenon and explain it in less than 200 words in terms that everyone can understand.

  `https://www.cap.ca/programs/art-physics/`

- **Fermilab Art Gallery:** The convergence of art and science occurs daily in the Fermilab Art Gallery open to the public. To initiate and stimulate communication and interactions among scientists, artists and the public, the laboratory hosts an artist-in-residence program. The artist-in-residence interacts with scientists to learn about their research and how it connects to society. They use this information to create a body of work, leading to presentations in the community and possibly an exhibition of the artwork at Fermilab.

  `http://events.fnal.gov/art-gallery/`

- **TRIUMF Science through Art:** TRIUMF's Science through Art initiatives explore the space where art and science collide. These programs bring artists and TRIUMF researchers, engineers, technicians, tradespeople, and students together to explore new ways of thinking about science, discovery, creativity, and our universe.

  `https://www.triumf.ca/science-through-art`

14.11 *Blogs and Twitter*

Lists of active blogs and tweets can be found on INSPIRE:

- **Scientist blogs:**

  `http://tinyurl.com/nmku27s`

- **Scientists with twitter accounts:**

  `http://tinyurl.com/nrg5k63`

- **Experiments with twitter accounts:**

  `http://tinyurl.com/q86kma8`

- **Institutions with twitter accounts:**

  `http://tinyurl.com/mzcm3nw`

List of physicists on Twitter at TrueSciPhi:

`http://truesciphi.org/phy.html`

Some selected particle physics related blogs:

- **ATLAS blog:**

  `https://atlas.cern/updates/blog`

- **Life and Physics:** Jon Butterworth's blog in the Guardian.

  `http://www.guardian.co.uk/science/life-and-physics`

- **Of Particular Significance:** Conversations about science, with a current focus on particle physics, with theoretical physicist Matt Strassler.

  `http://profmattstrassler.com/`

- **Particle People:** This interactions.org page highlights a new blogger involved in particle physics research each month.

  `http://www.interactions.org/particle-people`

- **Preposterous Universe:** Theoretical physicist Sean Carroll's blog.

  `https://www.preposterousuniverse.com/blog/`

- **Quantum diaries:** Thoughts on work and life from particle physicists from around the world, from 2005 to 2016.

  `http://www.quantumdiaries.org/`

- **Quantum diaries survivor:** Experimental particle physicist Tommaso Dorigo's blog.

  `https://www.science20.com/quantum_diaries_survivor`

- **Science blogs:** Launched in January 2006, ScienceBlogs features bloggers from a wide array of scientific disciplines, including physics.

  `http://scienceblogs.com/channel/physical-science/`

- **AstroBetter:** Blog with tips and tricks for professional astronomers.

  `https://www.astrobetter.com/`

Z_ψ of E_6 $\rightarrow$ $SO(10)\times U(1)_\psi$ (with $g_\psi = e/\cos\theta_W$)
Mass $m >$ 3900 GeV, CL = 95% (pp direct search)
Z_η of E_6 $\rightarrow$ $SU(3)\times SU(2)\times U(1)\times U(1)_\eta$ (with $g_\eta = e/\cos\theta_W$)
Mass $m >$ 3.900×10^3 GeV, CL = 95% (pp direct search)

Scalar Leptoquarks

$m >$ 1050 GeV, CL = 95% (1st gen., pair prod., $B(\tau t)=1$)
$m >$ 1755 GeV, CL = 95% (1st gen., single prod., $B(\tau b)=1$)
$m >$ 1420 GeV, CL = 95% (2nd gen., pair prod., $B(\mu t)=1$)
$m >$ 660 GeV, CL = 95% (2nd gen., single prod., $B(\mu q)=1$)
$m >$ 900 GeV, CL = 95% (3rd gen., pair prod., $B(e q)=1$)
$m >$ 740 GeV, CL = 95% (3rd gen., single prod., $B(e q)=1$)
(See the Particle Listings for assumptions on leptoquark quantum numbers and branching fractions.)

Diquarks

Mass $m >$ 6000 GeV, CL = 95% (E_6 diquark)

Axigluon

Mass $m >$ 6100 GeV, CL = 95%

Axions (A^0) and Other Very Light Bosons, Searches for

See the review on "Axions and other similar particles."

The best limit for the half-life of neutrinoless double beta decay with Majoron emission is $> 7.2 \times 10^{24}$ years (CL = 90%).

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when S > 1, which often indicates that the measurements are inconsistent. When S > 1.25, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[*a*] Theoretical value. A mass as large as a few MeV may not be precluded.

[*b*] ℓ indicates each type of lepton (e, μ, and τ), not sum over them.

[*c*] This represents the width for the decay of the W boson into a charged particle with momentum below detectability, p< 200 MeV.

[*d*] The Z-boson mass listed here corresponds to a Breit-Wigner resonance parameter. It lies approximately 34 MeV above the real part of the position of the pole (in the energy-squared plane) in the Z-boson propagator.

[*e*] This partial width takes into account Z decays into $\nu\overline{\nu}$ and any other possible undetected modes.

[*f*] This ratio has not been corrected for the τ mass.

[*g*] Here $A \equiv 2g_V g_A/(g_V^2 + g_A^2)$.

[*h*] This parameter is not directly used in the overall fit but is derived using the fit results; see the note "The Z boson" and ref. LEP-SLC 06 (Physics Reports (Physics Letters C) **427** 257 (2006)).

[*i*] Here ℓ indicates e or μ.

[*j*] The value is for the sum of the charge states or particle/antiparticle states indicated.

[*k*] This value is updated using the product of (i) the $Z \rightarrow b\overline{b}$ fraction from this listing and (ii) the b-hadron fraction in an unbiased sample of weakly decaying b-hadrons produced in Z-decays provided by the Heavy Flavor Averaging Group (HFLAV, http://www.slac.stanford.edu/xorg/hflav/osc/PDG_2009/#FRACZ).

[*l*] See the Z Particle Listings for the γ energy range used in this measurement.

[*n*] For $m_{\gamma\gamma} = (60 \pm 5)$ GeV.

Lepton Family number (*LF*), Lepton number (*L*), or Baryon number (*B*) violating modes

L means lepton number violation (*e.g.* $\tau^- \to e^+ \pi^- \pi^-$). Following common usage, *LF* means lepton family violation *and not* lepton number violation (*e.g.* $\tau^- \to e^- \pi^+ \pi^-$). *B* means baryon number violation.

Heavy Charged Lepton Searches

$L^\pm$ – charged lepton

Mass $m > 100.8$ GeV, CL = 95% [h]   Decay to νW.

$L^\pm$ – stable charged heavy lepton

Mass $m > 102.6$ GeV, CL = 95%

Neutrino Properties

See the note on “Neutrino properties listings” in the Particle Listings.

Mass $m < 1.1$ eV, CL = 90%   (tritium decay)
Mean life/mass, $\tau/m > 300$ s/eV, CL = 90%   (reactor)
Mean life/mass, $\tau/m > 7 \times 10^9$ s/eV   (solar)
Mean life/mass, $\tau/m > 15.4$ s/eV, CL = 90%   (accelerator)
Magnetic moment $\mu < 0.28 \times 10^{-10}\ \mu_B$, CL = 90%   (solar + radiochemical)

Number of Neutrino Types

Number $N = 2.996 \pm 0.007$ (Standard Model fits to LEP-SLC data)
Number $N = 2.92 \pm 0.05$ (S = 1.2)   (Direct measurement of invisible Z width)

Neutrino Mixing

The following values are obtained through data analyses based on the 3-neutrino mixing scheme described in the review “Neutrino Masses, Mixing, and Oscillations.”

$\sin^2(\theta_{12}) = 0.307 \pm 0.013$
$\Delta m^2_{21} = (7.53 \pm 0.18) \times 10^{-5}$ eV^2
$\sin^2(\theta_{23}) = 0.547 \pm 0.021$ (Inverted order)
$\sin^2(\theta_{23}) = 0.545 \pm 0.021$ (Normal order)
$\Delta m^2_{32} = (-2.546^{+0.034}_{-0.040}) \times 10^{-3}$ eV^2 (Inverted order)
$\Delta m^2_{32} = (2.453 \pm 0.034) \times 10^{-3}$ eV^2 (Normal order)
$\sin^2(\theta_{13}) = (2.18 \pm 0.07) \times 10^{-2}$
δ, CP violating phase $= 1.36 \pm 0.17\ \pi$ rad
$\left\langle \Delta m^2_{21} - \Delta \overline{m}^2_{21} \right\rangle < 1.1 \times 10^{-4}$ eV^2, CL = 99.7%
$\left\langle \Delta m^2_{32} - \Delta \overline{m}^2_{32} \right\rangle = (-0.12 \pm 0.25) \times 10^{-3}$ eV^2

NOTES

In this Summary Table:

When a quantity has “(S = . . .)” to its right, the error on the quantity has been enlarged by the “scale factor” S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when S > 1, which often indicates that the measurements are inconsistent. When S > 1.25, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[a] This is the best limit for the mode $e^- \to \nu\gamma$. The best limit for Nuclear de-excitation experiments is 6.4×10^{24} yr.

[b] See the review on “Muon Decay Parameters” for definitions and details.

[c] P_μ is the longitudinal polarization of the muon from pion decay. For $V{-}A$ coupling, $P_\mu = 1$ and $\rho = \delta = 3/4$.

[d] This only includes events with energy of $e > 45$ MeV and energy of $\gamma > 40$ MeV. Since the $e^- \overline{\nu}_e \nu_\mu$ and $e^- \overline{\nu}_e \nu_\mu \gamma$ modes cannot be clearly separated, we regard the latter mode as a subset of the former.

[e] See the relevant Particle Listings for the energy limits used in this measurement.

[f] A test of additive vs. multiplicative lepton family number conservation.

[g] Basis mode for the τ.

[h] $L^\pm$ mass limit depends on decay assumptions; see the Full Listings.

QUARKS

The u-, d-, and s-quark masses are estimates of so-called "current-quark masses," in a mass-independent subtraction scheme such as $\overline{\rm MS}$ at a scale $\mu \approx 2$ GeV. The c- and b-quark masses are the "running" masses in the $\overline{\rm MS}$ scheme. This can be different from the heavy quark masses obtained in potential models.

u

$I(J^P) = \frac{1}{2}(\frac{1}{2}^+)$

$m_u = 2.16^{+0.49}_{-0.26}$ MeV Charge $= \frac{2}{3}\ e$ $I_z = +\frac{1}{2}$

$m_u/m_d = 0.47^{+0.06}_{-0.07}$

d

$I(J^P) = \frac{1}{2}(\frac{1}{2}^+)$

$m_d = 4.67^{+0.48}_{-0.17}$ MeV Charge $= -\frac{1}{3}\ e$ $I_z = -\frac{1}{2}$

$m_s/m_d = 17$–22

$\overline{m} = (m_u + m_d)/2 = 3.45^{+0.55}_{-0.15}$ MeV

s

$I(J^P) = 0(\frac{1}{2}^+)$

$m_s = 93^{+11}_{-5}$ MeV Charge $= -\frac{1}{3}\ e$ Strangeness $= -1$

$m_s\ /\ ((m_u + m_d)/2) = 27.3^{+0.7}_{-1.3}$

c

$I(J^P) = 0(\frac{1}{2}^+)$

$m_c = 1.27 \pm 0.02$ GeV Charge $= \frac{2}{3}\ e$ Charm $= +1$

$m_c/m_s = 11.72 \pm 0.25$

$m_b/m_c = 4.577 \pm 0.008$

$m_b - m_c = 3.45 \pm 0.05$ GeV

b

$I(J^P) = 0(\frac{1}{2}^+)$

$m_b = 4.18^{+0.03}_{-0.02}$ GeV Charge $= -\frac{1}{3}\ e$ Bottom $= -1$

t

$I(J^P) = 0(\frac{1}{2}^+)$

Charge $= \frac{2}{3}\ e$ Top $= +1$

Mass (direct measurements) $m = 172.76 \pm 0.30$ GeV [a,b] (S = 1.2)

b' (4th Generation) Quark, Searches for

Mass $m >$ 190 GeV, CL = 95% ($p\overline{p}$, quasi-stable b')

Mass $m >$ 1130 GeV, CL = 95% ($B(b' \to Z b) = 1$)

Mass $m >$ 1350 GeV, CL = 95% ($B(b' \to W t) = 1$)

Mass $m >$ 46.0 GeV, CL = 95% ($e^+ e^-$, all decays)

t' (4th Generation) Quark, Searches for

$m(t'(2/3)) >$ 1280 GeV, CL = 95% ($B(t' \to Z t) = 1$)

$m(t'(2/3)) >$ 1295 GeV, CL = 95% ($B(t' \to W b) = 1$)

$m(t'(2/3)) >$ 1310 GeV, CL = 95% (singlet t')

$m(t'(5/3)) >$ 1350 GeV, CL = 95%

Free Quark Searches

All searches since 1977 have had negative results.

NOTES

[a] A discussion of the definition of the top quark mass in these measurements can be found in the review "The Top Quark."

[b] Based on published top mass measurements using data from Tevatron Run-I and Run-II and LHC at $\sqrt{s} = 7$ TeV. Including the most recent unpublished results from Tevatron Run-II, the Tevatron Electroweak Working Group reports a top mass of 173.2 ± 0.9 GeV. See the note "The Top Quark' in the Quark Particle Listings of this *Review*.

[c] This limit is for $\Gamma(t \to \gamma q)/\Gamma(t \to W b)$.

[d] This limit is for $\Gamma(t \to Z q)/\Gamma(t \to W b)$.

LIGHT UNFLAVORED MESONS ($S = C = B = 0$)

For $I = 1$ (π, b, ρ, a): $u\overline{d}$, $(u\overline{u}-d\overline{d})/\sqrt{2}$, $d\overline{u}$;
for $I = 0$ (η, η', h, h', ω, ϕ, f, f'): $c_1(u\overline{u} + d\overline{d}) + c_2(s\overline{s})$

$\pi^\pm$

$I^G(J^P) = 1^-(0^-)$

Mass $m = 139.57039 \pm 0.00018$ MeV (S = 1.8)
Mean life $\tau = (2.6033 \pm 0.0005) \times 10^{-8}$ s (S = 1.2)
$c\tau = 7.8045$ m

$\pi^\pm \to \ell^\pm \nu \gamma$ form factors [a]

$F_V = 0.0254 \pm 0.0017$
$F_A = 0.0119 \pm 0.0001$
F_V slope parameter $a = 0.10 \pm 0.06$
$R = 0.059^{+0.009}_{-0.008}$

π^- modes are charge conjugates of the modes below.

For decay limits to particles which are not established, see the section on Searches for Axions and Other Very Light Bosons.

Most decay modes (other than the semileptonic modes) that involve a neutral K meson are now given as K^0_S modes, not as $\overline{K}^0$ modes. Nearly always it is a K^0_S that is measured, and interference between Cabibbo-allowed and doubly Cabibbo-suppressed modes can invalidate the assumption that $2\,\Gamma(K^0_S) = \Gamma(\overline{K}^0)$.

$f_+(0)|V_{cd}|$ in $D^0 \to \pi^-\ell^+\nu_\ell = 0.1436 \pm 0.0026$ (S = 1.5)
$r_1 \equiv a_1/a_0$ in $D^0 \to \pi^-\ell^+\nu_\ell = -1.97 \pm 0.28$ (S = 1.4)
$r_2 \equiv a_1/a_0$ in $D^0 \to \pi^-\ell^+\nu_\ell = -0.2 \pm 2.2$ (S = 1.7)

Most decay modes (other than the semileptonic modes) that involve a neutral K meson are now given as K^0_S modes, not as $\overline{K}^0$ modes. Nearly always it is a K^0_S that is measured, and interference between Cabibbo-allowed and doubly Cabibbo-suppressed modes can invalidate the assumption that $2\,\Gamma(K^0_S) = \Gamma(\overline{K}^0)$.

$I(J^P) = 0(2^+)$

J^P is natural, width and decay modes consistent with 2^+.

Mass $m = 2569.1 \pm 0.8$ MeV (S = 2.4)
Full width $\Gamma = 16.9 \pm 0.7$ MeV

$D_{s2}^*(2573)^-$ modes are charge conjugates of the modes below.

$D_{s2}^*(2573)^+$ DECAY MODES	Fraction (Γ_i/Γ)	p (MeV/c)
$D^0 K^+$	seen	431
$D^*(2007)^0 K^+$	not seen	238

$D_{s1}^*(2700)^\pm$

$I(J^P) = 0(1^-)$

Mass $m = 2708.3^{+4.0}_{-3.4}$ MeV
Full width $\Gamma = 120 \pm 11$ MeV

BOTTOM MESONS
($B = \pm 1$)

$B^+ = u\overline{b}$, $B^0 = d\overline{b}$, $\overline{B}^0 = \overline{d}\,b$, $B^- = \overline{u}\,b$, similarly for B^*'s

B-particle organization

Many measurements of B decays involve admixtures of B hadrons. Previously we arbitrarily included such admixtures in the $B^\pm$ section, but because of their importance we have created two new sections: "$B^\pm/B^0$ Admixture" for $\Upsilon(4S)$ results and "$B^\pm/B^0/B_s^0/b$-baryon Admixture" for results at higher energies. Most inclusive decay branching fractions and χ_b at high energy are found in the Admixture sections. B^0-$\overline{B}^0$ mixing data are found in the B^0 section, while B_s^0-$\overline{B}_s^0$ mixing data and B-$\overline{B}$ mixing data for a B^0/B_s^0 admixture are found in the B_s^0 section. *CP*-violation data are found in the $B^\pm$, B^0, and $B^\pm$ B^0 Admixture sections. b-baryons are found near the end of the Baryon section.

The organization of the B sections is now as follows, where bullets indicate particle sections and brackets indicate reviews.

- $B^\pm$
  mass, mean life, *CP* violation, branching fractions
- B^0
  mass, mean life, B^0-$\overline{B}^0$ mixing, *CP* violation, branching fractions
- $B^\pm/B^0$ Admixtures
  CP violation, branching fractions
- $B^\pm/B^0/B_s^0/b$-baryon Admixtures
  mean life, production fractions, branching fractions
- B^*
  mass
- $B_1(5721)^+$
  mass
- $B_1(5721)^0$
  mass
- $B_2^*(5747)^+$
  mass
- $B_2^*(5747)^0$
  mass
- $B_J^*(5970)^+$
  mass
- $B_J^*(5970)^0$
  mass
- B_s^0
  mass, mean life, B_s^0-$\overline{B}_s^0$ mixing, *CP* violation, branching fractions
- B_s^*
  mass
- $B_{s1}(5830)^0$
  mass
- $B_{s2}^*(5840)^0$
  mass
- $B_c^\pm$
  mass, mean life, branching fractions

At the end of Baryon Listings:

- Λ_b
  mass, mean life, branching fractions
- $\Lambda_b(5912)^0$
  mass, mean life
- $\Lambda_b(5920)^0$
  mass, mean life
- Σ_b
  mass
- Σ_b^*
  mass
- Ξ_b^0, Ξ_b^-
  mass, mean life, branching fractions
- $\Xi'_b(5935)^-$
  mass

- $\Xi_b(5945)^0$
  mass
- $\Xi_b^*(5955)^-$
  mass
- Ω_b^-
  mass, branching fractions
- b-baryon Admixture
  mean life, branching fractions

$B^{\pm}$

$I(J^P) = \frac{1}{2}(0^-)$

I, J, P need confirmation. Quantum numbers shown are quark-model predictions.

Mass $m_{B^{\pm}} = 5279.34 \pm 0.12$ MeV
Mean life $\tau_{B^{\pm}} = (1.638 \pm 0.004) \times 10^{-12}$ s
$c\tau = 491.1$ μm

CP violation

B^- modes are charge conjugates of the modes below. Modes which do not identify the charge state of the B are listed in the $B^\pm/B^0$ ADMIXTURE section.

The branching fractions listed below assume 50% $B^0 \overline{B}^0$ and 50% $B^+ B^-$ production at the $\Upsilon(4S)$. We have attempted to bring older measurements up to date by rescaling their assumed $\Upsilon(4S)$ production ratio to 50:50 and their assumed D, D_s, D^*, and ψ branching ratios to current values whenever this would affect our averages and best limits significantly.

Indentation is used to indicate a subchannel of a previous reaction. All resonant subchannels have been corrected for resonance branching fractions to the final state so the sum of the subchannel branching fractions can exceed that of the final state.

For inclusive branching fractions, *e.g.*, $B \to D^\pm X$, the values usually are multiplicities, not branching fractions. They can be greater than one.

B^+ DECAY MODES		Fraction (Γ_i/Γ)	Scale factor/ Confidence level	p (MeV/c)
Semileptonic and leptonic modes				
$\ell^+ \nu_\ell X$	[lll]	(10.99 ± 0.28) %		–

B^0

$I(J^P) = \frac{1}{2}(0^-)$

I, J, P need confirmation. Quantum numbers shown are quark-model predictions.

Mass $m_{B^0} = 5279.65 \pm 0.12$ MeV
$m_{B^0} - m_{B^\pm} = 0.31 \pm 0.05$ MeV
Mean life $\tau_{B^0} = (1.519 \pm 0.004) \times 10^{-12}$ s
$c\tau = 455.4\ \mu$m
$\tau_{B^+}/\tau_{B^0} = 1.076 \pm 0.004$ (direct measurements)

B^0-$\overline{B}^0$ mixing parameters

$\chi_d = 0.1858 \pm 0.0011$
$\Delta m_{B^0} = m_{B^0_H} - m_{B^0_L} = (0.5065 \pm 0.0019) \times 10^{12}\ \hbar\ s^{-1}$
$= (3.334 \pm 0.013) \times 10^{-10}$ MeV
$x_d = \Delta m_{B^0}/\Gamma_{B^0} = 0.769 \pm 0.004$
$\mathrm{Re}(\lambda_{CP} / |\lambda_{CP}|)\ \mathrm{Re}(z) = 0.047 \pm 0.022$
$\Delta\Gamma\ \mathrm{Re}(z) = -0.007 \pm 0.004$
$\mathrm{Re}(z) = (-4 \pm 4) \times 10^{-2}$ (S = 1.4)
$\mathrm{Im}(z) = (-0.8 \pm 0.4) \times 10^{-2}$

CP violation parameters

$\mathrm{Re}(\epsilon_{B^0})/(1+|\epsilon_{B^0}|^2) = (-0.5 \pm 0.4) \times 10^{-3}$

$\overline{B}^0$ modes are charge conjugates of the modes below. Reactions indicate the weak decay vertex and do not include mixing. Modes which do not identify the charge state of the B are listed in the $B^\pm/B^0$ ADMIXTURE section.

The branching fractions listed below assume 50% $B^0\overline{B}^0$ and 50% B^+B^- production at the $\Upsilon(4S)$. We have attempted to bring older measurements up to date by rescaling their assumed $\Upsilon(4S)$ production ratio to 50:50 and their assumed D, D_s, D^*, and ψ branching ratios to current values whenever this would affect our averages and best limits significantly.

Indentation is used to indicate a subchannel of a previous reaction. All resonant subchannels have been corrected for resonance branching fractions to the final state so the sum of the subchannel branching fractions can exceed that of the final state.

For inclusive branching fractions, *e.g.*, $B \to D^{\pm} X$, the values usually are multiplicities, not branching fractions. They can be greater than one.

$B^\pm/B^0$ ADMIXTURE

CP violation

$A_{CP}(B \to K^*(892)\gamma) = -0.003 \pm 0.011$

$A_{CP}(B \to s\gamma) = 0.015 \pm 0.011$

$A_{CP}(B \to (s+d)\gamma) = 0.010 \pm 0.031$

$A_{CP}(B \to X_s\ell^+\ell^-) = 0.04 \pm 0.11$

$A_{CP}(B \to X_s\ell^+\ell^-)$ $(1.0 < q^2 < 6.0\ \mathrm{GeV}^2/c^4) = -0.06 \pm 0.22$

$A_{CP}(B \to X_s\ell^+\ell^-)$ $(10.1 < q^2 < 12.9$ or $q^2 > 14.2\ \mathrm{GeV}^2/c^4) = 0.19 \pm 0.18$

$A_{CP}(B \to K^*e^+e^-) = -0.18 \pm 0.15$

$A_{CP}(B \to K^*\mu^+\mu^-) = -0.03 \pm 0.13$

$A_{CP}(B \to K^*\ell^+\ell^-) = -0.04 \pm 0.07$

$A_{CP}(B \to \eta\,\mathrm{anything}) = -0.13^{+0.04}_{-0.05}$

$\Delta A_{CP}(X_s\gamma) = A_{CP}(B^\pm \to X_s\gamma) - A_{CP}(B^0 \to X_s\gamma) = 0.041 \pm 0.023$

$\overline{A}_{CP}(B \to X_s\gamma) = (A_{CP}(B^+ \to X_s\gamma) + A_{CP}(B^0 \to X_s\gamma))/2 = 0.009 \pm 0.012$

$\Delta A_{CP}(B \to K^*\gamma) = A_{CP}(B^+ \to K^{*+}\gamma) - A_{CP}(B^0 \to K^{*0}\gamma) = 0.024 \pm 0.028$

$\overline{A}_{CP}(B \to K^*\gamma) = (A_{CP}(B^+ \to K^{*+}\gamma) + A_{CP}(B^0 \to K^{*0}\gamma))/2 = -0.001 \pm 0.014$

The branching fraction measurements are for an admixture of B mesons at the $\Upsilon(4S)$. The values quoted assume that $\mathrm{B}(\Upsilon(4S) \to B\overline{B}) = 100\%$.

For inclusive branching fractions, *e.g.*, $B \to D^\pm$ *anything*, the treatment of multiple D's in the final state must be defined. One possibility would be to count the number of events with one-or-more D's and divide by the total number of B's. Another possibility would be to count the total number of D's and divide by the total number of B's, which is the definition of average multiplicity. The two definitions are identical if only one D is allowed in the final state. Even though the "one-or-more" definition seems sensible, for practical reasons inclusive branching fractions are almost always measured using the multiplicity definition. For heavy final state particles, authors call their results inclusive branching fractions while for light particles some authors call their results multiplicities. In the B sections, we list all results as inclusive branching fractions, adopting a multiplicity definition. This means that inclusive branching fractions can exceed 100% and that inclusive partial widths can exceed total widths, just as inclusive cross sections can exceed total cross section.

$\overline{B}$ modes are charge conjugates of the modes below. Reactions indicate the weak decay vertex and do not include mixing.

$B^{\pm}/B^0/B_s^0/b$-baryon ADMIXTURE

These measurements are for an admixture of bottom particles at high energy (LHC, LEP, Tevatron, $Sp\overline{p}S$).

Mean life $\tau = (1.5668 \pm 0.0028) \times 10^{-12}$ s

Mean life $\tau = (1.72 \pm 0.10) \times 10^{-12}$ s Charged b-hadron admixture

Mean life $\tau = (1.58 \pm 0.14) \times 10^{-12}$ s Neutral b-hadron admixture

$\tau_{\text{charged } b\text{–hadron}} / \tau_{\text{neutral } b\text{–hadron}} = 1.09 \pm 0.13$

$\left|\Delta\tau_b\right| / \tau_{b,\overline{b}} = -0.001 \pm 0.014$

The branching fraction measurements are for an admixture of B mesons and baryons at energies above the $\Upsilon(4S)$. Only the highest energy results (LHC, LEP, Tevatron, $Sp\overline{p}S$) are used in the branching fraction averages. In the following, we assume that the production fractions are the same at the LHC, LEP, and at the Tevatron.

For inclusive branching fractions, *e.g.*, $B \to D^{\pm}$ anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

The modes below are listed for a $\overline{b}$ initial state. b modes are their charge conjugates. Reactions indicate the weak decay vertex and do not include mixing.

$\overline{b}$ DECAY MODES		Fraction (Γ_i/Γ)	Scale factor/ Confidence level	p (MeV/c)

PRODUCTION FRACTIONS

The production fractions for weakly decaying b-hadrons at high energy have been calculated from the best values of mean lives, mixing parameters, and branching fractions in this edition by the Heavy Flavor Averaging Group (HFLAV) as described in the note "B^0-$\overline{B}^0$ Mixing" in the B^0 Particle Listings. We no longer provide world averages of the b-hadron production fractions, where results from LEP, Tevatron and LHC are averaged together; indeed the available data (from CDF and LHCb) shows that the fractions depend on the kinematics (in particular the p_T) of the produced b hadron. Hence we would like to list the fractions in Z decays instead, which are well-defined physics observables. The production fractions in $p\overline{p}$ collisions at the Tevatron are also listed at the end of the section. Values assume

$$B(\overline{b} \to B^+) = B(\overline{b} \to B^0)$$
$$B(\overline{b} \to B^+) + B(\overline{b} \to B^0) + B(\overline{b} \to B_s^0) + B(b \to b\text{-baryon}) = 100\%.$$

The correlation coefficients between production fractions are also reported:

$cor(B_s^0,\ b\text{-baryon}) = 0.064$
$cor(B_s^0,\ B^{\pm}{=}B^0) = -0.633$
$cor(b\text{-baryon},\ B^{\pm}{=}B^0) = -0.813.$

The notation for production fractions varies in the literature (f_d, d_{B^0}, $f(b \to \overline{B}^0)$, $\mathrm{Br}(b \to \overline{B}^0)$). We use our own branching fraction notation here, $B(\overline{b} \to B^0)$.

Note these production fractions are b-hadronization fractions, not the conventional branching fractions of b-quark to a B-hadron, which may have considerable dependence on the initial and final state kinematic and production environment.

$\psi(3770)$

$I^G(J^{PC}) = 0^-(1^{--})$

Mass $m = 3773.7 \pm 0.4$ MeV (S = 1.4)
Full width $\Gamma = 27.2 \pm 1.0$ MeV
$\Gamma_{ee} = 0.262 \pm 0.018$ keV (S = 1.4)

In addition to the dominant decay mode to $D\overline{D}$, $\psi(3770)$ was found to decay into the final states containing the J/ψ (BAI 05, ADAM 06). ADAMS 06 and HUANG 06A searched for various decay modes with light hadrons and found a statistically significant signal for the decay to $\phi\eta$ only (ADAMS 06).

Due to the complexity of the $c\overline{c}$ threshold region, in this listing, "seen" ("not seen") means that a cross section for the mode in question has been measured at effective $\sqrt{s}$ near this particle's central mass value, more (less) than 2σ above zero, without regard to any peaking behavior in $\sqrt{s}$ or absence thereof. See mode listing(s) for details and references.

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as S $= \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when S $>$ 1, which often indicates that the measurements are inconsistent. When S $>$ 1.25, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[*a*] See the review on "Form Factors for Radiative Pion and Kaon Decays" for definitions and details.

[*b*] Measurements of $\Gamma(e^+\nu_e)/\Gamma(\mu^+\nu_\mu)$ always include decays with γ's, and measurements of $\Gamma(e^+\nu_e\gamma)$ and $\Gamma(\mu^+\nu_\mu\gamma)$ never include low-energy γ's. Therefore, since no clean separation is possible, we consider the modes with γ's to be subreactions of the modes without them, and let $[\Gamma(e^+\nu_e) + \Gamma(\mu^+\nu_\mu)]/\Gamma_{\text{total}} = 100\%$.

[*c*] See the $\pi^\pm$ Particle Listings for the energy limits used in this measurement; low-energy γ's are not included.

[*d*] Derived from an analysis of neutrino-oscillation experiments.

[*e*] Astrophysical and cosmological arguments give limits of order 10^{-13}.

[*f*] Forbidden by angular momentum conservation.

[*g*] C parity forbids this to occur as a single-photon process.

[*h*] The $\omega\rho$ interference is then due to $\omega\rho$ mixing only, and is expected to be small. If $e\mu$ universality holds, $\Gamma(\rho^0 \to \mu^+\mu^-) = \Gamma(\rho^0 \to e^+e^-) \times 0.99785$.

[*i*] See the "Note on $a_1(1260)$" in the $a_1(1260)$ Particle Listings in PDG 06, Journal of Physics **G33** 1 (2006).

[*j*] Our estimate. See the Particle Listings for details.

[*k*] See the note on "Non-$q\overline{q}$ mesons" in the Particle Listings in PDG 06, Journal of Physics **G33** 1 (2006).

[*l*] See also the $\omega(1650)$.

[*n*] See also the $\omega(1420)$.

[*o*] See the note in the $K^\pm$ Particle Listings.

[*p*] Neglecting photon channels. See, *e.g.*, A. Pais and S.B. Treiman, Phys. Rev. **D12**, 2744 (1975).

[*q*] The definition of the slope parameters of the $K \to 3\pi$ Dalitz plot is as follows (see also "Note on Dalitz Plot Parameters for $K \to 3\pi$ Decays" in the $K^\pm$ Particle Listings):

$$|M|^2 = 1 + g(s_3 - s_0)/m^2_{\pi^+} + \cdots .$$

[*r*] For more details and definitions of parameters see the Particle Listings.

[*s*] See the $K^\pm$ Particle Listings for the energy limits used in this measurement.

[*t*] Most of this radiative mode, the low-momentum γ part, is also included in the parent mode listed without γ's.

[*u*] Structure-dependent part.

[*v*] Direct-emission branching fraction.

[*x*] Violates angular-momentum conservation.

[*y*] Derived from measured values of ϕ_{+-}, ϕ_{00}, $|\eta|$, $|m_{K^0_L} - m_{K^0_S}|$, and $\tau_{K^0_S}$, as described in the introduction to "Tests of Conservation Laws."

[*z*] The CP-violation parameters are defined as follows (see also "Note on CP Violation in $K_S \to 3\pi$" and "Note on CP Violation in K^0_L Decay" in the Particle Listings):

$$\eta_{+-} = |\eta_{+-}|e^{i\phi_{+-}} = \frac{A(K^0_L \to \pi^+\pi^-)}{A(K^0_S \to \pi^+\pi^-)} = \epsilon + \epsilon'$$

$$\eta_{00} = |\eta_{00}|e^{i\phi_{00}} = \frac{A(K^0_L \to \pi^0\pi^0)}{A(K^0_S \to \pi^0\pi^0)} = \epsilon - 2\epsilon'$$

$$\delta = \frac{\Gamma(K^0_L \to \pi^-\ell^+\nu) - \Gamma(K^0_L \to \pi^+\ell^-\nu)}{\Gamma(K^0_L \to \pi^-\ell^+\nu) + \Gamma(K^0_L \to \pi^+\ell^-\nu)},$$

$$\text{Im}(\eta_{+-0})^2 = \frac{\Gamma(K^0_S \to \pi^+\pi^-\pi^0)^{CP\ \text{viol.}}}{\Gamma(K^0_L \to \pi^+\pi^-\pi^0)},$$

$$\text{Im}(\eta_{000})^2 = \frac{\Gamma(K^0_S \to \pi^0\pi^0\pi^0)}{\Gamma(K^0_L \to \pi^0\pi^0\pi^0)}.$$

where for the last two relations CPT is assumed valid, *i.e.*, $\text{Re}(\eta_{+-0}) \simeq 0$ and $\text{Re}(\eta_{000}) \simeq 0$.

[*aa*] See the K^0_S Particle Listings for the energy limits used in this measurement.

[*bb*] The value is for the sum of the charge states or particle/antiparticle states indicated.

[*cc*] $\text{Re}(\epsilon'/\epsilon) = \epsilon'/\epsilon$ to a very good approximation provided the phases satisfy CPT invariance.

[*dd*] This mode includes gammas from inner bremsstrahlung but not the direct emission mode $K^0_L \to \pi^+\pi^-\gamma(\text{DE})$.

[*ee*] See the K^0_L Particle Listings for the energy limits used in this measurement.

[*ff*] Allowed by higher-order electroweak interactions.

[*gg*] Violates CP in leading order. Test of direct CP violation since the indirect CP-violating and CP-conserving contributions are expected to be suppressed.

[*hh*] See the "Note on $f_0(1370)$" in the $f_0(1370)$ Particle Listings and in the 1994 edition.

[*ii*] See the note in the $L(1770)$ Particle Listings in Reviews of Modern Physics **56** S1 (1984), p. S200. See also the "Note on $K_2(1770)$ and the $K_2(1820)$" in the $K_2(1770)$ Particle Listings .

[*jj*] See the "Note on $K_2(1770)$ and the $K_2(1820)$" in the $K_2(1770)$ Particle Listings .

[*kk*] This result applies to $Z^0 \to c\overline{c}$ decays only. Here ℓ^+ is an average (not a sum) of e^+ and μ^+ decays.

[*ll*] See the Particle Listings for the (complicated) definition of this quantity.

[*nn*] The branching fraction for this mode may differ from the sum of the submodes that contribute to it, due to interference effects. See the relevant papers in the Particle Listings.

[*oo*] These subfractions of the $K^-2\pi^+$ mode are uncertain: see the Particle Listings.

[*pp*] Submodes of the $D^+ \to K^-2\pi^+\pi^0$ and $K^0_S2\pi^+\pi^-$ modes were studied by ANJOS 92C and COFFMAN 92B, but with at most 142 events for the first mode and 229 for the second – not enough for precise results. With nothing new for 18 years, we refer to our 2008 edition, Physics Letters **B667** 1 (2008), for those results.

[*qq*] The unseen decay modes of the resonances are included.

[*rr*] This is *not* a test for the ΔC=1 weak neutral current, but leads to the $\pi^+\ell^+\ell^-$ final state.

[*ss*] This mode is not a useful test for a ΔC=1 weak neutral current because both quarks must change flavor in this decay.

[*tt*] In the 2010 *Review*, the values for these quantities were given using a measure of the asymmetry that was inconsistent with the usual definition.

[*uu*] This value is obtained by subtracting the branching fractions for 2-, 4- and 6-prongs from unity.

[*vv*] This is the sum of our $K^-2\pi^+\pi^-$, $K^-2\pi^+\pi^-\pi^0$, $\overline{K}^0 2\pi^+2\pi^-$, $K^+2K^-\pi^+$, $2\pi^+2\pi^-$, $2\pi^+2\pi^-\pi^0$, $K^+K^-\pi^+\pi^-$, and $K^+K^-\pi^+\pi^-\pi^0$, branching fractions.

[*xx*] This is the sum of our $K^-3\pi^+2\pi^-$ and $3\pi^+3\pi^-$ branching fractions.

[*yy*] The branching fractions for the $K^-e^+\nu_e$, $K^*(892)^-e^+\nu_e$, $\pi^-e^+\nu_e$, and $\rho^-e^+\nu_e$ modes add up to 6.17 ± 0.17 %.

[*zz*] This is a doubly Cabibbo-suppressed mode.

[*aaa*] Submodes of the $D^0 \to K^0_S\pi^+\pi^-\pi^0$ mode with a K^* and/or ρ were studied by COFFMAN 92B, but with only 140 events. With nothing new for 18 years, we refer to our 2008 edition, Physics Letters **B667** 1 (2008), for those results.

[*bbb*] This branching fraction includes all the decay modes of the resonance in the final state.

[*ccc*] This limit is for either D^0 or $\overline{D}^0$ to $p\,e^-$.

[*ddd*] This limit is for either D^0 or $\overline{D}^0$ to $\overline{p}\,e^+$.

[*eee*] This is the purely e^+ semileptonic branching fraction: the e^+ fraction from τ^+ decays has been subtracted off. The sum of our (non-τ) e^+ exclusive fractions — an $e^+\nu_e$ with an η, η', ϕ, K^0, or K^{*0} — is 5.99 ± 0.31 %.

[*fff*] This fraction includes η from η' decays.

[*ggg*] The sum of our exclusive η' fractions — $\eta' e^+\nu_e$, $\eta'\mu^+\nu_\mu$, $\eta'\pi^+$, $\eta'\rho^+$, and $\eta' K^+$ — is $11.8 \pm 1.6\%$.

[*hhh*] This branching fraction includes all the decay modes of the final-state resonance.

[*iii*] A test for $u\overline{u}$ or $d\overline{d}$ content in the D^+_s. Neither Cabibbo-favored nor Cabibbo-suppressed decays can contribute, and $\omega - \phi$ mixing is an unlikely explanation for any fraction above about 2×10^{-4}.

[*jjj*] We decouple the $D^+_s \to \phi\pi^+$ branching fraction obtained from mass projections (and used to get some of the other branching fractions) from the $D^+_s \to \phi\pi^+$, $\phi \to K^+K^-$ branching fraction obtained from the Dalitz-plot analysis of $D^+_s \to K^+K^-\pi^+$. That is, the ratio of these two branching fractions is not exactly the $\phi \to K^+K^-$ branching fraction 0.491.

[*kkk*] This is the average of a model-independent and a *K*-matrix parametrization of the $\pi^+\pi^-$ *S*-wave and is a sum over several f_0 mesons.

[*lll*] An ℓ indicates an *e* or a μ mode, not a sum over these modes.

[*nnn*] An $CP(\pm1)$ indicates the $CP{=}{+}1$ and $CP{=}{-}1$ eigenstates of the D^0-$\overline{D}^0$ system.

[*ooo*] D denotes D^0 or $\overline{D}^0$.

[*ppp*] D^{*0}_{CP+} decays into $D^0\pi^0$ with the D^0 reconstructed in *CP*-even eigenstates K^+K^- and $\pi^+\pi^-$.

[*qqq*] $\overline{D}^{**}$ represents an excited state with mass 2.2 < M < 2.8 GeV/c^2.

[*rrr*] $\chi_{c1}(3872)^+$ is a hypothetical charged partner of the $\chi_{c1}(3872)$.

[*sss*] $\Theta(1710)^{++}$ is a possible narrow pentaquark state and $G(2220)$ is a possible glueball resonance.

[*ttt*] $(\overline{\Lambda}_c^- p)_s$ denotes a low-mass enhancement near 3.35 GeV/c^2.

[*uuu*] Stands for the possible candidates of $K^*(1410)$, $K_0^*(1430)$ and $K_2^*(1430)$.

[*vvv*] B^0 and B_s^0 contributions not separated. Limit is on weighted average of the two decay rates.

[*xxx*] This decay refers to the coherent sum of resonant and nonresonant $J^P = 0^+$ $K\pi$ components with $1.60 < m_{K\pi} < 2.15$ GeV/c^2.

[*yyy*] $X(214)$ is a hypothetical particle of mass 214 MeV/c^2 reported by the HyperCP experiment, Physical Review Letters **94** 021801 (2005)

[*zzz*] $\Theta(1540)^+$ denotes a possible narrow pentaquark state.

[*aaaa*] Here *S* and *P* are the hypothetical scalar and pseudoscalar particles with masses of 2.5 GeV/c^2 and 214.3 MeV/c^2, respectively.

[*bbaa*] These values are model dependent.

[*ccaa*] Here "anything" means at least one particle observed.

[*ddaa*] This is a $B(B^0 \to D^{*-}\ell^+\nu_\ell)$ value.

[*eeaa*] D^{**} stands for the sum of the $D(1\,^1P_1)$, $D(1\,^3P_0)$, $D(1\,^3P_1)$, $D(1\,^3P_2)$, $D(2\,^1S_0)$, and $D(2\,^1S_1)$ resonances.

[*ffaa*] $D^{(*)}\overline{D}^{(*)}$ stands for the sum of $D^*\overline{D}^*$, $D^*\overline{D}$, $D\overline{D}^*$, and $D\overline{D}$.

[*ggaa*] $X(3915)$ denotes a near-threshold enhancement in the $\omega J/\psi$ mass spectrum.

[*hhaa*] Inclusive branching fractions have a multiplicity definition and can be greater than 100%.

[*iiaa*] D_j represents an unresolved mixture of pseudoscalar and tensor D^{**} (*P*-wave) states.

[*jjaa*] Not a pure measurement. See note at head of B_s^0 Decay Modes.

[*kkaa*] For $E_\gamma > 100$ MeV.

[*llaa*] Includes $p\overline{p}\pi^+\pi^-\gamma$ and excludes $p\overline{p}\eta$, $p\overline{p}\omega$, $p\overline{p}\eta'$.

[*nnaa*] See the "Note on the $\eta(1405)$" in the $\eta(1405)$ Particle Listings.

[*ooaa*] For a narrow state *A* with mass less than 960 MeV.

[*ppaa*] For a narrow scalar or pseudoscalar A^0 with mass 0.21–3.0 GeV.

[*qqaa*] For a narrow resonance in the range $2.2 < M(X) < 2.8$ GeV.

[*rraa*] J^{PC} known by production in e^+e^- via single photon annihilation. I^G is not known; interpretation of this state as a single resonance is unclear because of the expectation of substantial threshold effects in this energy region.

[*ssaa*] $2m_\tau < M(\tau^+\tau^-) < 9.2$ GeV

[*ttaa*] 2 GeV $< m_{K^+K^-} <$ 3 GeV

[*uuaa*] X = scalar with $m < 8.0$ GeV

[*vvaa*] $X\overline{X}$ = vectors with $m < 3.1$ GeV

[*xxaa*] X and $\overline{X}$ = zero spin with $m < 4.5$ GeV

[*yyaa*] 1.5 GeV $< m_X <$ 5.0 GeV

[*zzaa*] 201 MeV $< M(\mu^+\mu^-) <$ 3565 MeV

[*aabb*] 0.5 GeV $< m_X <$ 9.0 GeV, where m_X is the invariant mass of the hadronic final state.

[*bbbb*] Spectroscopic labeling for these states is theoretical, pending experimental information.

[*ccbb*] 1.5 GeV $< m_X <$ 5.0 GeV

[*ddbb*] 1.5 GeV $< m_X <$ 5.0 GeV

[*eebb*] For $m_{\tau^+\tau^-}$ in the ranges 4.03–9.52 and 9.61–10.10 GeV.

See also the table of suggested $q\overline{q}$ quark-model assignments in the Quark Model section.

• Indicates particles that appear in the preceding Meson Summary Table. We do not regard the other entries as being established.

Baryon Summary Table

This short table gives the name, the quantum numbers (where known), and the status of baryons in the Review. Only the baryons with 3- or 4-star status are included in the Baryon Summary Table. Due to insufficient data or uncertain interpretation, the other entries in the table are not established baryons. The names with masses are of baryons that decay strongly. The spin-parity J^P (when known) is given with each particle. For the strongly decaying particles, the J^P values are considered to be part of the names.

**** Existence is certain, and properties are at least fairly well explored.

*** Existence ranges from very likely to certain, but further confirmation is desirable and/or quantum numbers, branching fractions, etc. are not well determined.

** Evidence of existence is only fair.

* Evidence of existence is poor.

N BARYONS
$(S = 0, I = 1/2)$

$p, N^+ = uud; \quad n, N^0 = udd$

p

$I(J^P) = \frac{1}{2}(\frac{1}{2}^+)$

Mass $m = 1.00727646662 \pm 0.00000000009$ u (S = 3.1)
Mass $m = 938.272081 \pm 0.000006$ MeV [a]
$|m_p - m_{\overline{p}}|/m_p < 7 \times 10^{-10}$, CL = 90% [b]
$|\frac{q_{\overline{p}}}{m_{\overline{p}}}|/(\frac{q_p}{m_p}) = 1.00000000000 \pm 0.00000000007$
$|q_p + q_{\overline{p}}|/e < 7 \times 10^{-10}$, CL = 90% [b]
$|q_p + q_e|/e < 1 \times 10^{-21}$ [c]
Magnetic moment $\mu = 2.7928473446 \pm 0.0000000008\ \mu_N$
$(\mu_p + \mu_{\overline{p}}) / \mu_p = (0.002 \pm 0.004) \times 10^{-6}$

Electric polarizability $\alpha = (11.2 \pm 0.4) \times 10^{-4}$ fm^3
Magnetic polarizability $\beta = (2.5 \pm 0.4) \times 10^{-4}$ fm^3 (S = 1.2)
Charge radius, μp Lamb shift $= 0.84087 \pm 0.00039$ fm [d]
Charge radius $= 0.8409 \pm 0.0004$ fm [d]
Magnetic radius $= 0.851 \pm 0.026$ fm [e]
Mean life $\tau > 3.6 \times 10^{29}$ years, CL = 90% [f] ($p \to$ invisible mode)
Mean life $\tau > 10^{31}$ to 10^{33} years [f] (mode dependent)

See the "Note on Nucleon Decay" in our 1994 edition (Phys. Rev. **D50**, 1173) for a short review.

The "partial mean life" limits tabulated here are the limits on τ/B_i, where τ is the total mean life and B_i is the branching fraction for the mode in question. For N decays, p and n indicate proton and neutron partial lifetimes.

p DECAY MODES	Partial mean life (10^{30} years)	Confidence level	p (MeV/c)

$\Lambda_c(2595)^+$

$I(J^P) = 0(\frac{1}{2}^-)$

The spin-parity follows from the fact that $\Sigma_c(2455)\pi$ decays, with little available phase space, are dominant. This assumes that $J^P = 1/2^+$ for the $\Sigma_c(2455)$.

Mass $m = 2592.25 \pm 0.28$ MeV
$m - m_{\Lambda_c^+} = 305.79 \pm 0.24$ MeV
Full width $\Gamma = 2.6 \pm 0.6$ MeV

$\Lambda_c^+\pi\pi$ and its submode $\Sigma_c(2455)\pi$ — the latter just barely — are the only strong decays allowed to an excited Λ_c^+ having this mass; and the submode seems to dominate.

$\Lambda_c(2595)^+$ DECAY MODES		Fraction (Γ_i/Γ)	p (MeV/c)
$\Lambda_c^+\pi^+\pi^-$	[s]	—	117

b-baryon ADMIXTURE (Λ_b, Ξ_b, Ω_b)

These branching fractions are actually an average over weakly decaying b-baryons weighted by their production rates at the LHC, LEP, and Tevatron, branching ratios, and detection efficiencies. They scale with the b-baryon production fraction B($b \to$ b-baryon).

The branching fractions B(b-baryon $\to \Lambda \ell^- \overline{\nu}_\ell$anything) and B($\Lambda_b^0 \to \Lambda_c^+ \ell^- \overline{\nu}_\ell$anything) are not pure measurements because the underlying measured products of these with B($b \to$ b-baryon) were used to determine B($b \to$ b-baryon), as described in the note "Production and Decay of b-Flavored Hadrons."

For inclusive branching fractions, *e.g.*, $B \to D^\pm$anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

NOTES

This Summary Table only includes established baryons. The Particle Listings include evidence for other baryons. The masses, widths, and branching fractions for the resonances in this Table are Breit-Wigner parameters, but pole positions are also given for most of the N and Δ resonances.

For most of the resonances, the parameters come from various partial-wave analyses of more or less the same sets of data, and it is not appropriate to treat the results of the analyses as independent or to average them together. Furthermore, the systematic errors on the results are not well understood. Thus, we usually only give ranges for the parameters. We then also give a best guess for the mass (as part of the name of the resonance) and for the width. The *Note on N and Δ Resonances* and the *Note on Λ and Σ Resonances* in the Particle Listings review the partial-wave analyses.

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame. For any resonance, the *nominal* mass is used in calculating p. A dagger ("†") in this column indicates that the mode is forbidden when the nominal masses of resonances are used, but is in fact allowed due to the nonzero widths of the resonances.

[*a*] The masses of the p and n are most precisely known in u (unified atomic mass units). The conversion factor to MeV, 1 u = 931.494061(21) MeV, is less well known than are the masses in u.

[*b*] The $|m_p - m_{\overline{p}}|/m_p$ and $|q_p + q_{\overline{p}}|/e$ are not independent, and both use the more precise measurement of $|q_{\overline{p}}/m_{\overline{p}}|/(q_p/m_p)$.

[*c*] The limit is from neutrality-of-matter experiments; it assumes $q_n = q_p + q_e$. See also the charge of the neutron.

[*d*] The μp and ep values for the charge radius are much too different to average them. The disagreement is not yet understood.

[*e*] There is a lot of disagreement about the value of the proton magnetic charge radius. See the Listings.

[*f*] The first limit is for $p \to$ anything or "disappearance" modes of a bound proton. The second entry, a rough range of limits, assumes the dominant decay modes are among those investigated. For antiprotons the best limit, inferred from the observation of cosmic ray $\overline{p}$'s is $\tau_{\overline{p}} > 10^7$ yr, the cosmic-ray storage time, but this limit depends on a number of assumptions. The best direct observation of stored antiprotons gives $\tau_{\overline{p}}/B(\overline{p} \to e^-\gamma) > 7 \times 10^5$ yr.

[*g*] There is some controversy about whether nuclear physics and model dependence complicate the analysis for bound neutrons (from which the best limit comes). The first limit here is from reactor experiments with free neutrons.

[*h*] Lee and Yang in 1956 proposed the existence of a mirror world in an attempt to restore global parity symmetry—thus a search for oscillations between the two worlds. Oscillations between the worlds would be maximal when the magnetic fields B and B' were equal. The limit for any B' in the range 0 to 12.5 μT is >12 s (95% CL).

[*i*] The parameters g_A, g_V, and g_{WM} for semileptonic modes are defined by $\overline{B}_f[\gamma_\lambda(g_V + g_A\gamma_5) + i(g_{WM}/m_{B_i})\,\sigma_{\lambda\nu}\,q^\nu]B_i$, and ϕ_{AV} is defined by $g_A/g_V = |g_A/g_V|e^{i\phi_{AV}}$. See the "Note on Baryon Decay Parameters" in the neutron Particle Listings.

[*j*] Time-reversal invariance requires this to be 0° or 180°.

[*k*] This coefficient is zero if time invariance is not violated.

[*l*] This limit is for γ energies between 0.4 and 782 keV.

[n] The decay parameters γ and Δ are calculated from α and ϕ using

$$\gamma = \sqrt{1-\alpha^2}\,\cos\phi\,, \qquad \tan\Delta = -\frac{1}{\alpha}\,\sqrt{1-\alpha^2}\,\sin\phi\,.$$

See the "Note on Baryon Decay Parameters" in the neutron Particle Listings.

[o] See the Listings for the pion momentum range used in this measurement.

[p] Our estimate. See the Particle Listings for details.

[q] A theoretical value using QED.

[r] This branching fraction includes all the decay modes of the final-state resonance.

[s] See AALTONEN 11H, Fig. 8, for the calculated ratio of $\Lambda_c^+\pi^0\pi^0$ and $\Lambda_c^+\pi^+\pi^-$ partial widths as a function of the $\Lambda_c(2595)^+ - \Lambda_c^+$ mass difference. At our value of the mass difference, the ratio is about 4.

[t] A test that the isospin is indeed 0, so that the particle is indeed a Λ_c^+.

[u] P_c^+ is a pentaquark-charmonium state.

[v] Not a pure measurement. See note at head of Λ_b^0 Decay Modes.

[x] Here h^- means π^- or K^-.

SEARCHES not in other sections

Magnetic Monopole Searches

The most sensitive experiments obtain negative results.
Best cosmic-ray supermassive monopole flux limit:
$< 1.4 \times 10^{-16}$ cm^{-2}sr^{-1}s^{-1} for $1.1 \times 10^{-4} < \beta < 1$

Supersymmetric Particle Searches

All supersymmetric mass bounds here are model dependent.

The limits assume:

1) $\widetilde{\chi}^0_1$ is the lightest supersymmetric particle; 2) R-parity is conserved, unless stated otherwise;

See the Particle Listings for a Note giving details of supersymmetry.

$\widetilde{\chi}^0_i$ — neutralinos (mixtures of $\widetilde{\gamma}$, $\widetilde{Z}^0$, and $\widetilde{H}^0_i$)
Mass $m_{\widetilde{\chi}^0_1}$ $>$ 0 GeV, CL = 95%
[general MSSM, non-universal gaugino masses]
Mass $m_{\widetilde{\chi}^0_1}$ $>$ 46 GeV, CL = 95%
[all tanβ, all m_0, all $m_{\widetilde{\chi}^0_2} - m_{\widetilde{\chi}^0_1}$]
Mass $m_{\widetilde{\chi}^0_2}$ $>$ 62.4 GeV, CL = 95%
[1<tanβ <40, all m_0, all $m_{\widetilde{\chi}^0_2} - m_{\widetilde{\chi}^0_1}$]
Mass $m_{\widetilde{\chi}^0_3}$ $>$ 99.9 GeV, CL = 95%
[1<tanβ <40, all m_0, all $m_{\widetilde{\chi}^0_2} - m_{\widetilde{\chi}^0_1}$]
Mass $m_{\widetilde{\chi}^0_4}$ $>$ 116 GeV, CL = 95%
[1<tanβ <40, all m_0, all $m_{\widetilde{\chi}^0_2} - m_{\widetilde{\chi}^0_1}$]

$\widetilde{\chi}^\pm_i$ — charginos (mixtures of $\widetilde{W}^\pm$ and $\widetilde{H}^\pm_i$)
Mass $m_{\widetilde{\chi}^\pm_1}$ $>$ 94 GeV, CL = 95%
[tanβ < 40, $m_{\widetilde{\chi}^\pm_1} - m_{\widetilde{\chi}^0_1} > 3$ GeV, all m_0]
Mass $m_{\widetilde{\chi}^\pm_1}$ $>$ 810 GeV, CL = 95%
[$\ell^\pm \ell^\mp$, Tchi1chi1C, $m_{\widetilde{\chi}^0_1} = 0$ GeV]

$\widetilde{\chi}^\pm$ — long-lived chargino
Mass $m_{\widetilde{\chi}^\pm}$ $>$ 620 GeV, CL = 95% [stable $\widetilde{\chi}^\pm$]

$\widetilde{\nu}$ — sneutrino
Mass $m >$ 41 GeV, CL = 95% [model independent]
Mass $m >$ 94 GeV, CL = 95%
[CMSSM, $1 \leq \tan\beta \leq 40$, $m_{\widetilde{e}_R} - m_{\widetilde{\chi}^0_1}$ >10 GeV]
Mass $m >$ 3400 GeV, CL = 95% [R-Parity Violating]
[$\widetilde{\nu}_\tau \rightarrow e\mu$, $\lambda_{312} = \lambda_{321} = 0.07$, $\lambda'_{311} = 0.11$]

$\widetilde{e}$ — scalar electron (selectron)
Mass $m(\widetilde{e}_L) >$ 107 GeV, CL = 95% [all $m_{\widetilde{e}_L} - m_{\widetilde{\chi}^0_1}$]
Mass $m >$ 410 GeV, CL = 95% [R-Parity Violating]
[$\geq 4\ell^\pm$, $\widetilde{\ell} \rightarrow l\widetilde{\chi}^0_1$, $\widetilde{\chi}^0_1 \rightarrow \ell^\pm \ell^\mp \nu$]

$\widetilde{\mu}$ — scalar muon (smuon)
Mass $m >$ 94 GeV, CL = 95%
[CMSSM, $1 \leq \tan\beta \leq 40$, $m_{\widetilde{\mu}_R} - m_{\widetilde{\chi}^0_1}$ > 10 GeV]
Mass $m >$ 410 GeV, CL = 95% [R-Parity Violating]
[$\geq 4\ell^\pm$, $\widetilde{\ell} \rightarrow l\widetilde{\chi}^0_1$, $\widetilde{\chi}^0_1 \rightarrow \ell^\pm \ell^\mp \nu$]

$\widetilde{\tau}$ — scalar tau (stau)
Mass $m >$ 81.9 GeV, CL = 95%
[$m_{\widetilde{\tau}_R} - m_{\widetilde{\chi}^0_1}$ >15 GeV, all θ_τ, B($\widetilde{\tau} \rightarrow \tau\widetilde{\chi}^0_1$) = 100%]
Mass $m >$ 286 GeV, CL = 95% [long-lived $\widetilde{\tau}$]

$\widetilde{q}$ – squarks of the first two quark generations
Mass $m >$ 1.450×10^3 GeV, CL = 95%
[CMSSM, tanβ = 30, $A_0 = -2\max(m_0, m_{1/2})$, $\mu > 0$]
Mass $m >$ 1630 GeV, CL = 95%
[mass degenerate squarks]
Mass $m >$ 1130 GeV, CL = 95%
[single light squark bounds]
Mass $m >$ 1.600×10^3 GeV, CL = 95% [R-Parity Violating]
[$\widetilde{q} \rightarrow q\widetilde{\chi}^0_1$, $\widetilde{\chi}^0_1 \rightarrow \ell\ell\nu$, λ_{121},$\lambda_{122} \neq 0$, $m_{\widetilde{g}}$=2400GeV]

$\widetilde{q}$ — long-lived squark
Mass $m >$ 1340, CL = 95% [$\widetilde{t}$ R-hadrons]
Mass $m >$ 1250, CL = 95% [$\widetilde{b}$ R-hadrons]

$\widetilde{b}$ — scalar bottom (sbottom)
Mass $m >$ 1230 GeV, CL = 95%
[jets+$\not{E}_T$, Tsbot1, $m_{\widetilde{\chi}^0_1} = 0$ GeV]
Mass $m >$ 307 GeV, CL = 95% [R-Parity Violating]
[$\widetilde{b} \rightarrow td$ or ts, λ''_{332} or λ''_{331} coupling]

$\widetilde{t}$ — scalar top (stop)
Mass $m >$ 1190 GeV, CL = 95%
[jets+$\not{E}_T$, Tstop1, $m_{\widetilde{\chi}^0_1} = 0$ GeV]
Mass $m >$ 1100 GeV, CL = 95% [R-Parity Violating]
[$\widetilde{t} \rightarrow be$, Tstop2RPV, prompt]

$\widetilde{g}$ — gluino
Mass $m >$ 2.000×10^3 GeV, CL = 95%
[jets + $\not{E}_T$, Tglu1A, $m_{\widetilde{\chi}^0_1} = 0$ GeV]
Mass $m >$ 2.260×10^3 GeV, CL = 95% [R-Parity Violating]
[$\geq 4\ell$, $\lambda_{12k} \neq 0$, $m_{\widetilde{\chi}^0_1}$ > 1000 GeV]

Technicolor

The limits for technicolor (and top-color) particles are quite varied depending on assumptions. See the Technicolor section of the full *Review* (the data listings).

Quark and Lepton Compositeness, Searches for

Scale Limits Λ for Contact Interactions (the lowest dimensional interactions with four fermions)

If the Lagrangian has the form

$$\pm \frac{g^2}{2\Lambda^2} \overline{\psi}_L \gamma_\mu \psi_L \overline{\psi}_L \gamma^\mu \psi_L$$

(with $g^2/4\pi$ set equal to 1), then we define $\Lambda \equiv \Lambda^\pm_{LL}$. For the full definitions and for other forms, see the Note in the Listings on Searches for Quark and Lepton Compositeness in the full *Review* and the original literature.

Excited Leptons

The limits from $\ell^{*+}\ell^{*-}$ do not depend on λ (where λ is the $\ell\ell^*$ transition coupling). The λ-dependent limits assume chiral coupling.

$e^{*\pm}$ — excited electron

Mass $m >$ 103.2 GeV, CL = 95% (from $e^* e^*$)
Mass $m >$ 4.800×10^3 GeV, CL = 95% (from $e e^*$)
Mass $m >$ 356 GeV, CL = 95% (if $\lambda_\gamma = 1$)

$\mu^{*\pm}$ — excited muon

Mass $m >$ 103.2 GeV, CL = 95% (from $\mu^* \mu^*$)
Mass $m >$ 3.800×10^3 GeV, CL = 95% (from $\mu\mu^*$)

$\tau^{*\pm}$ — excited tau

Mass $m >$ 103.2 GeV, CL = 95% (from $\tau^* \tau^*$)
Mass $m >$ 2.500×10^3 GeV, CL = 95% (from $\tau\tau^*$)

ν^* — excited neutrino

Mass $m >$ 1.600×10^3 GeV, CL = 95% (from $\nu^* \nu^*$)
Mass $m >$ 213 GeV, CL = 95% (from $\nu^* X$)

q^* — excited quark

Mass $m >$ 338 GeV, CL = 95% (from $q^* q^*$)
Mass $m >$ 6.000×10^3 GeV, CL = 95% (from $q^* X$)

Color Sextet and Octet Particles

Color Sextet Quarks (q_6)

Mass $m >$ 84 GeV, CL = 95% (Stable q_6)

Color Octet Charged Leptons (ℓ_8)

Mass $m >$ 86 GeV, CL = 95% (Stable ℓ_8)

Color Octet Neutrinos (ν_8)

Mass $m >$ 110 GeV, CL = 90% ($\nu_8 \to \nu g$)

Extra Dimensions

Please refer to the Extra Dimensions section of the full *Review* for a discussion of the model-dependence of these bounds, and further constraints.

Constraints on the radius of the extra dimensions, for the case of two-flat dimensions of equal radii

$R <$ 30 μm, CL = 95% (direct tests of Newton's law)
$R <$ 4.8 μm, CL = 95% ($pp \to jG$)
$R <$ 0.16–916 nm (astrophysics; limits depend on technique and assumptions)

Constraints on the fundamental gravity scale

$M_{TT} >$ 9.02 TeV, CL = 95% ($pp \to$ dijet, angular distribution)
$M_c >$ 4.16 TeV, CL = 95% ($pp \to \ell\bar{\ell}$)

Constraints on the Kaluza-Klein graviton in warped extra dimensions

$M_G >$ 4.25 TeV, CL = 95% ($pp \to \gamma\gamma$)

Constraints on the Kaluza-Klein gluon in warped extra dimensions

$M_{g_{KK}} >$ 3.8 TeV, CL = 95% ($g_{KK} \to t\bar{t}$)

WIMP and Dark Matter Searches

No confirmed evidence found for galactic WIMPs from the GeV to the TeV mass scales and down to 1×10^{-10} pb spin independent cross section at M = 100 GeV.

Tests of Conservation Laws

Written August 2019 by A. Pich (IFIC, Valencia) and M. Ramsey-Musolf (Tsung-Dao Lee Inst.; SJTU; U. Massachusetts).

In keeping with the current interest in tests of conservation laws, we collect together a Table of experimental limits on all weak and electromagnetic decays, mass differences, and moments, and on a few reactions, whose observation would violate conservation laws. The Table is given only in the full Review of Particle Physics (RPP), not in the Particle Physics Booklet, and organizes the data in two main sections: "Discrete Space-Time Symmetries", *i.e.*, C, P, T, CP and CPT; and "Number Conservation Laws", *i.e.*, lepton, baryon, flavor and charge conservation. The references for these data can be found in the Particle Listings. The following text discusses the best limits among those included in the Table and gives a brief overview of the current status. For some topics, a more extensive discussion of the framework for theoretical interpretation is provided, particularly where the analogous discussion does not appear elsewhere in the RPP. References to more extensive review articles are also included where appropriate. Unless otherwise specified, all limits quoted in this review are given at a C.L. of 90%.

DISCRETE SPACE-TIME SYMMETRIES

Charge conjugation (C), parity (P) and time reversal (T) are empirically exact symmetries of the electromagnetic (QED) and strong (QCD) interactions, but they are violated by the weak forces. Owing to the left-handed nature of the $SU(2)_L \otimes U(1)_Y$ electroweak theory, C and P are maximally violated in the fermionic couplings of the $W^\pm$ and (up to $\sin^2\theta_W$ corrections) the Z. However, their product CP is still an exact symmetry when only one or two fermion families are considered. With three generations of fermions, CP is violated through the single complex phase present in the Cabibbo-Kobayashi-Maskawa (CKM) quark mixing matrix. An analogous CP-violating (CPV) phase appears in the lepton sector when non-vanishing neutrino masses are taken into account (plus two additional phases if neutrinos are Majorana particles). The product of the three discrete symmetries, CPT, is an exact symmetry of any local and Lorentz-invariant quantum field theory with a positive-definite hermitian Hamiltonian that preserves micro-causality [1, 2]. Therefore, the breaking of CP implies a corresponding violation of T.

Violations of charge-conjugation symmetry have never been observed in electromagnetic and strong phenomena. The most stringent limits are extracted from C-violating transitions of neutral (self-conjugate) particles such as $\mathrm{Br}(\pi^0 \to 3\gamma) < 3.1 \times 10^{-8}$ [3] and $\mathrm{Br}(J/\psi \to 2\gamma) < 2.7 \times 10^{-7}$ [4]. P (and CP) conservation has been also precisely tested through forbidden decays such as $\mathrm{Br}(\eta \to 4\pi^0) < 6.9 \times 10^{-7}$ [5], but the best limits on P and T are set by the non-observation of electric dipole moments (see section 2). Obviously, the interplay of the weak interaction puts a lower bound in sensitivity for this type of tests, beyond which violations of the corresponding conservation laws should be detected.

1 Violations of CP and T

The first evidence of CP non-invariance in particle physics was the observation in 1964 of $K_L^0 \to \pi^+\pi^-$ decays [6]. For many years afterwards, the non-zero ratio

$$\begin{aligned} |\eta_{+-}| &\equiv |\mathcal{M}(K_L^0 \to \pi^+\pi^-)/\mathcal{M}(K_S^0 \to \pi^+\pi^-)| \\ &= (2.232 \pm 0.011) \times 10^{-3} \end{aligned} \tag{1}$$

could be explained as a K^0–$\overline{K}^0$ mixing effect, $\eta_{+-} = \epsilon$ (superweak CP violation), which would imply an identical ratio $\eta_{00} \equiv \mathcal{M}(K_L^0 \to \pi^0\pi^0)/\mathcal{M}(K_S^0 \to \pi^0\pi^0)$ in the neutral decay mode and successfully predicts the observed CPV semileptonic asymmetry ($A_L(e) \approx 2\,\mathrm{Re}\,\epsilon$)

$$\begin{aligned} A_L(e) &\equiv \frac{\Gamma(K_L^0 \to \pi^- e^+ \nu_e) - \Gamma(K_L^0 \to \pi^+ e^- \bar\nu_e)}{\Gamma(K_L^0 \to \pi^- e^+ \nu_e) + \Gamma(K_L^0 \to \pi^+ e^- \bar\nu_e)} \\ &= (3.34 \pm 0.07) \times 10^{-3}\,. \end{aligned} \tag{2}$$

A tiny difference between η_{+-} and η_{00} was reported for the first time in 1988 by the CERN NA31 collaboration [7], and later established at the 7.2σ level with the full data samples from the NA31 [8], E731 [9], NA48 [10] and KTeV [11] experiments:

$$\mathrm{Re}(\epsilon'/\epsilon) = \frac{1}{3}\,(1 - |\eta_{00}/\eta_{+-}|) = (1.66 \pm 0.23) \times 10^{-3}\,. \tag{3}$$

This important measurement confirmed that CP violation is associated with a $\Delta S = 1$ transition, as predicted by the CKM mechanism. The Standard Model (SM) prediction, $\mathrm{Re}(\epsilon'/\epsilon) = (1.4 \pm 0.5) \times 10^{-3}$ [12, 13], is in good agreement with the measured ratio, although the theoretical uncertainty is unfortunately large.

Much larger CP asymmetries have been later measured in B meson decays, many of them involving the interference between B^0–$\overline{B}^0$ mixing and the decay amplitude. They provide many successful tests of the CKM unitarity structure, validating the SM mechanism of CP violation (see the review on CP violation in the quark sector). Prominent signals of direct CP violation have been also clearly established in several $B^\pm$, B_d^0 and B_s^0 decays, and, very recently, in charm decays [14]:

$$\begin{aligned} \Delta a_{CP}^{\mathrm{dir}} &\equiv a_{CP}^{\mathrm{dir}}(D^0 \to K^+K^-) - a_{CP}^{\mathrm{dir}}(D^0 \to \pi^+\pi^-) \\ &= (-15.7 \pm 2.9) \times 10^{-4}\,. \end{aligned} \tag{4}$$

These direct CP asymmetries necessarily involve the presence of a strong phase-shift difference between (at least) two interfering amplitudes, which makes very challenging to perform reliable SM predictions for heavy-flavored mesons.

Global fits to neutrino oscillation data provide some hints of a non-zero mixing phase [15, 16]. Although the statistical significance is not yet compelling, they suggest that CP-violation effects in neutrino oscillations could be large (see the review on neutrino masses, mixings and oscillations). The future DUNE and Hyper-Kamiokande experiments are expected to confirm the presence of CP violation in the lepton sector or constrain the phase in the leptonic mixing matrix to be smaller than $O(10^\circ)$.

While CP violation implies a breaking of time-reversal symmetry, direct tests of T violation are much more difficult. The CPLEAR experiment observed longtime ago a non-zero difference between the oscillation probabilities of $K^0 \to \overline{K}^0$ and $\overline{K}^0 \to K^0$ [17]. Initial neutral kaons with defined strangeness were produced from proton-antiproton annihilations at rest, $p\bar p \to K^-\pi^+K^0, K^+\pi^-\overline{K}^0$, and tagged by the accompanying charged kaon, while the strangeness of the final neutral kaon was identified through its semileptonic decay: $K^0 \to e^+\pi^-\nu_e$, $\overline{K}^0 \to e^-\pi^+\bar\nu_e$. The average asymmetry over the time interval from 1 to 20 K_S^0 lifetimes was found to be different from zero at 4σ [17]:

$$\begin{aligned} &\frac{R[\overline{K}^0\,(t=0) \to e^+\pi^-\nu_e\,(t)] - R[K^0\,(t=0) \to e^-\pi^+\bar\nu_e\,(t)]}{R[\overline{K}^0\,(t=0) \to e^+\pi^-\nu_e\,(t)] + R[K^0\,(t=0) \to e^-\pi^+\bar\nu_e\,(t)]} = \\ &= (6.6 \pm 1.3 \pm 1.0) \times 10^{-3}\,. \end{aligned} \tag{5}$$

Since this asymmetry violates also CP, its interpretation as direct evidence of T violation requires a detailed analysis of the underlying K^0–$\overline{K}^0$ mixing process [18–20].

More recently, the exchange of initial and final states has been made possible in B decays, taking advantage of the entanglement of the two daughter mesons produced in the decay $\Upsilon(4S) \to B\bar B$ which allows for both flavor ($B^0 \to \ell^+X$, $\overline{B}^0 \to \ell^-X$) and CP ($B_+ \to J/\psi K_L^0$, $B_- \to J/\psi K_S^0$) tagging. Selecting events where one B candidate is reconstructed in a CP eigenstate and the flavor of the other B is identified, one can compare the rates of the $\overline{B}^0 \to B_\pm$ and $B^0 \to B_\pm$ transitions with their T-reversed $B_\pm \to \overline{B}^0$ and $B_\pm \to B^0$ processes, as a function of the time difference Δt between the two B decays [21–23]. Neglecting the small width difference between the two B_d^0 mass eigenstates, each of these eight transitions has a time-dependent decay rate of the form $\mathrm{e}^{-\Gamma_d \Delta t}\,\{1 + S_{\alpha,\beta}^\pm \sin(\Delta m_d \Delta t) + C_{\alpha,\beta}^\pm \cos(\Delta m_d \Delta t)\}$, where Γ_d is the average decay width, Δm_d the B_d^0 mass difference, the subindices $\alpha = \ell^+, \ell^-$ and $\beta = K_S^0, K_L^0$ stand for the reconstructed final states of the two B mesons and the superindex +

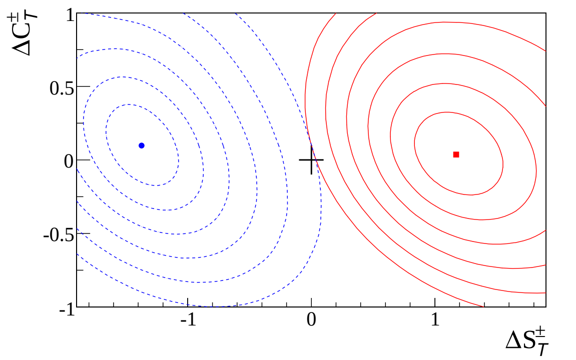

Figure 1: Measured values of ΔS_T^+, ΔC_T^+ (blue point, dashed lines) and ΔS_T^-, ΔC_T^- (red square, solid lines) [24]. The two-dimensional contours correspond to $1 - \mathrm{CL} = 0.317, 4.55 \times 10^{-2}, 2.70 \times 10^{-3}, 6.33 \times 10^{-5}, 5.73 \times 10^{-7}$, and 1.97×10^{-9}. The $+$ sign indicates the T-invariant point.

or $-$ indicates whether the decay to the flavor final state α occurs before or after the decay to the CP final state β. Figure 1 shows confidence-level contours for the T-asymmetry parameters $\Delta S_T^\pm \equiv S^\mp_{\ell^-,K^0_L} - S^\pm_{\ell^+,K^0_S}$ and $\Delta C_T^\pm \equiv C^\mp_{\ell^-,K^0_L} - C^\pm_{\ell^+,K^0_S}$, reported by the BABAR experiment [24], which clearly demonstrate a violation of T in $\Delta S_T^\pm$, with a significance of 14σ.

2 Electric dipole moments

Among the most powerful tests of CP invariance is the search for a permanent electric dipole moment (EDM) of an elementary fermion or non-degenerate quantum system. The EDM of an elementary spin-1/2 fermion f is defined by the effective, non-renormalizable interaction

$$\mathcal{L}_{\mathrm{EDM}} = -\frac{i}{2} d_f\, \bar{f}\sigma_{\mu\nu}\gamma_5 f\, F^{\mu\nu} \tag{6}$$

where $F^{\mu\nu}$ is the QED field strength tensor. The values for d_f are conventionally expressed in units of $e\,\mathrm{cm}$. The interaction (6) is separately odd under T and P. In the non-relativistic limit, Eq. (6) reduces to

$$\mathcal{L}_{\mathrm{EDM}} \to d_f\, \chi_f^\dagger \vec{\sigma}\chi \cdot \vec{E} \tag{7}$$

where χ is a two-component Pauli spinor and $\vec{E}$ is the electric field. Note the interaction (7) is manifestly T-odd and carries no direct information on CP. The observation of a non-zero EDM of a non-relativistic (and non-degenerate) quantum system, such as the mercury atom (see below) would imply CP violation under the assumption of CPT invariance.

To date, no experimental observation of an EDM of an elementary particle or non-degenerate bound quantum system has been observed. The most stringent limits have been obtained for the EDMs of the electron, mercury atom, and neutron. A selection of the representative, most stringent limits is given in Table 1. The limits on the electron EDM are inferred from experiments involving polar molecules, paramagnetic systems with an unpaired electron spin. In contrast, the neutron and ^{199}Hg atom are diamagnetic. A variety of experimental efforts aimed at improved sensitivities are underway. For reviews of the experimental and theoretical situation, see, *e.g.* [25–28].

EDMs in the Standard Model

The SM provides two sources of d_f: the CPV phase in the CKM matrix and the P- and T-odd 'θ term' in the QCD Lagrangian. The former is characterized by the Jarlskog invariant [35]

$$\mathcal{J} = \mathrm{Im}(V_{us}V_{cs}^* V_{cb}V_{ub}^*) \sim A^2\lambda^6\eta < 10^{-4}\,, \tag{8}$$

while the latter is given by

$$\mathcal{L}_{\bar\theta} = -\frac{g_3^2}{16\pi^2}\,\bar\theta\; \mathrm{Tr}\left(G^{\mu\nu}\tilde{G}_{\mu\nu}\right), \tag{9}$$

Table 1: Most stringent limits on electric dipole moments.

EDM	Limit ($e\,$cm)		Source
Electron	1.1×10^{-29}	(90% C.L.)	ThO [29]
	1.3×10^{-28}	(90% C.L.)	HfF$^+$ [30]
Muon	1.8×10^{-19}	(95% C.L.)	[31]
Neutron	1.8×10^{-26}	(90% C.L.)	[32]
^{199}Hg Atom	7.4×10^{-30}	(95% C.L.)	[33]
^{129}Xe Atom	1.5×10^{-27}	(95% C.L.)	[34]

where $G_{\mu\nu}$ ($\tilde{G}_{\mu\nu} = \epsilon_{\mu\nu\alpha\beta}\, G^{\alpha\beta}/2$) is the QCD field strength tensor (dual).

The CKM-induced EDMs of quarks and charged leptons arise at three- and four-loop orders, respectively [36–39]. The resulting numerical impact for the experimental observables (see below) falls well below present and prospective experimental sensitivities. The most important impact of $\mathcal{J}$ for the EDMs of the neutron and diamagnetic atoms arise via induced hadronic interactions. The resulting theoretical expectations for the electron, neutron and ^{199}Hg EDMs are

$$|d_e|_{\mathrm{CKM}} \approx 10^{-44}\; e\,\mathrm{cm} \quad [39], \tag{10a}$$

$$|d_n|_{\mathrm{CKM}} \approx (1-6) \times 10^{-32}\; e\,\mathrm{cm} \quad [40], \tag{10b}$$

$$|d_A(^{199}\mathrm{Hg})|_{\mathrm{CKM}} \lesssim 4 \times 10^{-34}\; e\,\mathrm{cm} \quad [25]. \tag{10c}$$

For d_n and $d_A(^{199}\mathrm{Hg})$, the dominant CKM contributions arise from four-quark operators (generated after integrating out the electroweak gauge bosons) rather than from the EDMs of the individual quarks. The corresponding sensitivities to the QCD $\bar\theta$ parameter are given by

$$|d_n|_{\bar\theta} \approx (0.9-1.2) \times 10^{-16}\; \bar\theta\; e\,\mathrm{cm} \quad [40], \tag{11a}$$

$$|d_A(^{199}\mathrm{Hg})|_{\bar\theta} \approx (0.07-8) \times 10^{-20}\; \bar\theta\; e\,\mathrm{cm} \quad [25,26], \tag{11b}$$

where the ranges quoted include the impacts of hadronic, nuclear, and atomic theory uncertainties. The neutron EDM puts then a stringent limit on 'strong' CP violation: $\bar\theta \lesssim 2 \times 10^{-10}$. The corresponding limit from $d_A(^{199}\mathrm{Hg})$ is weaker due to the large theoretical uncertainty.

EDMs Beyond the Standard Model

It is possible that the next generation of EDM searches will yield a non-zero result, arising from the $\bar\theta$-term interaction and/or physics beyond the SM (BSM). Most of the considered BSM scenarios involve new particles with masses well above the electroweak scale. At energies much lower than the BSM mass scale Λ, the dynamics can be described through an effective field theory (SMEFT) involving an infinite set of non-renormalizable operators $\mathcal{O}_k^{(d)}$, with dimensions $d > 4$, that are invariant under the SM gauge group:

$$\mathcal{L}_{\mathrm{SMEFT}} = \mathcal{L}_{\mathrm{SM}} + \sum_{k,d} \alpha_k^{(d)} \left(\frac{1}{\Lambda}\right)^{d-4} \mathcal{O}_k^{(d)}\,. \tag{12}$$

The operators contain only SM fields, while all short-distance information on the BSM physics is encoded in their Wilson coefficients $\alpha_k^{(d)}$. The $d = 4$ term corresponds to the SM Lagrangian.

For the systems of Table 1 and for many BSM scenarios of recent interest, it suffices to consider the leading contributions from $d = 6$ operators. Considering only the first-generation SM fermions, there exist 12 independent CPV pertinent operators. For a complete listing, see *e.g.*, Refs. [26, 41]. For a given elementary fermion f, two of these operators reduce to the EDM interaction in Eq. (6). Of the remaining, the most relevant include the chromo-electric dipole moments (cEDMs) of the quarks; a CP-odd three gluon operator; three semileptonic, four-fermion operators; two four-quark operators; and a CPV interaction involving two Higgs fields and a right-handed quark current. For the dipole operators, it is useful to define a rescaled Wilson coefficient $\alpha_{fV_j}^{(6)} \equiv g_j\, C_{fV_j}$, where V_j ($j = 1, 2, 3$) denote the gauge bosons for

Table 2: Pertinent dimension-six EDM and cEDM sources (first generation fermions only).

System	$d = 6$ Source	Wilson Coefficient
Paramagnetic	Electron EDM	Im $C_{e\gamma}$
	Electron-quark	$C_{eq}^{(\pm)}$
Diamagnetic	Quark EDM	Im $C_{q\gamma}$
	Quark cEDM	Im C_{qG}
	Three gluon	$C_{\tilde{G}}$
	Four quark	Im $C_{quqd}^{(1,8)}$
	Quark-Higgs	Im $C_{\varphi ud}$
	Electron-quark tensor*	Im $C_{\ell equ}^{(3)}$

*Applicable only to atoms.

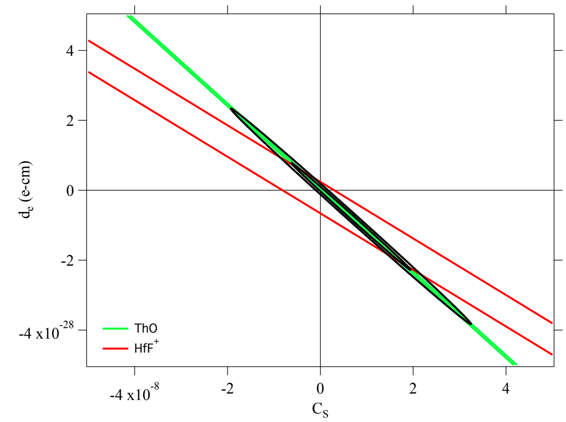

Figure 2: Constraints on d_e and C_S from EDM searches using polar molecules (updated by [44] from Ref. [25]).

the three SM gauge groups with corresponding couplings g_j; for all other $d = 6$ operators we correspondingly identify $\alpha_k^{(6)} \equiv C_k$. In this case, one has for the EDM (d_f) and cEDM ($\tilde{d}_q$)

$$d_f = -(1.13 \times 10^{-16}\ e\ \text{cm}) \left(\frac{v}{\Lambda}\right)^2 \text{Im}\ C_{f\gamma}\,, \tag{13a}$$

$$\tilde{d}_q = -(1.13 \times 10^{-16}\ \text{cm}) \left(\frac{v}{\Lambda}\right)^2 \text{Im}\ C_{qG}\,, \tag{13b}$$

with Im $C_{f\gamma}$ = Im $C_{fB} + 3I_3^f$ Im C_{fW}. As the expressions (13a,13b) illustrate, the magnitude of the BSM contributions scales with two inverse powers of the scale Λ. A similar conclusion holds for the contributions from the other $d = 6$ operators to the EDMs of Table 1.

It is important to emphasize that if the BSM mediators are light, with masses below the weak scale, the effective field theory description of Eq. (12) does not apply. For recent studies along these lines, see, *e.g.* [42, 43].

EDM Interpretation: From Short Distances to the Atomic Scale

The EDM limits in Table 1 are obtained using composite quantum systems, wherein the relevant dynamics involve physics at the hadronic, nuclear, atomic and molecular scales. The manifestation of a given CPV source (CKM, $\bar{\theta}$ term, BSM) involves an interplay of these dynamics. In all cases, one must first evolve the Wilson coefficients from the weak scale to the hadronic scale, then match onto the relevant low-energy degrees of freedom (electrons, nucleons, pions, *etc.*). At this level, the most straightforward interpretation involves the paramagnetic systems, for which two sources dominate: the electron EDM and the electron spin-dependent semileptonic interaction $\bar{e}\gamma_5 e\, \bar{q}q$. The latter gives rise to an spin-independent Hamiltonian, for an atom with Z electrons/protons and N neutrons,

$$\hat{H}_S = \frac{iG_F}{\sqrt{2}}\,\delta(\vec{r})\,\left[(Z+N)\,C_S^{(0)} + (Z-N)\,C_S^{(1)}\right]\gamma_0\gamma_5\,, \tag{14}$$

where $C_S^{(0)}$ ($C_S^{(1)}$) is proportional to $C_{eq}^{(+)}$ ($C_{eq}^{(-)}$). The computation of $C_S^{(0,1)}$ is relatively free from theoretical uncertainty since the operator $\bar{q}q$ essentially counts the number of quarks of flavor q in the nucleus. Experimental results for paramagnetic systems, thus, often quote bounds on

$$C_S \equiv C_S^{(0)} + \left(\frac{Z-N}{Z+N}\right) C_S^{(1)} \tag{15}$$

as well as on d_e, assuming only one of these two sources is non-vanishing. Combining results from ThO and HfF^+ (see Figure 2) allows one to obtain the global, 90% C.L. bounds

$$|d_e| < 1.8 \times 10^{-28}\ e\ \text{cm}\,, \qquad |C_S| < 9.8 \times 10^{-9}\,. \tag{16}$$

Note that the limits on d_e given in Table 1 have been obtained assuming $C_S = 0$.

For the diamagnetic systems, the situation is considerably more involved. For the neutron, a variety of approaches – including lattice QCD, chiral perturbation theory, QCD sum rules, and the quark model – have been employed to compute the relevant hadronic matrix elements of the CPV sources (see, *e.g.*, [26,27,45,46]). For diamagnetic atoms, the non-leptonic sources of Table 2 give rise to the EDM of the nucleus as well as other P- and T-odd nuclear moments, as allowed by the nuclear spin. However, according to a theorem by Schiff [47], the nuclear EDM generates no contribution to the neutral-atom EDM due to screening by atomic electrons. The leading contribution from these sources, instead, arises via the nuclear Schiff moment, $\vec{S}$, an r^3-weighted moment of the T- and P-odd component of the nuclear charge density. The resulting effective atomic Hamiltonian is

$$\hat{H}_{\text{Schiff}} = -4\pi\,\vec{\nabla}\rho_e(0)\cdot\vec{S}\,, \tag{17}$$

where $\vec{\nabla}\rho_e(0)$ is the gradient of the electron density at the nucleus. To date, computations of the nuclear Schiff moment have assumed that the leading contribution arises from a pion-exchange induced nuclear force, with the P- and T-odd πN interaction given by

$$\mathcal{L}_{\pi N}^{T,P} = \bar{N}\left[\bar{g}_\pi^{(0)}\vec{\tau}\cdot\vec{\pi} + \bar{g}_\pi^{(1)}\pi^0 + \bar{g}_\pi^{(2)}(3\tau_3\pi^0 - \vec{\tau}\cdot\vec{\pi})\right]N\,. \tag{18}$$

Chiral effective field theory power counting implies that in general the magnitude of $\bar{g}_\pi^{(2)}$ is suppressed with respect to the isoscalar and isovector couplings. The CPV sources then generate a diamagnetic atom EDM d_A via the sequence

$$\text{CPV source} \longrightarrow \bar{g}_\pi^{(i)} \longrightarrow \vec{S} \longrightarrow d_A\,. \tag{19}$$

The steps in this sequence involve dynamics at the hadronic, nuclear, and atomic scales, respectively. In addition, d_A may receive contributions from the nuclear spin-dependent interaction generated by the semileptonic tensor interaction listed in Table 2, with the corresponding atomic Hamiltonian

$$\hat{H}_T = \frac{2iG_F}{\sqrt{2}}\,\delta(\vec{r})\sum_N\left[C_T^{(0)} + C_T^{(1)}\tau_3\right]\vec{\sigma}_N\cdot\vec{\gamma}\,, \tag{20}$$

where σ_N is the nucleon spin Pauli matrix and $C_T^{(0,1)} \propto$ Im $C_{\ell equ}^{(3)}$.

Given the large number of CPV sources and existing diagmagnetic EDM limits, it is not possible to obtain a set of global constraints on the former. One may, however, do so for the low-energy effective parameters $\bar{g}_\pi^{(0,1)}$, $C_T^{(0,1)}$ and $\bar{d}_n^{\text{sr}}$, where the latter denotes a 'short-range' contribution to the neutron EDM [25, 48]. In this context, the dominant source of theoretical uncertainty involves computations of the nuclear Schiff moment. From the bounds on the low-energy parameters, one may then derive constraints on the CPV sources by utilizing computations of the hadronic matrix elements. Reducing the degree of theoretical hadronic and nuclear physics uncertainty is an area of active effort.

3 Tests of *CPT*

CPT symmetry implies the equality of the masses and widths of a particle and its antiparticle. The most constraining limits are extracted from the neutral kaons [49, 50]:

$$2\,\frac{|m_{K^0}-m_{\overline{K}^0}|}{(m_{K^0}+m_{\overline{K}^0})} < 6\times10^{-19}\,,\qquad 2\,\frac{|\Gamma_{K^0}-\Gamma_{\overline{K}^0}|}{(\Gamma_{K^0}+\Gamma_{\overline{K}^0})} = (8\pm8)\times10^{-18}\,. \tag{21}$$

The limit on the K^0–$\overline{K}^0$ mass difference assumes that there is no other source of CPT violation. An upper bound on CPT breaking in $K^0_L\to2\pi$ has been also set through the measured phase difference of the CPV ratios η_{00} and η_{+-}, $\phi_{00}-\phi_{+-}=(0.34\pm0.32)^\circ$, thanks to the small value of $(1-|\eta_{00}/\eta_{+-}|)$ (see the review on CP violation in K^0_L decays).

The measured masses and electric charges of the electron, the proton and their antiparticles provide also strong limits on CPT violation [51–53]:

$$2\,\frac{|m_{e^+}-m_{e^-}|}{m_{e^+}+m_{e^-}} < 8\times10^{-9}\,,\qquad \frac{|q_{e^+}+q_{e^-}|}{e} < 4\times10^{-8}\,,\qquad \left|\frac{q_{\bar p}/m_{\bar p}}{q_p/m_p}\right| - 1 = (0.1\pm6.9)\times10^{-11}\,. \tag{22}$$

Worth mentioning are also the tight constraints derived from the lepton and antilepton magnetic moments [54, 55],

$$2\,\frac{g_{e^+}-g_{e^-}}{g_{e^+}+g_{e^-}} = (-0.5\pm2.1)\times10^{-12}\,,\qquad 2\,\frac{g_{\mu^+}-g_{\mu^-}}{g_{\mu^+}+g_{\mu^-}} = (-0.11\pm0.12)\times10^{-8}\,, \tag{23}$$

those of the proton and antiproton [56],

$$(\mu_p+\mu_{\bar p})/\mu_p = (2\pm4)\times10^{-9}\,, \tag{24}$$

and the recent measurement of the 1S-2S atomic transition in antihydrogen which agrees with the corresponding frequency spectral line in hydrogen at a relative precision of 2×10^{-12} [57].

A violation of CPT in an interacting local quantum field theory would imply that Lorentz symmetry is also violated [58]. Signatures of Lorentz-invariance violation have been searched for with atomic clocks, penning traps, matter and antimatter spectroscopy, colliders and astroparticle experiments, with so far negative results [59]. A compilation of experimental bounds is given in Ref. [60], parametrized through the coefficients of the so-called Standard Model Extension (SME) Lagrangian which contains all possible Lorentz- and CPT-violating operators preserving gauge invariance, renormalizability, locality and observer causality [61].

QUANTUM-NUMBER CONSERVATION LAWS

Conservation laws of several quantum numbers have been empirically established with a very high degree of confidence. They are usually associated with some global phase symmetry. However, while some of them are deeply rooted in basic principles such as gauge invariance (charge conservation; local symmetry implies global symmetry) or Lorentz symmetry (fermion number conservation), others appear to be accidental symmetries of the SM Lagrangian and could be broken by new physics interactions.

In fact, if one only assumes the SM gauge symmetries and particle content, the most general dynamics at energies below the BSM mass scale is described by the SMEFT Lagrangian in Eq. (12). All $d=4$ operators (*i.e.*, the SM) happen to preserve the B and L quantum numbers, but this is no-longer true for the gauge-invariant structures of higher dimensionality. There is only one operator with $d=5$ (up to hermitian conjugation and flavor assignments), and it violates lepton number by two units [62], giving rise to Majorana neutrino masses after the electroweak spontaneous symmetry breaking. With $d=6$, there are five operators that violate B and L [63, 64]. Thus, violations of these quantum numbers can be generically expected, unless there is an explicit symmetry protecting them.

4 Electric charge

The conservation of electric charges is associated with the QED gauge symmetry. The most precise tests are the non-observation of the decays $e\to\nu_e\gamma$ (lifetime larger than 6.6×10^{28} yr [65]) and $n\to p\nu_e\bar\nu_e$ (Br $<8\times10^{-27}$, 68% C.L. [66]). The neutrality of matter can be also interpreted as a test of electric charge conservation. Worth mentioning are the experimental limits on the electric charge of the neutron, $q_n/e=(-0.2\pm0.8)\times10^{-21}$, and on the sum of the proton and electron charges, $|q_p+q_e|/e<1\times10^{-21}$ (68% CL) [67].

The isotropy of the cosmic microwave background has been used to set stringent limits on a possible charge asymmetry of the Universe [68]. Assuming that charge asymmetries produced by different particles are not anticorrelated, this implies upper bounds on the photon ($|q_\gamma|/e<1\times10^{-35}$) and neutrino ($|q_\nu|/e<4\times10^{-35}$) electric charges. A much stronger upper bound on the photon charge ($|q_\gamma|/e<1\times10^{-46}$) has been derived from the non-observation of Aharonov-Bohm phase differences in interferometric experiments with photons that have traversed cosmological distances, under the assumption that both positive and negative charged photons exist [69].

5 Lepton family numbers

In the SM with massless left-handed neutrinos there is a separate conservation number for each lepton family. However, neutrino oscillations show that neutrinos have tiny masses and there are sizable mixings among the different lepton flavors. Compelling evidence from solar, atmospheric, accelerator and reactor neutrino experiments has established a quite solid pattern of neutrino mass differences and mixing angles [15, 16] (see the review on neutrino masses, mixings and oscillations). Nevertheless, flavor mixing among the different charged leptons has never been observed.

If neutrino masses and mixings among the three active neutrinos were the only sources of lepton-flavor violation (LFV), neutrinoless transitions from one charged lepton flavor to another would be heavily suppressed by powers of m_{ν_i} (GIM mechanism), leading to un-observably small rates; for instance [72–77],

$$\mathrm{Br}(\mu\to e\gamma)=\frac{3\alpha}{32\pi}\left|\sum_i U^*_{\mu i}U_{ei}\,\frac{m^2_{\nu_i}-m^2_{\nu_1}}{M_W^2}\right|^2<10^{-54}\,, \tag{25}$$

where U_{ia} are the relevant elements of the PMNS mixing matrix. This contribution is clearly too small to be observed in any realistic experiment, so any experimentally accessible effect would arise from BSM physics with sources of LFV not related to m_{ν_i}. The search for charged LFV (CLFV) remains an area of active interest, which has the potential to probe physics at scales much higher than the TeV.

Among the most sensitive probes are searches for the CLFV decays of the muon, $\mu\to e\gamma$ and $\mu\to3e$, as well as the conversion process $\mu^-+A(N,Z)\to e^-+A(N,Z)$, where $A(N,Z)$ denotes a nucleus with N neutrons and Z protons. Searches for rare τ decays such as $\tau\to\ell\gamma$ ($\ell=e,\mu$) also provide interesting probes of CLFV. A variety of BSM scenarios predict that rates for these CLFV processes could be sufficiently large to be observed in the present or planned searches. To date, no observation has been reported, and the resulting null results place strong constraints on BSM scenarios. For extensive reviews of the experimental and theoretical status and prospects, see Refs. [71, 78, 79].

A detailed set of upper bounds on CLFV branching rations is given in the listings for the muon and tau leptons. Here we emphasize those with the strongest limits:

$$\mathrm{Br}(\mu\to e\gamma)<4.2\times10^{-13}\quad[80],\qquad \mathrm{Br}(\mu\to3e)<1.0\times10^{-12}\quad[81] \tag{26}$$

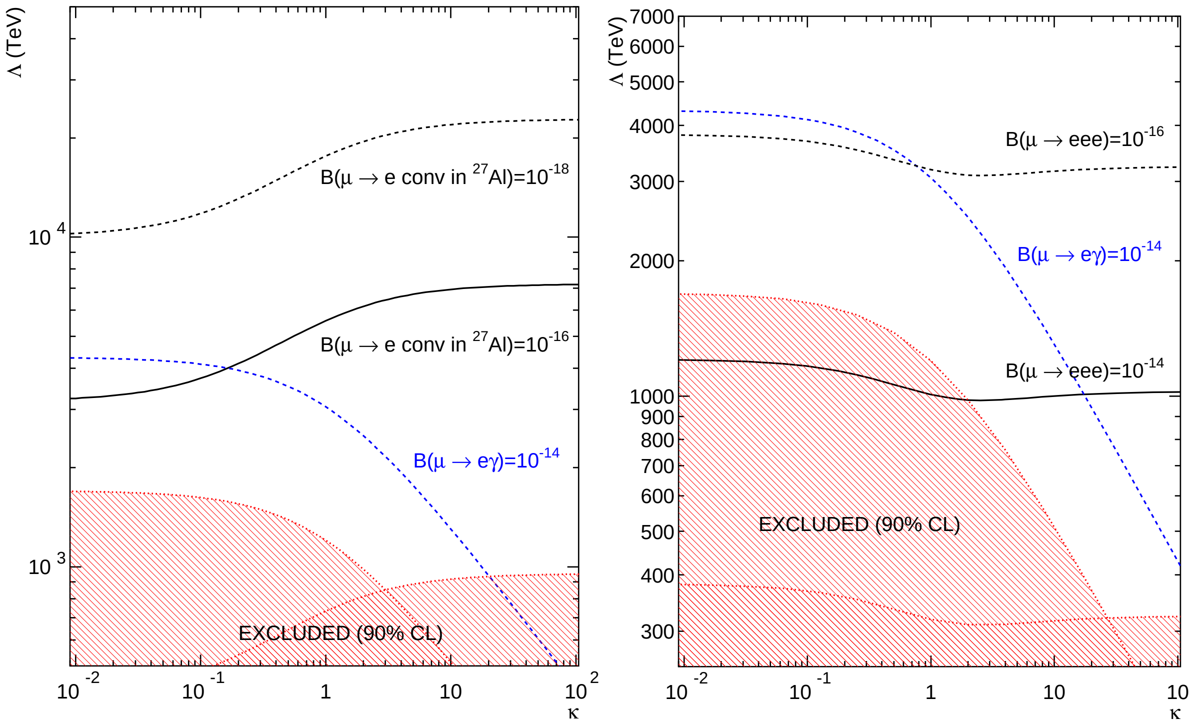

Figure 3: Model-independent CLFV sensitivities based on Eq (31). Left panel shows the comparison of present constraints with prospective future sensitivities for $\mu \to e\gamma$ and $\mu \to e$ conversion. Right panel gives analogous comparison for $\mu \to e\gamma$ and $\mu \to 3e$. Updated by [70] from Ref. [71].

and

$$B_{\mu\to e} \equiv \frac{\Gamma(\mu^- + A(N,Z) \to e^- + A(N,Z)}{\Gamma(\mu^- + A(N,Z) \to \nu + A(N+1,Z-1)} \tag{27}$$

with the best limit so far, $B_{\mu\to e} < 7 \times 10^{-13}$ [82], obtained with gold. Several proposed experiments aim to improve these limits by several orders of magnitude with different atoms.

One may interpret both $\mu \to e\gamma$ and $\mu \to e$ conversion in terms of the amplitudes to emit a real or virtual photon:

$$\begin{aligned}\mathcal{M}_{\mu\to e\gamma^{(*)}} &= eG_\mu \varepsilon^{\alpha *}\bar{e}(p-q)\Big[\left(q^2\gamma_\alpha - \not{q}q_\alpha\right)\left(\tilde{A}_1^R P_R + \tilde{A}_1^L P_L\right)\\ &\quad + im_\mu \sigma_{\alpha\beta}q^\beta\left(\tilde{A}_2^R P_R + \tilde{A}_2^L P_L\right)\Big]\mu(p)\,,\end{aligned} \tag{28}$$

where it is conventional to normalize the amplitude to the Fermi constant. One then has

$$\mathrm{Br}(\mu \to e\gamma) = 48\pi^3\alpha\left(|\tilde{A}_2^R|^2 + |\tilde{A}_2^L|^2\right)\,. \tag{29}$$

For the conversion process, the virtual photon is absorbed by the quarks in the nucleus, yielding an effective four-fermion operator. In general, the exchange of other particles could lead to similar or alternate Lorentz structures, and it is not possible to distinguish between the exchange of a virtual photon or other particle. It is conventional to write the most general four-fermion amplitude, valid for energies below the electroweak scale as (adapted from Ref. [88])

$$\mathcal{M}_{\mu\to e} = G_\mu \sum_{n,a,q} a_{a,q}^{(n)}\,\bar{e}\Gamma^n P_a \mu\,\bar{q}\Gamma_n q\,, \tag{30}$$

where P_a ($a = L, R$) denote the left and right-handed projectors and Γ^n denotes 1, γ_5, γ^μ, $\gamma^\mu\gamma_5$, and $\sigma_{\mu\nu}$. If any of the coefficients $a_{a,q}^{(n)}$ are generated by physics at a scale $\Lambda > v$, then their effects would be encoded in the SMEFT Lagrangian (12). For scenarios in which the leading CLFV operators occur at $d = 6$, the $a_{a,q}^{(n)}$ will scale as $(v/\Lambda)^2$. The corresponding decay and conversion rates will then scale as $(v/\Lambda)^4$. Note that the scalar and time component of the vector interactions are coherent over the nucleus, essentially counting the number of quarks. Consequently, these interactions typically yield the greatest sensitivities to high BSM mass scales.

It is sometimes convenient to compare the relative sensitivities of the decay and conversion processes using the following simplified effective Lagrangian [71]:

$$\begin{aligned}\mathcal{L}_{\text{eff}}^{\text{CLFV}} &= \frac{m_\mu}{(\kappa+1)\Lambda^2}\,\bar{\mu}_R\sigma_{\mu\nu}e_L\,F^{\mu\nu}\\ &\quad + \frac{\kappa}{(\kappa+1)\Lambda^2}\,\bar{\mu}\gamma_\mu e\sum_q \bar{q}\gamma^\mu q + \text{h.c.}\,.\end{aligned} \tag{31}$$

Note that one may replace the second term in Eq. (31) by any one of the other four-fermion interactions given in Eq. (30). An analogous expression applies to the process $\mu \to 3e$ when replacing the sum over quarks by the corresponding electron bilinear. A comparison of the present and prospective sensitivities for various muon CLFV searches in this framework is shown in Figure 3.

Stringent limits have been also set on the LFV decay modes of the τ lepton [89]. As shown in Figure 4, the large τ data samples collected at the B factories have made possible to reach a 10^{-8} sensitivity for many of its leptonic ($\tau \to \ell\gamma$, $\tau \to \ell'\ell^+\ell^-$) and semileptonic ($\tau \to \ell P^0$, $\tau \to \ell V^0$, $\tau \to \ell P^0 P^0$, $\tau \to \ell P^+ P'^-$) neutrinoless LFV decays, and BELLE-II is expected to push these limits beyond the 10^{-9} level [84]. Being a third generation lepton, the τ could be more sensitive to heavier new-physics scales, which makes his LFV decays particularly interesting. Compared to the muon, the τ decay amplitudes could be enhanced by a chirality ratio $(m_\tau/m_\mu)^2 \sim 280$ and/or by lepton-mixing factors such as $|U_{\tau 3}/U_{e3}|^2 \sim 20$, but the exact relation is model dependent. In any case, the τ LFV decays provide a rich data set that is very complementary to the μ bounds. If LFV is finally observed, the correlations between μ and τ data, and among different LFV τ decays will allow to probe the underlying mechanism of lepton flavor breaking.

Interesting limits on LFV are also obtained in meson decays.

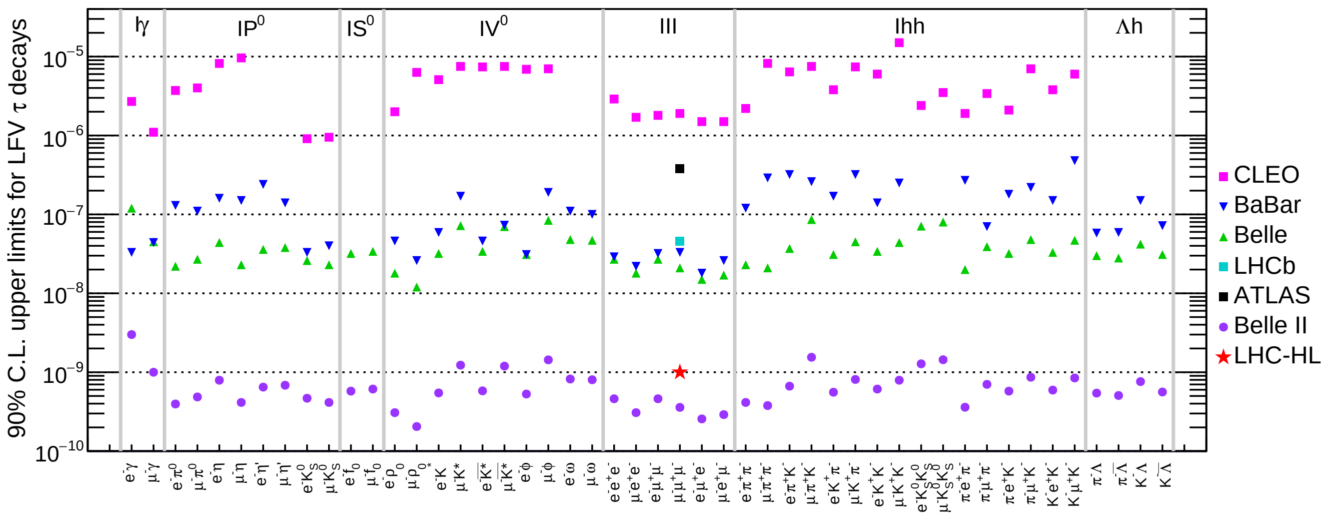

Figure 4: Current experimental limits on neutrinoless LFV τ decays [83]. Also shown are the future projections at Belle-II [84] and at the HL-LHC [85].

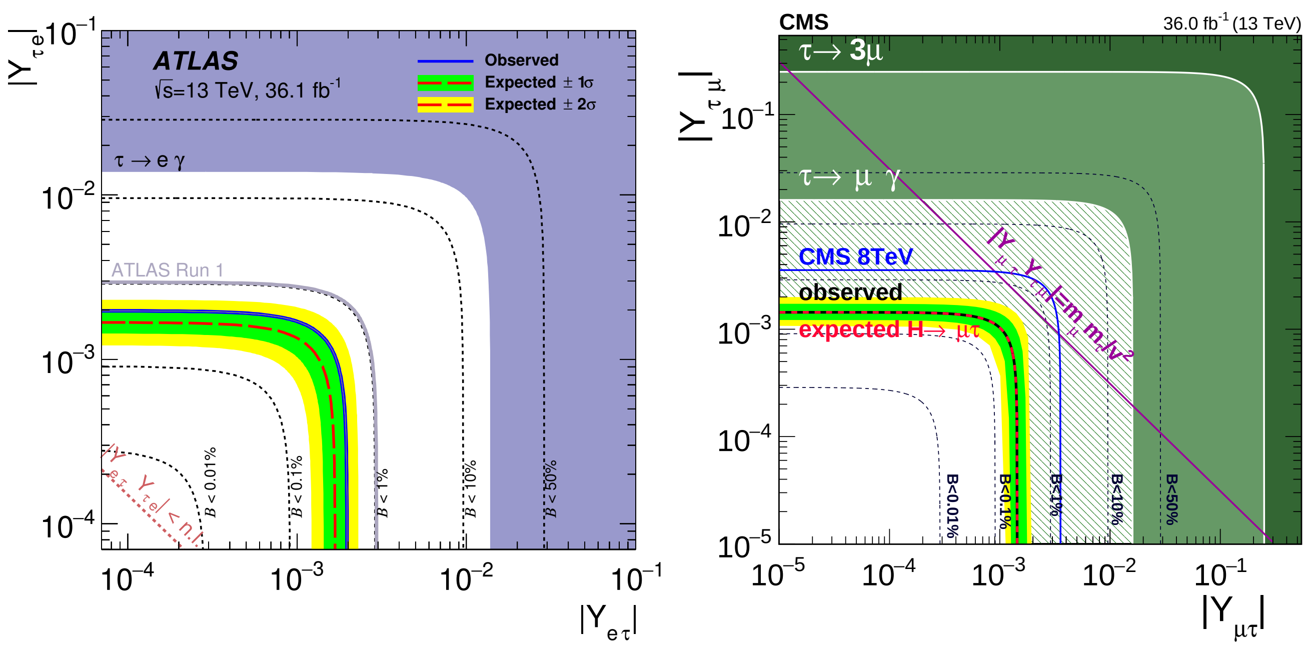

Figure 5: Current limits on the Higgs LFV τ Yukawas from direct $H^0 \to \ell^\pm\tau^\mp$ decays ($\ell = e, \mu$), and indirect constraints from τ decays [86, 87].

The best bounds come from kaon experiments, e.g., $\mathrm{Br}(K_L^0 \to e^\pm\mu^\mp) < 4.7 \times 10^{-12}$ [90], $\mathrm{Br}(K^+ \to \pi^+\mu^+e^-) < 1.3 \times 10^{-11}$ [91]. Quite strong limits have also been set in decays of B and D mesons, the best upper bounds being $\mathrm{Br}(B^0 \to e^\pm\mu^\mp) < 1.0 \times 10^{-9}$ [92] and $\mathrm{Br}(D^0 \to e^\pm\mu^\mp) < 1.3 \times 10^{-8}$ [93].

The LFV decays of the Z boson were probed at LEP at the 10^{-5} to 10^{-6} level. The LHC ATLAS collaboration has put recently a stronger bound on the $Z \to e^\pm\mu^\mp$ decay mode [94]. Currently, the best (95% C.L.) limits are [94–96]:

$$\mathrm{Br}(Z \to e^\pm\mu^\mp) < 7.5 \times 10^{-7}\,, \qquad \mathrm{Br}(Z \to e^\pm\tau^\mp) < 9.8 \times 10^{-6}\,, \qquad \mathrm{Br}(Z \to \mu^\pm\tau^\mp) < 1.2 \times 10^{-5}\,. \tag{32}$$

LHC is now starting to test LFV in Higgs decays, within the available statistics. From the current (95% C.L.) experimental upper bounds [86, 87, 97],

$$\mathrm{Br}(H^0 \to e^\pm\mu^\mp) < 6.1 \times 10^{-5}\,, \qquad \mathrm{Br}(H^0 \to e^\pm\tau^\mp) < 0.47\%\,, \qquad \mathrm{Br}(H^0 \to \mu^\pm\tau^\mp) < 0.25\%\,, \tag{33}$$

one can derive direct limits on the LFV Yukawa couplings of the Higgs boson,

$$\mathcal{L}_Y = -H^0 \sum_{i \neq j} \left(Y_{\ell_i\ell_j}\, \bar{\ell}_L^i \ell_R^j + \mathrm{h.c.} \right)\,. \tag{34}$$

From $H^0 \to e^\pm\mu^\mp$, one obtains $\sqrt{Y_{\mu e}^2 + Y_{e\mu}^2} < 2.2 \times 10^{-4}$, which is not yet competitive with the indirect limit set by $\mu \to e\gamma$ through a (one-loop) virtual Higgs exchange:

$$\sqrt{Y_{\mu e}^2 + Y_{e\mu}^2} < 3.6 \times 10^{-6}\,. \tag{35}$$

However, the LHC data provides at present the strongest bounds on the LFV τ Yukawas [86, 87]:

$$\sqrt{Y_{e\tau}^2 + Y_{\tau e}^2} < 2.0 \times 10^{-3} , \qquad \sqrt{Y_{\mu\tau}^2 + Y_{\tau\mu}^2} < 1.4 \times 10^{-3} . \tag{36}$$

Figure 5 compares the Higgs exclusion limits on the τ Yukawas with the current indirect constraints from LFV τ decays.

6 Baryon and Lepton Number

The transitions discussed in the previous section preserve the total lepton number $L = L_e + L_\mu + L_\tau$. In the SM, conservation of $B - L$ is an accidental symmetry of the Lagrangian. At the classical level, $B + L$ is also conserved, though it is violated at the loop level by the anomaly. The latter is a topological effect that is highly suppressed at zero temperature and, moreover, does not contribute to the processes discussed in the review. Going beyond renormalizable interactions, there exists a tower of operators in the SMEFT Lagrangian (12), containing only SM fields, that break one or both of these symmetries. We briefly review these possibilities in turn.

Lepton Number

The lowest-dimension operator containing only SM fields that breaks baryon or lepton number is the $d = 5$, lepton-number-violating (LNV) 'Weinberg' neutrino-mass operator [62]:

$$\mathcal{L}^{\mathrm{LNV}} = \frac{y}{\Lambda} \bar{L}^C H H^T L . \tag{37}$$

When the neutral component of the Higgs field obtains its vacuum expectation value, this $\Delta L = 2$ interaction yields a Majorana mass for the light, active neutrinos. The most comprehensive approach for probing this effect is the search for neutrinoless double-beta decay ($0\nu\beta\beta$) of atomic nuclei, $(Z, A) \to (Z+2, A) + e^- + e^-$ [98, 99] (see the review on neutrinoless double-β decay). The detection of a non-zero $0\nu\beta\beta$ signal could represent a spectacular evidence of Majorana neutrinos. The current best limit, $\tau_{1/2} > 1.07 \times 10^{26}$ yr, was obtained by the KamLAND-Zen experiment with ^{136}Xe [100].

Theoretically, the interaction (37) can arise from BSM interactions in the well-known see-saw mechanism for neutrino mass (for a review, see [101]). In this context, the conventional choice for the scale Λ is of order the GUT scale, yielding light neutrino masses of order eV and below when the couplings y are of order the charged elementary fermion Yukawa couplings. BSM theories may also give rise to LNV observables in other contexts. In these scenarios, if the LNV scale is of order 1 TeV, one may observe signatures of LNV not only in $0\nu\beta\beta$ but also in collider searches for final states containing same sign dileptons. Searches for same sign dileptons plus a di-jet pair at the LHC have placed constraints on TeV-scale LNV [102, 103] that in some cases complement those obtained from $0\nu\beta\beta$.

Stringent constraints on violations of L have been also set in $\mu^- \to e^+$ conversion in muonic atoms, the best limit being $\sigma(\mu^- \mathrm{Ti} \to e^+ \mathrm{Ca})/\sigma(\mu^- \mathrm{Ti} \to \mathrm{all}) < 3.6 \times 10^{-11}$ [104], and at the flavor factories through L-violating decays of the τ lepton and K, D and B mesons. Some representative examples are $\mathrm{Br}(\tau^- \to e^+ \pi^- \pi^-) < 2.0 \times 10^{-8}$ [105], $\mathrm{Br}(K^+ \to \pi^- \mu^+ \mu^+) < 4.2 \times 10^{-11}$ [106], $\mathrm{Br}(D^+ \to \pi^- \mu^+ \mu^+) < 2.2 \times 10^{-8}$ [107] and $\mathrm{Br}(B^+ \to K^- e^+ e^+) < 3.0 \times 10^{-8}$ [108]. All these $|\Delta L| = 2$ processes could be mediated by a massive Majorana neutrino. They provide useful bounds on the effective Majorana neutrino mass matrix $m_{\ell\ell'} \sim \sum_i U_{\ell i} U_{\ell' i} m_{\nu_i}$ [109], although not as strong as the $0\nu\beta\beta$ constraint on m_{ee}.

Baryon Number

Grand Unified Theories (GUTs) combine leptons and quarks in the same symmetry multiplets and, therefore, predict the violation of the baryon and lepton quantum numbers. Many experiments have searched for B-violating transitions, but no positive signal has been identified so far. Proton decay would be the most relevant violation of B, as it would imply the unstability of matter. The current lower bound on the proton lifetime is 3.6×10^{29} yr [110]. Stronger limits have been set for particular decay modes, such as $\tau(p \to e^+ \pi^0) > 1.6 \times 10^{34}$ yr [111]. For a discussion of proton decay in the context of GUTs, see the review on Grand Unified Theories.

Another spectacular signal would be neutron-antineutron oscillations. Searches have been performed for quasi-free n–$\bar{n}$ oscillations and for $n\bar{n}$ annihilation products in a nucleus. The latter would arise when the $\bar{n}$ produced through oscillations annihilates with another neutron in the nuclear medium. The corresponding best limits, expressed in terms of the free and bound oscillation times, $\tau_{n\bar{n}}$ and τ_m, respectively, are:

$$\tau_{n\bar{n}} > 0.86 \times 10^8 \text{ s} \quad [112], \tag{38a}$$

$$\tau_m > 1.9 \times 10^{32} \text{ yr} \quad [113]. \tag{38b}$$

From the latter, one may infer a bound $\tau_{n\bar{n}} > 2.7 \times 10^8$ s, as discussed below. See Ref. [114] for a recent review.

The theoretical interpretation of these bounds starts with an assumed, effective Hamiltonian for the free (anti-)neutron, $\mathcal{H}_{\mathrm{eff}}$ that contains a B-violating part, yielding matrix elements

$$\langle n|\mathcal{H}_{\mathrm{eff}}|n\rangle = \langle \bar{n}|\mathcal{H}_{\mathrm{eff}}|\bar{n}\rangle = m - i\frac{\lambda}{2} , \tag{39a}$$

$$\langle n|\mathcal{H}_{\mathrm{eff}}|\bar{n}\rangle = \langle \bar{n}|\mathcal{H}_{\mathrm{eff}}|n\rangle \equiv \delta m , \tag{39b}$$

where CPT is assumed to be conserved, the neutron lifetime $\tau_n = 1/\lambda$ and $\tau_{n\bar{n}} = 1/|\delta m|$. The rate for a neutron to oscillate into an antineutron after a time t is given by

$$\mathcal{P}_{n\bar{n}}(t) = \sin^2\left(\frac{t}{\tau_{n\bar{n}}}\right) e^{-\lambda t} . \tag{40}$$

For $t << \tau_n << \tau_{n\bar{n}}$, one has

$$\mathcal{P}_{n\bar{n}}(t) \to (t/\tau_{n\bar{n}})^2 . \tag{41}$$

In realistic experiments, there exist effects, such as background magnetic fields, that split the energies of the neutron and antineutron. One must ensure that the observation time is sufficiently short so that these effects do not overwhelm the small B-violating term δm and that Eq. (40) applies.

In nuclei, the interactions of neutrons and antineutrons with the surrounding medium are sufficiently distinct that one must take the corresponding matter potentials into account. In particular, the matrix elements in Eq. (39a) become

$$\langle n|\mathcal{H}_{\mathrm{eff}}|n\rangle = m + V_n , \qquad \langle \bar{n}|\mathcal{H}_{\mathrm{eff}}|\bar{n}\rangle = m + V_{\bar{n}} , \tag{42}$$

with V_n being essentially real ($V_n \equiv V_{nR}$) and $V_{\bar{n}} = V_{\bar{n}R} - iV_{\bar{n}I}$. The imaginary part $V_{\bar{n}I}$ characterizes the annihilation of the antineutron with bound nucleons into secondary hadrons. The rate for a bound neutron to disappear is given by

$$\Gamma_m = \frac{2(\delta m)^2 |V_{\bar{n}I}|}{(V_{nR} - V_{\bar{n}R})^2 + V_{\bar{n}I}^2} \equiv \left(R\, \tau_{n\bar{n}}^2\right)^{-1} . \tag{43}$$

For the nuclei of experimental interest, nuclear theory computations yield $R \sim 10^{23} s^{-1}$. Null results of bound n-$\bar{n}$ oscillation searches thus allow one to infer a bound on $\tau_{n\bar{n}}$ via Eq. (43).

From an elementary particle standpoint, n-$\bar{n}$ oscillations involve the conversion of three quarks into three antiquarks (and vice-versa). The lowest-dimension operators mediating such process arise at dimension nine in the SMEFT:

$$\mathcal{L}_{n\text{-}\bar{n}} = \frac{1}{\Lambda^5} \sum_j \alpha_j^{(9)}\, \mathcal{O}_j^{\mathrm{BNV}} . \tag{44}$$

Consequently, one expects

$$\delta m \sim \alpha_j^{(9)} \frac{\Lambda_{\mathrm{HAD}}^6}{\Lambda^5} , \tag{45}$$

where Λ_{HAD} is a hadronic scale set by the n-$\bar{n}$ matrix elements in Eq. (39b). Taking Λ_{HAD} to be of order the QCD scale and using the present bounds on $\tau_{n\bar{n}}$ yields a lower bound on the B-violating mass scale of ~ 100 TeV.

The search for B-violating decays of short-lived particles such as Z bosons, τ leptons and B mesons provides also relevant constraints. The best limits are $\mathrm{Br}(Z \to pe, p\mu) < 1.8 \times 10^{-6}$ (95% C.L.) [115], $\mathrm{Br}(\tau^- \to \Lambda\pi^-) < 7.2 \times 10^{-8}$ [116] and $\mathrm{Br}(B^+ \to \Lambda e^+) < 3.2 \times 10^{-8}$ [117].

7 Quark flavors

While strong and electromagnetic forces preserve the quark flavor, the charged-current weak interactions generate transitions among the different quark species (see the review on the CKM quark-mixing matrix). Since the SM flavor-changing mechanism is associated with the $W^{\pm}$ fermionic vertices, the tree-level transitions satisfy a $\Delta F = \Delta Q$ rule where ΔQ denotes the change in charge of the relevant hadrons. Remember that the flavor quantum number F is defined to be $+1$ for positively charged quarks ($F = U, C, T$) and -1 for quarks with negative charges ($F = D, S, B$). The strongest tests on this conservation law have been obtained in kaon decays such as $\mathrm{Br}(K^+ \to \pi^+\pi^+e^-\bar{\nu}_e) < 1.3 \times 10^{-8}$ [118], and $(\mathrm{Re}\,x, \mathrm{Im}\,x) = (-0.002 \pm 0.006, 0.0012 \pm 0.0021)$ [119, 120] where $x \equiv \mathcal{M}(\overline{K}^0 \to \pi^-\ell^+\nu)/\mathcal{M}(K^0 \to \pi^-\ell^+\nu)$.

The $\Delta F = \Delta Q$ rule can be violated through quantum loop contributions giving rise to flavor-changing neutral-current transitions (FCNCs). Owing to the GIM mechanism, processes of this type are very suppressed in the SM, which makes them a superb tool in the search for new physics associated with the flavor dynamics. Within the SM itself, these transitions are also sensitive to the heavy-quark mass scales and have played a crucial role identifying the size of the charm (K^0–$\overline{K}^0$ mixing) and top (B^0–$\overline{B}^0$ mixing) masses before the discovery of those quarks. In addition to the well-established $\Delta F = 2$ mixings in neutral K and B mesons, $\Delta M_{K^0} \equiv M_{K^0_L} - M_{K^0_S} = (0.5293 \pm 0.0009) \times 10^{10}\ \mathrm{s}^{-1}$, $\Delta M_{B^0} \equiv M_{B^0_H} - M_{B^0_L} = (0.5065 \pm 0.0019) \times 10^{12}\ \mathrm{s}^{-1}$ and $\Delta M_{B^0_s} \equiv M_{B^0_{sH}} - M_{B^0_{sL}} = (17.757 \pm 0.0021) \times 10^{12}\ \mathrm{s}^{-1}$, there is now strong evidence for the mixing of the D^0 meson and its antiparticle [121],

$$x_D \equiv (M_{D^0_H} - M_{D^0_L})/\Gamma_{D^0} = (3.9\,^{+\,1.1}_{-\,1.2}) \times 10^{-3}\,, \qquad (46)$$

showing that there is a nonzero mass difference between the two neutral charm-meson eigenstates, of the expected size. The SM prediction for x_D is dominated by long-distance physics, because it involves virtual loops with down-type light quarks, and has unfortunately quite large uncertainties [122].

The FCNC kaon decays into lepton-antilepton pairs put stringent constraints on new flavor-changing interactions. The measured $K^0_L \to \mu^+\mu^-$ rate, $\mathrm{Br}(K^0_L \to \mu^+\mu^-) = (6.84 \pm 0.11) \times 10^{-9}$, is completely dominated by the known 2γ absorptive contribution, leaving very little room for new-physics, and $\mathrm{Br}(K^0_L \to e^+e^-) = (9^{+6}_{-4}) \times 10^{-12}$ [123] (the tiniest branching ratio ever measured) also agrees with the SM expectation [124]. The experimental K^0_S upper bounds on the electron, $\mathrm{Br}(K^0_S \to e^+e^-) < 9 \times 10^{-9}$ [125], and muon, $\mathrm{Br}(K^0_S \to \mu^+\mu^-) < 2.1 \times 10^{-10}$ [126], modes are still five and two orders of magnitude, respectively, larger than their SM predictions [124]. Another very clean test of FCNCs will be soon provided by the decay $K^+ \to \pi^+\nu\bar{\nu}$. With a predicted SM branching fraction of $(7.8 \pm 0.8) \times 10^{-11}$ [127], the CERN NA62 experiment is aiming to collect around one hundred events. Even more interesting is the CP-violating neutral mode $K^0_L \to \pi^0\nu\bar{\nu}$, expected at a rate of $(2.4 \pm 0.4) \times 10^{-11}$ [127] that is still far away from the current upper bound of 3.0×10^{-9} [128]. The KOTO experiment at KEK is expected to substantially increase the sensitivity to this mode.

The strongest bound on FCNC transitions in charm decays is $\mathrm{Br}(D^0 \to \mu^+\mu^-) < 6.2 \times 10^{-9}$ [129], while in B decays the LHC experiments have recently reached the SM sensitivity: $\mathrm{Br}(B^0_d \to \mu^+\mu^-) = (0.14\,^{+0.16}_{-0.14}) \times 10^{-9}$ and $\mathrm{Br}(B^0_s \to \mu^+\mu^-) = (3.0 \pm 0.4) \times 10^{-9}$. At present, there is a lot of interest on the decays $B \to K^{(*)}\ell^+\ell^-$ where sizable discrepancies between the measured data and the SM predictions have been reported [130]. In particular, the LHCb experiment has found the ratios of produced muons versus electrons to be around 2.5σ below the SM predictions, both in $B \to K^*\ell^+\ell^-$ [131] and in $B^+ \to K^+\ell^+\ell^-$ [132] (for dilepton invariant-masses squared in the range $q^2 \le 6\ \mathrm{GeV}^2$), suggesting a significant violation of lepton universality. The current Belle-II measurements of these ratios [133, 134] are consistent with the SM, but they are also compatible with the LHCb results. Future analyses from LHCb and Belle-II are expected to clarify the situation.

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when S > 1, which often indicates that the measurements are inconsistent. When S > 1.25, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

[a] Forbidden by angular momentum conservation.

[b] C parity forbids this to occur as a single-photon process.

[c] See the Particle Listings for the (complicated) definition of this quantity.

[d] Time-reversal invariance requires this to be 0° or 180°.

[e] This coefficient is zero if time invariance is not violated.

[f] Allowed by higher-order electroweak interactions.

[g] Violates CP in leading order. Test of direct CP violation since the indirect CP-violating and CP-conserving contributions are expected to be suppressed.

[h] In the 2010 *Review*, the values for these quantities were given using a measure of the asymmetry that was inconsistent with the usual definition.

[i] $\mathrm{Re}(\epsilon'/\epsilon) = \epsilon'/\epsilon$ to a very good approximation provided the phases satisfy CPT invariance.

[j] This mode includes gammas from inner bremsstrahlung but not the direct emission mode $K_L^0 \to \pi^+\pi^-\gamma(\mathrm{DE})$.

[k] Neglecting photon channels. See, *e.g.*, A. Pais and S.B. Treiman, Phys. Rev. **D12**, 2744 (1975).

[l] Derived from measured values of ϕ_{+-}, ϕ_{00}, $|\eta|$, $|m_{K_L^0} - m_{K_S^0}|$, and $\tau_{K_S^0}$, as described in the introduction to "Tests of Conservation Laws."

[n] The $|m_p - m_{\overline{p}}|/m_p$ and $|q_p + q_{\overline{p}}|/e$ are not independent, and both use the more precise measurement of $|q_{\overline{p}}/m_{\overline{p}}|/(q_p/m_p)$.

[o] The value is for the sum of the charge states or particle/antiparticle states indicated.

[p] A test of additive vs. multiplicative lepton family number conservation.

[q] Derived from an analysis of neutrino-oscillation experiments.

[r] This limit is for either D^0 or $\overline{D}^0$ to pe^-.

[s] This limit is for either D^0 or $\overline{D}^0$ to $\overline{p}e^+$.

[t] The first limit is for $p \to$ anything or "disappearance" modes of a bound proton. The second entry, a rough range of limits, assumes the dominant decay modes are among those investigated. For antiprotons the best limit, inferred from the observation of cosmic ray $\overline{p}$'s is $\tau_{\overline{p}} > 10^7$ yr, the cosmic-ray storage time, but this limit depends on a number of assumptions. The best direct observation of stored antiprotons gives $\tau_{\overline{p}}/\mathrm{B}(\overline{p} \to e^-\gamma) > 7 \times 10^5$ yr.

[u] There is some controversy about whether nuclear physics and model dependence complicate the analysis for bound neutrons (from which the

best limit comes). The first limit here is from reactor experiments with free neutrons.

[*v*] This is the best limit for the mode $e^- \to \nu\gamma$. The best limit for Nuclear de-excitation experiments is 6.4×10^{24} yr.

[*x*] The limit is from neutrality-of-matter experiments; it assumes $q_n = q_p + q_e$. See also the charge of the neutron.

[*y*] See the K^0_S Particle Listings for the energy limits used in this measurement.

[*z*] See the K^0_L Particle Listings for the energy limits used in this measurement.

[*aa*] An ℓ indicates an e or a μ mode, not a sum over these modes.

[*bb*] Here S and P are the hypothetical scalar and pseudoscalar particles with masses of 2.5 GeV/c^2 and 214.3 MeV/c^2, respectively.

[*cc*] This limit is for $\Gamma(t \to Zq)/\Gamma(t \to Wb)$.

1. Physical Constants (a major revision)

Table 1.1. Revised 2019 by C.G. Wohl (LBNL). Reviewed by P.J. Mohr and D.B. Newell (NIST). Mainly from "CODATA Recommended Values of the Fundamental Physical Constants: 2018," E. Tiesinga, D.B. Newell, P.J. Mohr, and B.N. Taylor, NIST SP961 (May 2019). The electron charge magnitude e, and the Planck, Boltzmann, and Avogadro constants h, k, and N_A, now join c as having defined values; the free-space permittivity and permeability constants ϵ_0 and μ_0 are no longer exact. These changes affect practically everything else in the Table. Figures in parentheses after the values are the 1-standard-deviation uncertainties in the last digits; the fractional uncertainties in parts per 10^9 (ppb) are in the last column. The full 2018 CODATA Committee on Data for Science and Technology set of constants are found at `https://physics.nist.gov/constants`. The last set of constants (beginning with the Fermi coupling constant) comes from the Particle Data Group. See also "The International System of Units (SI)," 9th ed. (2019) of the International Bureau of Weights and Measures (BIPM), `https://www.bipm.org/utils/common/pdf/si-brochure/SI-Brochure-9-EN.pdf`.

$^\sharp$ CODATA recommends that the unit be J/Hz to stress that in $h = E/\nu$ the frequency ν is in cycles/sec (Hz), not radians/sec.

* These are calculated from exact values and are exact to the number of places given (*i.e.* no rounding).

** The molar mass of ^{12}C is 11.999 999 9958(36) g.

† At $Q^2 = 0$. At $Q^2 \approx m_W^2$ the value is $\sim 1/128$.

‡ Absolute laboratory measurements of G_N have been made only on scales of about 1 cm to 1 m.

‡‡ See the discussion in Sec. 10, "Electroweak model and constraints on new physics."

†† The corresponding $\sin^2\theta$ for the effective angle is 0.23153(4).

2. Astrophysical Constants and Parameters

Table 2.1: Revised August 2019 by D.E. Groom (LBNL) and D. Scott (U. of British Columbia). The figures in parentheses after some values give the 1-σ uncertainties in the last digit(s). Physical constants are from Ref. [1]. While every effort has been made to obtain the most accurate current values of the listed quantities, the table does not represent a critical review or adjustment of the constants, and is not intended as a primary reference. The values and uncertainties for the cosmological parameters depend on the exact data sets, priors, and basis parameters used in the fit. Many of the derived parameters reported in this table have non-Gaussian likelihoods. Parameters may be highly correlated, so care must be taken in propagating errors. Unless otherwise specified, cosmological parameters are derived from a 6-parameter ΛCDM cosmology fit to *Planck* cosmic microwave background 2018 temperature (TT) + polarization (TE,EE+lowE) + lensing data [2]. For more information see Ref. [3] and the original papers.

4. Periodic Table of the Elements

Table 4.1. Revised June 2019 by D.E. Groom (LBNL). The atomic number (top left) is the number of protons in the nucleus. The atomic masses (bottom) of stable elements are weighted by isotopic abundances in the Earth's surface. Atomic masses are relative to the mass of ^{12}C, defined to be exactly 12 unified atomic mass units (u) (1 u ≈ 1 g/mole). The exceptions are Th, Pa, and U, which have no stable isotopes but do have characteristic terrestrial compositions. Relative isotopic abundances often vary considerably, both in natural and commercial samples; this is reflected in the number of significant figures given for the mass. Masses may be found at `https://www.nist.gov/pml/atomic-weights-and-isotopic-compositions-relative-atomic-masses`. If there is no stable isotope, the atomic mass of the most stable isotope known as of June 2019 is given in parentheses.

IUPAC announced verification of the discoveries of elements 113, 115, 117, and 118 in December 2015. The names were approved November 2016. The 7th period of the periodic table is now complete.

5. Electronic Structure of the Elements

Table 5.1. Reviewed 2011 by J.E. Sansonetti (NIST). The electronic configurations and the ionization energies are from the NIST database, “Ground Levels and Ionization Energies for the Neutral Atoms,” W.C. Martin, A. Musgrove, S. Kotochigova, and J.E. Sansonetti, `http://www.nist.gov/pml/data/ion_energy.cfm`. The electron configuration for, say, iron indicates an argon electronic core (see argon) plus six $3d$ electrons and two $4s$ electrons.

	Element		Electron configuration ($3d^5$ = five $3d$ electrons, *etc.*)		Ground state $^{2S+1}L_J$	Ionization energy (eV)
1	H	Hydrogen	$1s$		$^2S_{1/2}$	13.5984
2	He	Helium	$1s^2$		$^1S_0$	24.5874
3	Li	Lithium	(He) $2s$		$^2S_{1/2}$	5.3917
4	Be	Beryllium	(He) $2s^2$		$^1S_0$	9.3227
5	B	Boron	(He) $2s^2$ $2p$		$^2P_{1/2}$	8.2980
6	C	Carbon	(He) $2s^2$ $2p^2$		$^3P_0$	11.2603
7	N	Nitrogen	(He) $2s^2$ $2p^3$		$^4S_{3/2}$	14.5341
8	O	Oxygen	(He) $2s^2$ $2p^4$		$^3P_2$	13.6181
9	F	Fluorine	(He) $2s^2$ $2p^5$		$^2P_{3/2}$	17.4228
10	Ne	Neon	(He) $2s^2$ $2p^6$		$^1S_0$	21.5645
11	Na	Sodium	(Ne) $3s$		$^2S_{1/2}$	5.1391

6. Atomic and Nuclear Properties of Materials

Table 6.1 Abridged from `pdg.lbl.gov/AtomicNuclearProperties` by D.E. Groom (2017). See web pages for more detail about entries in this table and for several hundred others. Parentheses in the dE/dx and density columns indicate gases at 20° C and 1 atm. Boiling points are at 1 atm. Refractive indices n are evaluated at the sodium D line blend (589.2 nm); values ≫1 in brackets indicate $(n-1)\times10^6$ for gases at 0° C and 1 atm.

Material	Z	A	$\langle Z/A\rangle$	Nucl.coll. length λ_T {g cm^{-2}}	Nucl.inter. length λ_I {g cm^{-2}}	Rad.len. X_0 {g cm^{-2}}	$dE/dx\vert_{\rm min}$ { MeV g^{-1}cm^2}	Density {g cm^{-3}} ({g ℓ^{-1}})	Melting point (K)	Boiling point (K)	Refract. index @ Na D

7.1. Impedances (SI units)

ρ = resistivity at room temperature in $10^{-8}\,\Omega$ m:
~ 1.7 for Cu ~ 5.5 for W
~ 2.4 for Au ~ 73 for SS 304
~ 2.8 for Al ~ 100 for Nichrome
(Al alloys may have double the Al value.)

For alternating currents, instantaneous current I, voltage V, angular frequency ω:

$$V = V_0\, e^{j\omega t} = ZI\ . \tag{7.1}$$

Impedance of self-inductance L: $Z = j\omega L$.

Impedance of capacitance C: $Z = 1/j\omega C$.

Impedance of free space: $Z = \sqrt{\mu_0/\epsilon_0} = 376.7\ \Omega$.

High-frequency surface impedance of a good conductor:

$$Z = \frac{(1+j)\,\rho}{\delta}\ , \quad \text{where } \delta = \text{skin depth}\ ; \tag{7.2}$$

$$\delta = \sqrt{\frac{\rho}{\pi\nu\mu}} \approx \frac{6.6\text{ cm}}{\sqrt{\nu\,(\text{Hz})}} \quad \text{for Cu}\ . \tag{7.3}$$

7.2. Capacitors, inductors, and transmission Lines

The capacitance between two parallel plates of area A spaced by the distance d and enclosing a medium with the dielectric constant ε is

$$C = K\varepsilon A/d\,, \tag{7.4}$$

where the correction factor K depends on the extent of the fringing field. If the dielectric fills the capacitor volume without extending beyond the electrodes. the correction factor $K \approx 0.8$ for capacitors of typical geometry.

The inductance at high frequencies of a straight wire whose length ℓ is much greater than the wire diameter d is

$$L \approx 2.0 \left[\frac{\text{nH}}{\text{cm}}\right] \cdot \ell \left(\ln\left(\frac{4\ell}{d}\right) - 1\right)\ . \tag{7.5}$$

For very short wires, representative of vias in a printed circuit board, the inductance is

$$L(\text{in nH}) \approx \ell/d\,. \tag{7.6}$$

A transmission line is a pair of conductors with inductance L and capacitance C. The characteristic impedance $Z = \sqrt{L/C}$ and the phase velocity $v_p = 1/\sqrt{LC} = 1/\sqrt{\mu\varepsilon}$, which decreases with the inverse square root of the dielectric constant of the medium. Typical coaxial and ribbon cables have a propagation delay of about 5 ns/cm.

The impedance of a coaxial cable with outer diameter D and inner diameter d is

$$Z = 60\,\Omega \cdot \frac{1}{\sqrt{\varepsilon_r}} \ln\frac{D}{d}\,, \tag{7.7}$$

where the relative dielectric constant $\varepsilon_r = \varepsilon/\varepsilon_0$. A pair of parallel wires of diameter d and spacing $a > 2.5\,d$ has the impedance

$$Z = 120\,\Omega \cdot \frac{1}{\sqrt{\varepsilon_r}} \ln\frac{2a}{d}\,. \tag{7.8}$$

This yields the impedance of a wire at a spacing h above a ground plane,

$$Z = 60\,\Omega \cdot \frac{1}{\sqrt{\varepsilon_r}} \ln\frac{4h}{d}\,. \tag{7.9}$$

A common configuration utilizes a thin rectangular conductor above a ground plane with an intermediate dielectric (microstrip). Detailed calculations for this and other transmission line configurations are given by Gunston.*

* M.A.R. Gunston. Microwave Transmission Line Data, Noble Publishing Corp., Atlanta (1997) ISBN 1-884932-57-6, TK6565.T73G85.

7.3. Synchrotron radiation (CGS units)

For a particle of charge e, velocity $v = \beta c$, and energy $E = \gamma mc^2$, traveling in a circular orbit of radius R, the classical energy loss per revolution δE is

$$\delta E = \frac{4\pi}{3}\,\frac{e^2}{R}\,\beta^3\,\gamma^4\ . \tag{7.10}$$

For high-energy electrons or positrons ($\beta \approx 1$), this becomes

$$\delta E\ (\text{in MeV}) \approx 0.0885\ [E(\text{in GeV})]^4/R(\text{in m})\ . \tag{7.11}$$

For $\gamma \gg 1$, the energy radiated per revolution into the photon energy interval $d(\hbar\omega)$ is

$$dI = \frac{8\pi}{9}\alpha\,\gamma\ F(\omega/\omega_c)\ d(\hbar\omega)\ , \tag{7.12}$$

where $\alpha = e^2/\hbar c$ is the fine-structure constant and

$$\omega_c = \frac{3\gamma^3 c}{2R} \tag{7.13}$$

is the critical frequency. The normalized function $F(y)$ is

$$F(y) = \frac{9}{8\pi}\sqrt{3}\ y \int_y^\infty K_{5/3}\,(x)\ \ dx\ , \tag{7.14}$$

where $K_{5/3}\,(x)$ is a modified Bessel function of the third kind. For electrons or positrons,

$$\hbar\omega_c\,(\text{in keV}) \approx 2.22\ [E(\text{in GeV})]^3/R(\text{in m})\ . \tag{7.15}$$

Fig. 7.1 shows $F(y)$ over the important range of y.

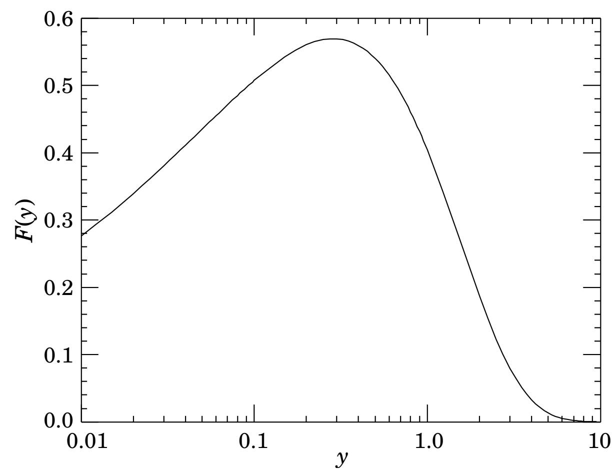

Figure 7.1: The normalized synchrotron radiation spectrum $F(y)$.

For $\gamma \gg 1$ and $\omega \ll \omega_c$,

$$\frac{dI}{d(\hbar\omega)} \approx 3.3\alpha\,(\omega R/c)^{1/3}\ , \tag{7.16}$$

whereas for

$$\gamma \gg 1 \text{ and } \omega \gtrsim 3\omega_c\ ,$$

$$\frac{dI}{d(\hbar\omega)} \approx \sqrt{\frac{3\pi}{2}}\,\alpha\,\gamma\left(\frac{\omega}{\omega_c}\right)^{1/2} e^{-\omega/\omega_c}\left[1 + \frac{55}{72}\frac{\omega_c}{\omega} + \ldots\right]\ . \tag{7.17}$$

The radiation is confined to angles $\lesssim 1/\gamma$ relative to the instantaneous direction of motion. For $\gamma \gg 1$, where Eq. (7.12) applies, the mean number of photons emitted per revolution is

$$N_\gamma = \frac{5\pi}{\sqrt{3}}\alpha\gamma\ , \tag{7.18}$$

and the mean energy per photon is

$$\langle\hbar\omega\rangle = \frac{8}{15\sqrt{3}}\hbar\omega_c\ . \tag{7.19}$$

When $\langle\hbar\omega\rangle \gtrsim \mathrm{O}(E)$, quantum corrections are important.

See J.D. Jackson, *Classical Electrodynamics*, 3rd edition (John Wiley & Sons, New York, 1998) for more formulae and details. (Note that earlier editions had ω_c twice as large as Eq. (7.13).

8. Naming Scheme for Hadrons

Revised August 2019 by V. Burkert (Jefferson Lab), S. Eidelman (Budker Inst., Novosibirsk; Novosibirsk U.), C. Hanhart (Jülich), E. Klempt (Bonn U.), R.E. Mitchell (Indiana U.), U. Thoma (Bonn U.), L. Tiator (KPH, JGU Mainz) and R.L. Workman (George Washington U.).

In the 1986 edition [1], the Particle Data Group extended and systematized the naming scheme for mesons and baryons. The extensions were necessary in order to name the new particles containing c or b quarks that were rapidly being discovered. With the discoveries of particles that are candidates for states with more complicated structures than just $q\overline{q}$ or qqq, it is necessary to extend the naming scheme again.

8.1 "Neutral-flavor" mesons

The naming of mesons is based on their quantum numbers. Although we use names established within the naive quark model, the name does *not* necessarily designate a (predominantly) $q\overline{q}$ state. In other words, the name provides information on the quantum numbers of a given state and not about its dominant component, which might well be $q\overline{q}$ (if allowed) or tetraquark, molecule, etc. In many cases, exotic states will be difficult to distinguish from $q\overline{q}$ states and will likely mix with them, and we make no attempt to, e.g., distinguish those that are "mostly gluonium" from those that are "mostly $q\overline{q}$."

Table 8.1: Symbols for mesons with strangeness and heavy-flavor quantum numbers equal to zero. States that do not yet appear in the RPP are listed in parentheses.

$J^{PC} = \{$	0^{-+}, 2^{-+}, $\vdots$	1^{+-}, 3^{+-}, $\vdots$	1^{--}, 2^{--}, $\vdots$	0^{++}, 1^{++}, $\vdots$
Minimal quark content				
$u\bar{d}, u\bar{u}-d\bar{d}, d\bar{u}$ $(I=1)$	π	b	ρ	a
$d\bar{d}+u\bar{u}$ and/or $s\bar{s}$ $(I=0)$	η,η'	h,h'	ω,ϕ	f,f'
$c\bar{c}$	η_c	h_c	ψ^*	χ_c
$b\bar{b}$	η_b	h_b	Υ	χ_b
$I=1$ with $c\bar{c}$	(Π_c)	Z_c	R_c	(W_c)
$I=1$ with $b\bar{b}$	(Π_b)	Z_b	(R_b)	(W_b)

*The J/ψ remains the J/ψ.

Table 8.1 shows the names for mesons having strangeness and all heavy-flavor quantum numbers equal to zero. The rows of Table 8.1 give the minimal $q\overline{q}$ content. The columns give the possible parity/charge-conjugation states,

$$PC = -+,\ +-,\ --,\ \text{and}\ ++\ .$$

Within the naive quark model, these combinations correspond one-to-one to the angular-momentum state $^{2S+1}L_J$ of the $q\overline{q}$ system being

$$^1(L\ \text{even})_J,\ ^1(L\ \text{odd})_J,\ ^3(L\ \text{even})_J,\ \text{or}\ ^3(L\ \text{odd})_J\ ,$$

respectively. Here S, L, and J are the spin, orbital, and total angular momenta of the $q\overline{q}$ system. Within the naive quark model, the quantum numbers are related by $P = (-1)^{L+1}$, $C = (-1)^{L+S}$, and G parity $= (-1)^{L+S+I}$, where the quantum number C is only relevant to neutral mesons with neutral-flavor quantum numbers and G extends to isovector mesons; see the review on the quark model. These expressions impose restrictions on the quantum numbers that are allowed for $q\overline{q}$ states. However, they do not apply to more complicated structures such as tetraquarks.

The spin J is added as a subscript in the name except for pseudoscalar and vector mesons, and the mass is added in parentheses for mesons that decay strongly. However, for some of the familiar mesons (e.g. η', ϕ, ω), we omit the mass.

Measurements of the mass, quark content (where relevant), and quantum numbers I, J, P, and C (or G) of a meson thus determine its symbol. Conversely, these properties may be inferred unambiguously from the symbol. The name X is used for states with still unknown quantum numbers.

The mass label used in particle names is chosen using the best information available when a name is assigned. A more accurate value of a particle mass may become available at a later time. PDG will decide on a case-by-case basis whether to revise the mass label, taking into account the updated information.

With u, d, and s quarks, there are two isospin-0 mesons. A prime is used to distinguish one from the other (e.g. η and η'). Vector mesons decoupling to $u\overline{u}+d\overline{d}$ and $s\overline{s}$ (ideal mixing) are labeled ω and ϕ, respectively. As usual, we assign the spectroscopic name (e.g. $\Upsilon(1S)$) as the primary name to most of those ψ, Υ, and χ states whose spectroscopic identity is known. We use the form $\Upsilon(9460)$ as an alternative, and as the primary name when the spectroscopic identity is not known.

Since the top quark is so heavy that it decays too rapidly to form bound states, no name is assigned to structures like $t\bar{t}$.

Mesons with quantum numbers $J^{PC} = 0^{--}, 0^{+-}, 1^{-+}, 2^{+-}, 3^{-+}$, etc. cannot be $q\overline{q}$. For such a "manifestly exotic" meson, we use the same symbol as for a $q\overline{q}$ meson; the exotic nature of the meson can be inferred from the values of the P and C quantum numbers (given by the symbol), and the spin J (given by the subscript). For example, an isospin-0 1^{-+} meson containing only u, d, and s quarks and antiquarks would be denoted η_1 and an isospin-1 0^{--} meson containing only u, d, and s quarks and antiquarks would be denoted ρ_0.

The last two lines of Table 8.1 list isospin-1 states that also contain hidden heavy flavor, i.e. whose minimal quark content includes $c\bar{c}$ or $b\bar{b}$. We have assigned new names to these states, in keeping with the practice in the light-quark sector, where the $I = 0$ and $I = 1$ states have distinct names. The currently established $I = 1$ states in the heavy-quark sector have quantum numbers $J^{PC} = 1^{+-}$ and the proposed scheme keeps their original names Z.

8.2 Remarks on "neutral-flavor" mesons with hidden charm or bottom not classified as $q\overline{q}$

In the heavy-quark sector, there are several states with properties – such as masses, decay patterns, and widths – that are in disagreement with predictions from the naive quark model. For example, the vector state at 4260 MeV does not decay into $D\overline{D}$, although within the naive quark model its quantum numbers would call for this decay channel to be dominant. In recent literature, these states have been called X, Y, or Z, with their masses added in parentheses. This nomenclature conflicts with the rules outlined in the previous section, since the meson names are not related to their quantum numbers. However, these states have properties in conflict with the naive quark model and therefore deserve some special labeling.

Therefore in the Review of Particle Physics we will keep two names, one that carries the quantum number information and the other the original name. However, the former name will be given priority. In particular, it will be used when the particle appears as a decay product. Thus, in the Listings as well as Summary Tables from the 2018 edition onwards (listed are only some examples of the particles that appear in the Summary Tables),

- $X(3872)$ will appear as '$\chi_{c1}(3872)$ also known as $X(3872)$';
- $X(3900)^{\pm}$ will appear as '$Z_c(3900)^{\pm}$';
- $X(4260)$ will appear as '$\psi(4260)$ also known as $Y(4260)$';

In addition, states with quantum numbers allowed by the naive quark model but showing some peculiarities, such as an unusual decay pattern, will have the following information in the header:

> This state shows properties different from a conventional $q\overline{q}$ state. A candidate for an exotic structure. See the minireview on non-$q\overline{q}$ states.

The states that cannot be classified as $q\overline{q}$ states (such as charged states with strong decays to heavy quarkonia) will have in the header:

Properties incompatible with a $q\overline{q}$ structure (exotic state). See the minireview on non-$q\overline{q}$ states.

The names Z_c and Z_b used in the literature for isovector states in the $c\overline{c}$ and $b\overline{b}$ sector, respectively, will now also be the official PDG names. No heavy isovector $PC = -+, --$, or $++$ states have yet been confirmed, but provisional names for such states – Π, R, and W, respectively – are listed in Table 8.1. Note that the heavy isovector $PC = ++$ states were predicted to exist as spin partners of the Z states in [2], where the name W was also introduced.

By analogy to the light-quark sector, states with quantum numbers that are in conflict with the naive quark model are labeled according to their I, P, C, and spin J. The exotic nature can be inferred from the quantum numbers.

8.3 Mesons with nonzero S, C and/or B

Mesons with nonzero strangeness S or heavy flavor C and/or B are not eigenstates of charge conjugation, and in each of them one of the quarks is heavier than the other (as above, states containing top quarks are not considered). The rules have been and remain:

1. The main symbol is an upper-case italic letter indicating the heavier quark as follows:

   $$s \to \overline{K} \qquad c \to D \qquad b \to \overline{B},$$

   We use the convention that *the flavor quantum number and the charge of a quark have the same sign*. Thus the strangeness of the s quark is negative, the charm of the c quark is positive, and the bottomness of the b quark is negative. The effect of this convention is as follows: *any flavor carried by a charged meson has the same sign as its charge*. Thus the K^+, D^+, and B^+ have positive strangeness, charm, and bottomness, respectively, and all have positive I_3. The D_s^+ has positive charm *and* strangeness. Furthermore, the $\Delta(\text{flavor}) = \Delta Q$ rule, best known for the strange kaons, applies to every flavor.
2. If the lighter quark is not a u or a d quark, its identity is given by a subscript. The D_s^+ is an example.
3. When the spin-parity is in the natural series, $J^P = 0^+, 1^-, 2^+, \cdots$, a superscript "*" is added.
4. The spin is added as a subscript except for pseudoscalar or vector mesons.

8.4 Ordinary (3-quark) baryons

All baryons having quantum numbers consistent with a minimal quark content of three quarks are denoted by the symbols N, Δ, Λ, Σ, Ξ, and Ω introduced more than 50 years ago. These symbols are followed by J^P signifying their spin J and parity P. For those where the minimal content involves one or more heavier quarks than the light (u, d, and s) quarks, subscripts are added to their symbols, (c and b) as appropriate. The rules are:

1. Baryons with miminal content of *three* u and/or d quarks are N's (isospin 1/2) or Δ's (isospin 3/2).
2. Baryons with *two* u and/or d quarks are Λ's (isospin 0) or Σ's (isospin 1). If the third quark is a c or b quark, its identity is given by a subscript.
3. Baryons with *one* u or d quark are Ξ's (isospin 1/2). One or two subscripts are used if one or both of the remaining quarks are heavy: thus Ξ_c, Ξ_{cc}, Ξ_b, etc.*
4. Baryons with *no* u or d quarks are Ω's (isospin 0), and subscripts indicate any heavy-quark content.
5. A baryon that decays strongly has its mass in parentheses. Examples are the $\Delta(1232)$ $3/2^+$, $\Sigma(1385)$ $3/2^+$, $N(1440)$ $1/2^+$, $\Xi_c(2645)$ $3/2^+$.

In short, the minimal number of u plus d quarks together with the isospin determine the main symbol, and subscripts indicate any content of heavy quarks. A Σ always has isospin 1, an Ω always has isospin 0, etc.

8.5 Exotic baryons

In 2003, several experiments reported finding a strangeness $S = +1$, charge $Q = +1$ baryon, and one experiment reported finding an $S = -2$, $Q = -2$ baryon. Baryons with such quantum numbers cannot be made from three quarks, and thus they are exotic with respect to the naive quark model. However, these "discoveries" were then ruled out by many experiments with far larger statistics: See our 2008 *Review* [3].

More recently, the LHCb collaboration found a series of candidates for pentaquark states in the $J/\psi p$ system extracted from data on $\Lambda_b^0 \to J/\psi K^- p$ [4,5].** These have the quantum numbers of excited nucleons, but have a minimal quark content of $c\bar{c}uud$. Following the name established by the LHCb collaboration, we label these $P_c^+(\text{mass})J^P$, with the mass given in parentheses.

8.6 Change of meson names

For the recently discovered particles above open-flavor threshold in the charmonium and bottomonium systems (previously the "XYZ" mesons), there are a number of differences between the names newly adopted by the PDG and those that have commonly appeared in the literature. Table 8.2 maps the names now used in the PDG to former commonly used names.

Footnotes and References:

* See the "Note on Charmed Baryons" in the Charmed Baryon Listings.

** See our review "Pentaquarks" in the 2016 Edition.

Table 8.2: A comparison of current PDG names to former names commonly used in the literature.

Mesons with complete $I^G J^{PC}$ assignment	
PDG Name	Former Common Name(s)
$\psi_2(3823)^*$	$X(3823)$
$\chi_{c1}(3872)$	$X(3872)$
$Z_c(3900)$	$Z_c(3900)$
$\chi_{c2}(3930)^\dagger$	$\chi_{c2}(2P)$, $Z(3930)$
$\chi_{c1}(4140)$	$Y(4140)$
$Z_c(4200)$	$Z_c(4200)$
$\psi(4230)$	$Y(4230)$
$R_{c0}(4240)$	$Z_c(4240)$
$\psi(4260)$	$Y(4260)$
$\chi_{c1}(4274)$	$Y(4274)$
$\psi(4360)$	$Y(4360)$
$Z_c(4430)$	$Z_c(4430)$
$\chi_{c0}(4500)$	$X(4500)$
$\psi(4660)$	$X(4630)$, $Y(4660)$
$\chi_{c0}(4700)$	$X(4700)$
$Z_b(10610)$	$Z_b(10610)$
$Z_b(10650)$	$Z_b^{(\prime)}(10650)$
Mesons with incomplete $I^G J^{PC}$ assignment	
PDG Name	Former Common Name(s)
$X(3915)^\ddagger$	$\chi_{c0}(3915)$, $X(3915)$, $Y(3940)$
$X(3940)$	$X(3940)$
$X(4020)$	$Z_c^{(\prime)}(4020)$
$X(4050)^\pm$	$Z_1(4050)$
$X(4055)^\pm$	$Z_c(4055)$
$X(4160)$	$X(4160)$
$X(4250)^\pm$	$Z_2(4250)$
$X(4350)$	$X(4350)$

*The 2016 edition used $\psi(3823)$.

†The 2016 edition used $\chi_{c2}(2P)$. The mass is now used in the name following the current prescription.

‡The 2016 edition used $\chi_{c0}(3915)$. The J^{PC} have since been questioned.

9. Quantum Chromodynamics

Revised August 2019 by J. Huston (Michigan State U.), K. Rabbertz (KIT) and G. Zanderighi (MPI Munich).

9.1 Basics

Quantum Chromodynamics (QCD), the gauge field theory that describes the strong interactions of colored quarks and gluons, is the SU(3) component of the SU(3)×SU(2)×U(1) Standard Model of Particle Physics. The Lagrangian of QCD is given by

$$\mathcal{L} = \sum_q \bar{\psi}_{q,a}(i\gamma^\mu\partial_\mu\delta_{ab} - g_s\gamma^\mu t^C_{ab}\mathcal{A}^C_\mu - m_q\delta_{ab})\psi_{q,b} - \frac{1}{4}F^A_{\mu\nu}F^{A\,\mu\nu}\,, \tag{9.1}$$

where repeated indices are summed over. The γ^μ are the Dirac γ-matrices. The $\psi_{q,a}$ are quark-field spinors for a quark of flavor q and mass m_q, with a color-index a that runs from $a = 1$ to $N_c = 3$, *i.e.* quarks come in three "colors." Quarks are said to be in the fundamental representation of the SU(3) color group.

The $\mathcal{A}^C_\mu$ correspond to the gluon fields, with C running from 1 to $N_c^2 - 1 = 8$, *i.e.* there are eight kinds of gluon. Gluons transform under the adjoint representation of the SU(3) color group. The t^C_{ab} correspond to eight 3×3 matrices and are the generators of the SU(3) group (*cf.* the section on "SU(3) isoscalar factors and representation matrices" in this *Review*, with $t^C_{ab} \equiv \lambda^C_{ab}/2$). They encode the fact that a gluon's interaction with a quark rotates the quark's color in SU(3) space. The quantity g_s (or $\alpha_s = \frac{g_s^2}{4\pi}$) is the QCD coupling constant. Besides quark masses, who have electroweak origin, it is the only fundamental parameter of QCD. Finally, the field tensor $F^A_{\mu\nu}$ is given by

$$\begin{aligned} F^A_{\mu\nu} &= \partial_\mu\mathcal{A}^A_\nu - \partial_\nu\mathcal{A}^A_\mu - g_s\, f_{ABC}\mathcal{A}^B_\mu\mathcal{A}^C_\nu\,, \\ [t^A, t^B] &= i f_{ABC} t^C\,, \end{aligned} \tag{9.2}$$

where the f_{ABC} are the structure constants of the SU(3) group.

Neither quarks nor gluons are observed as free particles. Hadrons are color-singlet (*i.e.* color-neutral) combinations of quarks, anti-quarks, and gluons.

Ab-initio predictive methods for QCD include lattice gauge theory and perturbative expansions in the coupling. The Feynman rules of QCD involve a quark-antiquark-gluon ($q\bar{q}g$) vertex, a 3-gluon vertex (both proportional to g_s), and a 4-gluon vertex (proportional to g_s^2). A full set of Feynman rules is to be found for example in Refs. [1,2].

Useful color-algebra relations include: $t^A_{ab}t^A_{bc} = C_F\delta_{ac}$, where $C_F \equiv (N_c^2 - 1)/(2N_c) = 4/3$ is the color-factor ("Casimir") associated with gluon emission from a quark; $f_{ACD}f_{BCD} = C_A\delta_{AB}$, where $C_A \equiv N_c = 3$ is the color-factor associated with gluon emission from a gluon; $t^A_{ab}t^B_{ab} = T_R\delta_{AB}$, where $T_R = 1/2$ is the color-factor for a gluon to split to a $q\bar{q}$ pair.

There is freedom for an additional CP-violating term to be present in the QCD Lagrangian, $\theta\frac{\alpha_s}{8\pi}F^A_{\mu\nu}\tilde{F}^{A\,\mu\nu}$, where $\tilde{F}^{A\,\mu\nu}$ is the dual of the gluon field tensor, $\frac{1}{2}\epsilon_{\mu\nu\sigma\rho}F^{A\,\sigma\rho}$, where $\epsilon_{\mu\nu\sigma\rho}$ is the fully antisymmetric Levi-Civita symbol. Experimental limits on ultracold neutrons [3,4] and atomic mercury [5] constrain the QCD vacuum angle to satisfy $|\theta| \lesssim 10^{-10}$. Further discussion is to be found in Ref. [6] and in the Axions section in the Listings of this *Review*.

This section will concentrate mainly on perturbative aspects of QCD as they relate to collider physics. Related textbooks and lecture notes include Refs. [1,2,7–9]. Aspects specific to Monte Carlo event generators are reviewed in the dedicated section 41. Lattice QCD is also reviewed in a section of its own, Sec. 17, with further discussion of perturbative and non-perturbative aspects to be found in the sections on "Quark Masses", "The CKM quark-mixing matrix", "Structure Functions", "Fragmentation Functions", "Passage of Particles Through Matter" and "Heavy-Quark and Soft-Collinear Effective Theory" in this *Review*.

9.1.1 *Running coupling*

In the framework of perturbative QCD (pQCD), predictions for observables are expressed in terms of the renormalized coupling $\alpha_s(\mu_R^2)$, a function of an (unphysical) renormalization scale μ_R. When one takes μ_R close to the scale of the momentum transfer Q in a given process, then $\alpha_s(\mu_R^2 \simeq Q^2)$ is indicative of the effective strength of the strong interaction in that process.

The coupling satisfies the following renormalization group equation (RGE):

$$\mu_R^2\frac{d\alpha_s}{d\mu_R^2} = \beta(\alpha_s) = -(b_0\alpha_s^2 + b_1\alpha_s^3 + b_2\alpha_s^4 + \cdots)\,, \tag{9.3}$$

where $b_0 = (11C_A - 4n_fT_R)/(12\pi) = (33 - 2n_f)/(12\pi)$ is referred to as the 1-loop β-function coefficient, the 2-loop coefficient is $b_1 = (17C_A^2 - n_fT_R(10C_A + 6C_F))/(24\pi^2) = (153 - 19n_f)/(24\pi^2)$, and the 3-loop coefficient is $b_2 = (2857 - \frac{5033}{9}n_f + \frac{325}{27}n_f^2)/(128\pi^3)$ for the SU(3) values of C_A and C_F. Here n_f is the number of quark flavours. The 4-loop coefficient, b_3, is to be found in Refs. [10,11], while the 5-loop coefficient, b_4, is in Refs. [12–16]. The coefficients b_2 and b_3 (and beyond) are renormalization-scheme-dependent and given here in the modified minimal subtraction ($\overline{\text{MS}}$) scheme [17], by far the most widely used scheme in QCD and the one adopted in the following.

The minus sign in Eq. (9.3) is the origin of Asymptotic Freedom [18,19], *i.e.* the fact that the strong coupling becomes weak for processes involving large momentum transfers ("hard processes"). For momentum transfers in the 0.1–1 TeV range, $\alpha_s \sim 0.1$, while the theory is strongly interacting for scales around and below 1 GeV.

The β-function coefficients, the b_i, are given for the coupling of an *effective theory* in which n_f of the quark flavors are considered light ($m_q \ll \mu_R$), and in which the remaining heavier quark flavors decouple from the theory. One may relate the coupling for the theory with $n_f + 1$ light flavors to that with n_f flavors through an equation of the form

$$\begin{aligned} \alpha_s^{(n_f+1)}(\mu_R^2) =& \alpha_s^{(n_f)}(\mu_R^2)\times \\ & \times\left(1 + \sum_{n=1}^{\infty}\sum_{\ell=0}^{n} c_{n\ell}\,[\alpha_s^{(n_f)}(\mu_R^2)]^n \ln^\ell\frac{\mu_R^2}{m_h^2}\right)\,, \end{aligned} \tag{9.4}$$

where m_h is the mass of the $(n_f+1)^{\text{th}}$ flavor, and the first few $c_{n\ell}$ coefficients are $c_{11} = \frac{1}{6\pi}$, $c_{10} = 0$, $c_{22} = c_{11}^2$, $c_{21} = \frac{11}{24\pi^2}$, and $c_{20} = -\frac{11}{72\pi^2}$ when m_h is the $\overline{\text{MS}}$ mass at scale m_h, while $c_{20} = \frac{7}{24\pi^2}$ when m_h is the pole mass (mass definitions are discussed below in Sec. (9.1.2) and in the review on "Quark Masses"). Terms up to $c_{4\ell}$ are to be found in Refs. [20,21]. Numerically, when one chooses $\mu_R = m_h$, the matching is a modest effect, owing to the zero value for the c_{10} coefficient. Relations between n_f and $(n_f{+}2)$ flavors where the two heavy flavors are close in mass are given to three loops in Ref. [22].

Working in an energy range where the number of flavors is taken constant, a simple exact analytic solution exists for Eq. (9.3) only if one neglects all but the b_0 term, giving $\alpha_s(\mu_R^2) = (b_0\ln(\mu_R^2/\Lambda^2))^{-1}$. Here Λ is a constant of integration, which corresponds to the scale where the perturbatively-defined coupling would diverge. Its value is indicative of the energy range where non-perturbative dynamics dominates. A convenient approximate analytic solution to the RGE that includes terms up to b_4 is given by solving iteratively Eq. (9.3)

$$\begin{aligned} \alpha_s(\mu_R^2) \simeq \frac{1}{b_0t}\Bigg(&1 - \frac{b_1}{b_0^2}\frac{\ell}{t} + \frac{b_1^2(\ell^2 - \ell - 1) + b_0b_2}{b_0^4t^2} + \\ &+ \frac{b_1^3\left(-2\ell^3 + 5\ell^2 + 4\ell - 1\right) - 6b_0b_2b_1\ell + b_0^2b_3}{2b_0^6t^3} + \\ &+ \frac{18b_0b_2b_1^2\left(2\ell^2 - \ell - 1\right) + b_1^4\left(6\ell^4 - 26\ell^3 - 9\ell^2 + 24\ell + 7\right)}{6b_0^8t^4} \\ &+ \frac{-b_0^2b_3b_1(12\ell + 1) + 2b_0^2\left(5b_2^2 + b_0b_4\right)}{6b_0^8t^4}\Bigg)\,, \end{aligned} \tag{9.5}$$

with $t \equiv \ln \frac{\mu_R^2}{\Lambda^2}$ and $\ell = \ln t$, again parametrized in terms of a constant Λ. Note that Eq. (9.5) is one of several possible approximate 4-loop solutions for $\alpha_s(\mu_R^2)$, and that a value for Λ only defines $\alpha_s(\mu_R^2)$ once one knows which particular approximation is being used. An alternative to the use of formulas such as Eq. (9.5) is to solve the RGE exactly, numerically (including the discontinuities, Eq. (9.4), at flavor thresholds). In such cases the quantity Λ does not directly arise (though it can be defined, *cf.* Eqs. (1–3) of Ref. [23]). For these reasons, in determinations of the coupling, it has become standard practice to quote the value of α_s at a given scale (typically the mass of the Z boson, M_Z) rather than to quote a value for Λ.

A discussion of determinations of the coupling and a graph illustrating its scale dependence ("running") are to be found in Section 9.4. The RunDec package [24–26] is often used to calculate the evolution of the coupling. For a discussion of electroweak effects in the evolution of the QCD coupling, see Ref. [27] and references therein.

9.1.2 *Quark masses*

Free quarks have never been observed, which is understood as a result of a long-distance, confining property of the strong QCD force: up, down, strange, charm, and bottom quarks all *hadronize*, *i.e.* become part of a meson or baryon, on a timescale $\sim 1/\Lambda$; the top quark instead decays before it has time to hadronize. This means that the question of what one means by the quark mass is a complex one, which requires one to adopt a specific prescription. A perturbatively defined prescription is the pole mass, m_q, which corresponds to the position of the divergence of the propagator. This is close to one's physical picture of mass. However, when relating it to observable quantities, it suffers from substantial non-perturbative ambiguities (see *e.g.* Ref. [28–30]). An alternative is the $\overline{\rm MS}$ mass, $\overline{m}_q(\mu_R^2)$, which depends on the renormalization scale μ_R.

Results for the masses of heavier quarks are often quoted either as the pole mass or as the $\overline{\rm MS}$ mass evaluated at a scale equal to the mass, $\overline{m}_q(\overline{m}_q^2)$; light quark masses are often quoted in the $\overline{\rm MS}$ scheme at a scale $\mu_R \sim 2\,\text{GeV}$. The pole and $\overline{\rm MS}$ masses are related by a series that starts as $m_q = \overline{m}_q(\overline{m}_q^2)(1 + \frac{4\alpha_s(\overline{m}_q^2)}{3\pi} + \mathcal{O}(\alpha_s^2))$, while the scale-dependence of $\overline{\rm MS}$ masses is given at lowest order by

$$\mu_R^2 \frac{d\overline{m}_q(\mu_R^2)}{d\mu_R^2} = \left[-\frac{\alpha_s(\mu_R^2)}{\pi} + \mathcal{O}(\alpha_s^2)\right]\overline{m}_q(\mu_R^2)\,. \tag{9.6}$$

A more detailed discussion is to be found in a dedicated section of the *Review*, "Quark Masses", with detailed formulas also in Ref. [31] and references therein.

In perturbative QCD calculations of scattering processes, it is common to work in an approximation in which one neglects (*i.e.* sets to zero) the masses of all quarks, whose mass is significantly smaller than the momentum transfer in the process.

9.2 Structure of QCD predictions

9.2.1 *Fully inclusive cross sections*

The simplest observables in perturbative QCD are those that do not involve initial-state hadrons and that are fully inclusive with respect to details of the final state. One example is the total cross section for $e^+e^- \to$ hadrons at center-of-mass energy Q, for which one can write

$$\frac{\sigma(e^+e^- \to \text{hadrons}, Q)}{\sigma(e^+e^- \to \mu^+\mu^-, Q)} \equiv R(Q) = R_{\rm EW}(Q)(1 + \delta_{\rm QCD}(Q))\,, \tag{9.7}$$

where $R_{\rm EW}(Q)$ is the purely electroweak prediction for the ratio and $\delta_{\rm QCD}(Q)$ is the correction due to QCD effects. To keep the discussion simple, we can restrict our attention to energies $Q \ll M_Z$, where the process is dominated by photon exchange (neglecting electroweak and finite-quark-mass corrections $R_{\rm EW} = N_c \sum_q e_q^2$, where the e_q are the electric charges of the quarks) and

$$\delta_{\rm QCD}(Q) = \sum_{n=1}^{\infty} c_n \cdot \left(\frac{\alpha_s(Q^2)}{\pi}\right)^n + \mathcal{O}\left(\frac{\Lambda^4}{Q^4}\right)\,. \tag{9.8}$$

The first four terms in the α_s series expansion are then to be found in Ref. [32],

$$c_1 = 1\,, \qquad c_2 = 1.9857 - 0.1152 n_f\,, \tag{9.9a}$$

$$c_3 = -6.63694 - 1.20013 n_f - 0.00518 n_f^2 - 1.240\eta\,, \tag{9.9b}$$

$$c_4 = -156.61 + 18.775 n_f - 0.7974 n_f^2 + 0.0215 n_f^3 - (17.828 - 0.575 n_f)\eta\,, \tag{9.9c}$$

with $\eta = (\sum e_q)^2/(3\sum e_q^2)$. For corresponding expressions including also Z exchange and finite-quark-mass effects, see Refs. [33–35].

A related series holds also for the QCD corrections to the hadronic decay width of the τ lepton, which essentially involves an integral of $R(Q)$ over the allowed range of invariant masses of the hadronic part of the τ decay (see *e.g.* Ref. [36]). The series expansions for QCD corrections to Higgs-boson hadronic (partial) decay widths in the limit of heavy top quark and massless light flavours at N^{4}LO are given in Ref. [37].

One characteristic feature of Eqs. (9.8) and (9.9) is that the coefficients of α_s^n increase order by order: calculations in perturbative QCD tend to converge more slowly than would be expected based just on the size of α_s. The situation is significantly worse near thresholds or in the presence of tight kinematic cuts. Another feature is the existence of an extra "power-correction" term $\mathcal{O}(\Lambda^4/Q^4)$ in Eq. (9.8), which accounts for contributions that are fundamentally non-perturbative. All high-energy QCD predictions involve power corrections $(\Lambda/Q)^p$, although typically the suppression of these corrections with Q is smaller than given in Eq. (9.8) where $p = 4$. The exact power p depends on the observable and, for many processes and observables, it is possible to introduce an operator product expansion and associate power suppressed terms with specific higher-dimension (non-perturbative) operators [38].

Scale dependence. In Eq. (9.8) the renormalization scale for α_s has been chosen equal to Q. The result can also be expressed in terms of the coupling at an arbitrary renormalization scale μ_R,

$$\delta_{\rm QCD}(Q) = \sum_{n=1}^{\infty} \overline{c}_n\left(\frac{\mu_R^2}{Q^2}\right) \cdot \left(\frac{\alpha_s(\mu_R^2)}{\pi}\right)^n + \mathcal{O}\left(\frac{\Lambda^4}{Q^4}\right)\,, \tag{9.10}$$

where $\overline{c}_1(\mu_R^2/Q^2) \equiv c_1$, $\overline{c}_2(\mu_R^2/Q^2) = c_2 + \pi b_0 c_1 \ln(\mu_R^2/Q^2)$, $\overline{c}_3(\mu_R^2/Q^2) = c_3 + (2b_0c_2\pi + b_1c_1\pi^2) \times \ln(\mu_R^2/Q^2) + b_0^2c_1\pi^2\ln^2(\mu_R^2/Q^2)$, *etc.* Given an infinite number of terms in the α_s expansion, the μ_R dependence of the $\overline{c}_n(\mu_R^2/Q^2)$ coefficients will exactly cancel that of $\alpha_s(\mu_R^2)$, and the final result will be independent of the choice of μ_R: physical observables do not depend on unphysical scales.[1]

With just terms up to some finite $n = N$, a residual μ_R dependence will remain, which implies an uncertainty on the prediction of $R(Q)$ due to the arbitrariness of the scale choice. This uncertainty will be $\mathcal{O}(\alpha_s^{N+1})$, *i.e.* of the same order as the neglected higher-order terms. For this reason it is customary to use QCD predictions' scale dependence as an estimate of the uncertainties due to neglected terms. One usually takes a central value for $\mu_R \sim Q$, in order to avoid the poor convergence of the perturbative series that results from the large $\ln^{n-1}(\mu_R^2/Q^2)$ terms in the $\overline{c}_n$ coefficients when $\mu_R \ll Q$ or $\mu_R \gg Q$. Uncertainties are then

[1] With respect to pQCD there is an important caveat to this statement: at sufficiently high orders, perturbative series generally suffer from "renormalon" divergences $\alpha_s^n n!$ (reviewed in Ref. [28]). This phenomenon is not usually visible with the limited number of perturbative terms available today. However it is closely connected with non-perturbative contributions and sets a limit on the possible precision of perturbative predictions. The cancellation of scale dependence will also ultimately be affected by this renormalon-induced breakdown of perturbation theory.

commonly determined by varying μ_R by a factor of two up and down around the central scale choice. A more detailed discussion on the accuracy of theoretical predictions and on ways to estimate the theoretical uncertainties can be found in Section 9.2.4.

9.2.2 *Processes with initial-state hadrons*

Deep-Inelastic Scattering. To illustrate the key features of QCD cross sections in processes with initial-state hadrons, let us consider deep-inelastic scattering (DIS), $ep \to e + X$, where an electron e with four-momentum k emits a highly off-shell photon (momentum q) that interacts with the proton (momentum p). For photon virtualities $Q^2 \equiv -q^2$ far above the squared proton mass (but far below the Z mass), the differential cross section in terms of the kinematic variables Q^2, $x = Q^2/(2p\cdot q)$ and $y = (q\cdot p)/(k\cdot p)$ is

$$\frac{d^2\sigma}{dxdQ^2} = \frac{4\pi\alpha^2}{2xQ^4}\left[(1+(1-y)^2)F_2(x,Q^2) - y^2F_L(x,Q^2)\right], \tag{9.11}$$

where α is the electromagnetic coupling and $F_2(x,Q^2)$ and $F_L(x,Q^2)$ are proton structure functions, which encode the interaction between the photon (in given polarization states) and the proton. In the presence of parity-violating interactions (*e.g.* νp scattering) an additional F_3 structure function is present. For an extended review, including equations for the full electroweak and polarized cases, see Sec. 18 of this *Review*.

Structure functions are not calculable in perturbative QCD, nor is any other cross section that involves QCD interactions and initial-state hadrons. To zeroth order in α_s, the structure functions are given directly in terms of non-perturbative parton (quark or gluon) distribution functions (PDFs),

$$F_2(x,Q^2) = x\sum_q e_q^2 f_{q/p}(x), \qquad F_L(x,Q^2) = 0, \tag{9.12}$$

where $f_{q/p}(x)$ is the non-perturbative PDF for quarks of type q inside the proton, *i.e.* the number density of quarks of type q inside a fast-moving proton that carry a fraction x of its longitudinal momentum (the quark flavor index q, here, is not to be confused with the photon momentum q in the lines preceding Eq. (9.11)). Recently, some first determinations on lattice started to appear [39–43] but there is also some debate about the underlying methods [44]. Accordingly, for all practical uses, PDFs are currently determined from data (*cf.* Sec. 18 of this *Review* and also Refs. [45, 46]) [2].

The above result, with PDFs $f_{q/p}(x)$ that are independent of the scale Q, corresponds to the "quark-parton model" picture in which the photon interacts with point-like free quarks, or equivalently, one has incoherent elastic scattering between the electron and individual constituents of the proton. As a consequence, in this picture also F_2 and F_L are independent of Q [50]. When including higher orders in pQCD,

$$F_2(x,Q^2) = x\sum_{n=0}^{\infty}\frac{\alpha_s^n(\mu_R^2)}{(2\pi)^n}\times$$
$$\times\sum_{i=q,g}\int_x^1\frac{dz}{z}C_{2,i}^{(n)}(z,Q^2,\mu_R^2,\mu_F^2)f_{i/p}\left(\frac{x}{z},\mu_F^2\right) + \mathcal{O}\left(\frac{\Lambda^2}{Q^2}\right). \tag{9.13}$$

Just as in Eq. (9.10), we have a series in powers of $\alpha_s(\mu_R^2)$, each term involving a coefficient $C_{2,i}^{(n)}$ that can be calculated using Feynman graphs. At variance with the parton model, the PDFs in pQCD depend on an additional scale, the factorization scale μ_F, whose significance will be discussed in the following. Another important difference is the additional integral over z. The parton that comes from the proton can undergo a splitting before it interacts with the photon. As a result, the $C_{2,i}^{(n)}$ coefficients are functions that depend on the ratio, z, of the parton's momentum before and after radiation, and one must integrate over that ratio. For the electromagnetic component of DIS with light quarks and gluons, the zeroth order coefficient functions are $C_{2,q}^{(0)} = e_q^2\delta(1-z)$ and $C_{2,g}^{(0)} = 0$. Corrections are known up to $\mathcal{O}(\alpha_s^3)$ (next-to-next-to-next-to-leading order, N^{3}LO) for both electromagnetic [51] and weak currents [52, 53]. For heavy-quark production they are known to $\mathcal{O}(\alpha_s^2)$ [54, 55] (next-to-leading order, NLO, insofar as the series starts at $\mathcal{O}(\alpha_s)$). For precise comparisons of LHC cross sections with theoretical predictions, the photon PDF of the proton is also needed. It has been computed precisely in Ref. [56] and has now been implemented in most global PDF fits.

The majority of the emissions that modify a parton's momentum are collinear (parallel) to that parton, and do not depend on the fact that the parton is destined to interact with a photon. It is natural to view these emissions as modifying the proton's structure rather than being part of the coefficient function for the parton's interaction with the photon. Technically, one uses a procedure known as *collinear factorization* to give a well-defined meaning to this distinction, most commonly through the $\overline{\mathrm{MS}}$ factorization scheme, defined in the context of dimensional regularization. The $\overline{\mathrm{MS}}$ factorization scheme involves an arbitrary choice of *factorization scale*, μ_F, whose meaning can be understood roughly as follows: emissions with transverse momenta above μ_F are included in the $C_{2,q}^{(n)}(z,Q^2,\mu_R^2,\mu_F^2)$; emissions with transverse momenta below μ_F are accounted for within the PDFs, $f_{i/p}(x,\mu_F^2)$. While collinear factorization is generally believed to be valid for suitable (sufficiently inclusive) observables in processes with hard scales, Ref. [57], which reviews the factorization proofs in detail, is cautious in the statements it makes about their exhaustivity, notably for the hadron-collider processes which we shall discuss below. Further discussion is to be found in Refs. [58, 59].

The PDFs' resulting dependence on μ_F is described by the Dokshitzer-Gribov-Lipatov-Altarelli-Parisi (DGLAP) equations [60], which to leading order (LO) read[3]

$$\mu_F^2\frac{\partial f_{i/p}(x,\mu_F^2)}{\partial\mu_F^2} = \sum_j\frac{\alpha_s(\mu_F^2)}{2\pi}\int_x^1\frac{dz}{z}P_{i\leftarrow j}^{(1)}(z)f_{j/p}\left(\frac{x}{z},\mu_F^2\right), \tag{9.14}$$

with, for example, $P_{q\leftarrow g}^{(1)}(z) = T_R(z^2+(1-z)^2)$. The other LO splitting functions are listed in Sec. 18 of this *Review*, while results up to NLO, α_s^2, and NNLO, α_s^3, are given in Refs. [61] and [62] respectively. At N^{3}LO accuracy, only partial results are currently available Ref. [63–65].

Splitting functions for polarized PDFs are given in Ref. [66]. Beyond LO, the coefficient functions are also μ_F dependent, for example $C_{2,i}^{(1)}(x,Q^2,\mu_R^2,\mu_F^2) = C_{2,i}^{(1)}(x,Q^2,\mu_R^2,Q^2) - \ln\left(\frac{\mu_F^2}{Q^2}\right)\sum_j\int_x^1\frac{dz}{z}\times C_{2,j}^{(0)}(\frac{x}{z})P_{j\leftarrow i}^{(1)}(z)$. In certain contexts, higher-order QED and mixed QED-QCD corrections to the splitting functions are also needed [67].

As with the renormalization scale, the choice of factorization scale is arbitrary, but if one has an infinite number of terms in the perturbative series, the μ_F-dependencies of the coefficient functions and PDFs will compensate each other fully. Given only N terms of the series, a residual $\mathcal{O}(\alpha_s^{N+1})$ uncertainty is associated with the ambiguity in the choice of μ_F. As with μ_R, varying μ_F provides an input in estimating uncertainties on predictions. In inclusive DIS predictions, the default choice for the scales is

[2] PDFs can be determined from data in a global fit at LO, NLO and NNLO, depending on the order of the matrix elements used to describe the data. In modern global PDF fits, data are included from DIS, DY, jets and $t\bar{t}$ processes, and more LHC collider data, with the global PDF fits using 3000-4000 data points. There is a large change in the PDFs from LO to NLO, with a much smaller change from NLO to NNLO. LO PDFs can be unreliable for collider predictions, especially at low and high x. The uncertainties for the resulting PDFs are determined from the experimental uncertainties of the data that serves as input to the global PDF fits. The PDF uncertainties can either be determined through a Hessian approach or through the use of Monte Carlo replicas. It is now relatively straightforward to convert results from one approach to the other. The PDF4LHC15 PDF set is formed by combining replicas of the CT14, MMHT2014 and NNPDF3.0 PDF sets, at NLO and at NNLO [47]. Recently, theoretical uncertainties related to missing higher orders have been included in global PDF determinations but so far only at NLO [48, 49].

[3] LO is generally taken to mean the lowest order at which a quantity is non-zero.

usually $\mu_R = \mu_F = Q$.

As is the case for the running coupling, in DGLAP evolution one can introduce flavor thresholds near the heavy quark masses: below a given heavy quark's mass, that quark is not considered to be part of the proton's structure, while above it is considered to be part of the proton's structure and evolves with massless DGLAP splitting kernels. With appropriate parton distribution matching terms at threshold, such a variable flavor number scheme (VFNS), when used with massless coefficient functions, gives the full heavy-quark contributions at high Q^2 scales. For scales near the threshold, it is instead necessary to appropriately adapt the standard massive coefficient functions to account for the heavy-quark contribution already included in the PDFs [68–70].

At sufficiently small x and Q^2 in inclusive DIS, resummation of small x logarithms may be necessary [71,72]. This may in fact have been observed in Refs. [73] based on HERA data [74], in a kinematic region where useful information for PDFs for collider predictions is present. A better description of the data in this region can be gained by small x resummation matched to NNLO [73,75], or by the inclusion of power-suppressed contributions [76] or by using an x-dependent factorization scale in the NNLO DIS predictions [77].

Hadron-hadron collisions. The extension to processes with two initial-state hadrons can be illustrated with the example of the total (inclusive) cross section for W boson production in collisions of hadrons h_1 and h_2, which can be written as

$$\begin{aligned}\sigma(h_1 h_2 \to W + X) = &\sum_{n=0}^{\infty} \alpha_s^n(\mu_R^2) \\ &\times \sum_{i,j} \int dx_1 dx_2\, f_{i/h_1}\left(x_1, \mu_F^2\right) f_{j/h_2}\left(x_2, \mu_F^2\right) \\ &\times \hat{\sigma}^{(n)}_{ij\to W+X}\left(x_1 x_2 s, \mu_R^2, \mu_F^2\right) + \mathcal{O}\left(\frac{\Lambda^2}{M_W^4}\right), \end{aligned} \tag{9.15}$$

where s is the squared center-of-mass energy of the collision. At LO, $n = 0$, the hard (partonic) cross section $\hat{\sigma}^{(0)}_{ij\to W+X}(x_1 x_2 s, \mu_R^2, \mu_F^2)$ is simply proportional to $\delta(x_1 x_2 s - M_W^2)$, in the narrow W-boson width approximation (see Sec. 50 of this *Review* for detailed expressions for this and other hard scattering cross sections). It is non-zero only for choices of i, j that can directly give a W, such as $i = u$, $j = \bar{d}$. At higher orders, $n \geq 1$, new partonic channels contribute, such as gq, and $x_1 x_2 s \geq M_W^2$ in the narrow W-boson width approximation.

Eq. (9.15) involves a collinear factorization between the hard cross section and the PDFs, just like Eq. (9.13). As long as the same factorization scheme is used in DIS and pp or $p\bar{p}$ (usually the $\overline{\text{MS}}$ scheme), then PDFs extracted in DIS can be directly used in pp and $p\bar{p}$ predictions [57,78] (with the anti-quark distributions in an anti-proton being the same as the quark distributions in a proton).

Fully inclusive hard cross sections are known to NNLO, *i.e.* corrections up to relative order α_s^2, for Drell-Yan (DY) lepton-pair and vector-boson production [79,80], Higgs-boson production in association with a vector boson [81], Higgs-boson production via vector-boson fusion [82] (in an approximation that factorizes the production of the two vector bosons), Higgs-pair production with full m_t dependence [83], top-antitop production [84] and vector-boson pair production [85–87].[4] Inclusive Higgs production through gluon fusion in the large m_t limit was calculated at N^{3}LO [88, 89]. A calculation at this order, differential in the Higgs rapidity has also been presented recently [90]. Vector-boson fusion Higgs production is also known to N^{3}LO [91] in the factorized approximation. A discussion of many other calculations for Higgs production processes is to be found in Ref. [92].

Photoproduction. γp (and $\gamma\gamma$) collisions are similar to pp collisions, with the subtlety that the photon can behave in two ways: there is "direct" photoproduction, in which the photon behaves as a point-like particle and takes part directly in the hard collision, with hard subprocesses such as $\gamma g \to q\bar{q}$; there is also resolved photoproduction, in which the photon behaves like a hadron, with non-perturbative partonic substructure and a corresponding PDF for its quark and gluon content, $f_{i/\gamma}(x, Q^2)$. While useful to understand the general structure of γp collisions, the distinction between direct and resolved photoproduction is not well defined beyond leading order, as discussed for example in Ref. [93].

The high-energy (BFKL) limit. In situations in which the total center-of-mass energy $\sqrt{s}$ is much larger than all other momentum-transfer scales in the problem (*e.g.* Q in DIS, m_b for $b\bar{b}$ production in pp collisions, *etc.*), each power of α_s beyond LO can be accompanied by a power of $\ln(s/Q^2)$ (or $\ln(s/m_b^2)$, *etc.*). This is variously referred to as the high-energy, small-x or Balitsky-Fadin-Kuraev-Lipatov (BFKL) limit [72,94,95]. Currently it is possible to account for the dominant and first sub-dominant [96,97] power of $\ln s$ at each order of α_s, and also to estimate further sub-dominant contributions that are numerically large (see Refs. [98–101] and references therein). Progress towards NNLO is discussed in Ref. [102].

Physically, the summation of all orders in α_s can be understood as leading to a growth with s of the gluon density in the proton. At sufficiently high energies this implies non-linear effects (commonly referred to as parton saturation), whose treatment has been the subject of intense study (see for example Refs. [103,104] and references thereto).

9.2.3 *Cross sections with phase-space restrictions*

QCD final states always consist of hadrons, while perturbative QCD calculations deal with partons. Physically, an energetic parton fragments ("showers") into many further partons, which then, on later timescales, undergo a transition to hadrons ("hadronization"). Fixed-order perturbation theory captures only a small part of these dynamics. This does not matter for the fully inclusive cross sections discussed above: the showering and hadronization stages are approximately unitary, *i.e.* they do not substantially change the overall probability of hard scattering, because they occur long after it has taken place (they introduce at most a correction proportional to a power of the ratio of timescales involved, *i.e.* a power of Λ/Q, where Q is the hard scattering scale).

Less inclusive measurements, in contrast, may be affected by the extra dynamics. For those sensitive just to the main directions of energy flow (jet rates, event shapes, *cf.* Sec. 9.3.1) fixed-order perturbation theory is often still adequate, because showering and hadronization do not substantially change the overall energy flow. This means that one can make a prediction using just a small number of partons, which should correspond well to a measurement of the same observable carried out on hadrons. For observables that instead depend on distributions of individual hadrons (which, *e.g.*, are the inputs to detector simulations), it is mandatory to account for showering and hadronization. The range of predictive techniques available for QCD final states reflects this diversity of needs of different measurements.

While illustrating the different methods, we shall for simplicity mainly use expressions that hold for e^+e^- scattering. The extension to cases with initial-state partons will be mostly straightforward (space constraints unfortunately prevent us from addressing diffraction and exclusive hadron-production processes; extensive discussion is to be found in Refs. [105,106]).

9.2.3.1 *Soft and collinear limits*

Before examining specific predictive methods, it is useful to be aware of a general property of QCD matrix elements in the soft and collinear limits. Consider a squared tree-level matrix element $|M_n^2(p_1, \ldots, p_n)|$ for the process $e^+e^- \to n$ partons with momenta $p_1, \ldots, p_n$, and a corresponding phase-space integration measure $d\Phi_n$. If particle n is a gluon, which becomes collinear (parallel) to another particle i and additionally its momentum tends to zero

[4] Processes with jets or photons in the final state have divergent cross sections unless one places a cut on the jet or photon momentum. Accordingly, they are discussed below in Section 9.2.3.2.

(is "soft"), the matrix element simplifies as follows,

$$\lim_{\theta_{in}\to 0,\, E_n\to 0} d\Phi_n |M_n^2(p_1,\ldots,p_n)| = d\Phi_{n-1}|M_{n-1}^2(p_1,\ldots,p_{n-1})| \frac{\alpha_s C_i}{\pi}\frac{d\theta_{in}^2}{\theta_{in}^2}\frac{dE_n}{E_n}\,, \tag{9.16}$$

where $C_i = C_F$ (C_A) if i is a quark (gluon). This formula has non-integrable divergences both for the inter-parton angle $\theta_{in} \to 0$ and for the gluon energy $E_n \to 0$, which are mirrored also in the structure of divergences in loop diagrams. These divergences are important for at least two reasons: firstly, they govern the typical structure of events (inducing many emissions either with low energy or at small angle with respect to hard partons); secondly, they will determine which observables can be calculated within perturbative QCD.

9.2.3.2 *Fixed-order predictions*

Let us consider an observable $\mathcal{O}$ that is a function $\mathcal{O}_n(p_1,\ldots,p_n)$ of the four-momenta of the n final-state particles in an event (either partons or hadrons). In what follows, we shall consider the cross section for events weighted with the value of the observable, $\sigma_{\mathcal{O}}$. As examples, if $\mathcal{O}_n \equiv 1$ for all n, then $\sigma_{\mathcal{O}}$ is just the total cross section; if $\mathcal{O}_n \equiv \hat{\tau}(p_1,\ldots,p_n)$ where $\hat{\tau}$ is the value of the Thrust for that event (see Sec. 9.3.1.2), then the average value of the Thrust is $\langle\tau\rangle = \sigma_{\mathcal{O}}/\sigma_{\rm tot}$; if $\mathcal{O}_n \equiv \delta(\tau - \hat{\tau}(p_1,\ldots,p_n))$ then one gets the differential cross section as a function of the Thrust, $\sigma_{\mathcal{O}} \equiv d\sigma/d\tau$.

In the expressions below, we shall omit to write the non-perturbative power correction term, which for most common observables is proportional to a single power of Λ/Q.

Leading Order. If the observable $\mathcal{O}$ is non-zero only for events with at least n final-state particles, then the LO QCD prediction for the weighted cross section in e^+e^- annihilation is

$$\sigma_{\mathcal{O},LO} = \alpha_s^{n-2}(\mu_R^2)\int d\Phi_n |M_n^2(p_1,\ldots,p_n)|\,\mathcal{O}_n(p_1,\ldots,p_n)\,, \tag{9.17}$$

where the squared tree-level matrix element, $|M_n^2(p_1,\ldots,p_n)|$, including relevant symmetry factors, has been summed over all subprocesses (*e.g.* $e^+e^- \to q\bar{q}q\bar{q}$, $e^+e^- \to q\bar{q}gg$) and has had all factors of α_s extracted in front. In processes other than e^+e^- collisions, the center-of-mass energy of the LO process is generally not fixed, and so the powers of the coupling are often brought inside the integrals, with the scale μ_R chosen event by event, as a function of the event kinematics.

Other than in the simplest cases (see the review on Cross Sections in this *Review*), the matrix elements in Eq. (9.17) are usually calculated automatically with programs such as CompHEP [107], MadGraph [108], Alpgen [109], Comix/Sherpa [110], and Helac/Phegas [111]. Some of these (CompHEP, MadGraph) use formulas obtained from direct evaluations of Feynman diagrams. Others (Alpgen, Helac/Phegas and Comix/Sherpa) use methods designed to be particularly efficient at high multiplicities, such as Berends-Giele recursion [112], which builds up amplitudes for complex processes from simpler ones (see also Refs. [113–116] for reviews on the topic and for other tree-level calculational methods).

The phase-space integration is usually carried out by Monte Carlo sampling, in order to deal with the possibly involved kinematic cuts that are used in the corresponding experimental measurements. Because of the divergences in the matrix element, Eq. (9.16), the integral converges only if the observable vanishes for kinematic configurations in which one of the n particles is arbitrarily soft or it is collinear to another particle. As an example, the cross section for producing any configuration of n partons will lead to an infinite integral, whereas a finite result will be obtained for the cross section for producing n deposits of energy (or jets, see Sec. 9.3.1.1), each above some energy threshold and well separated from each other in angle.

At a practical level, LO calculations can be carried out for $2 \to n$ processes with $n \lesssim 6-10$. The exact upper limit depends on the process, the method used to evaluate the matrix elements (recursive methods are more efficient), and the extent to which the phase-space integration can be optimized to work around the large variations in the values of the matrix elements.

NLO. Given an observable that is non-zero starting from n final-state particles, its prediction at NLO involves supplementing the LO result, Eq. (9.17), with the $2 \to (n+1)$-particle squared tree-level matrix element ($|M_{n+1}^2|$), and the interference of a $2 \to n$ tree-level and $2 \to n$ 1-loop amplitude ($2\mathrm{Re}(M_n M^*_{n,1-\mathrm{loop}})$),

$$\begin{aligned}\sigma_{\mathcal{O}}^{NLO} = \sigma_{\mathcal{O}}^{LO} &+ \alpha_s^{n-1}(\mu_R^2)\int d\Phi_{n+1}|M_{n+1}^2(p_1,\ldots,p_{n+1})|\\ &\times \mathcal{O}_{n+1}(p_1,\ldots,p_{n+1}) + \alpha_s^{n-1}(\mu_R^2)\\ &\times \int d\Phi_n\, 2\mathrm{Re}\,[\, M_n(p_1,\ldots,p_n)\, M^*_{n,1-\mathrm{loop}}(p_1,\ldots,p_n)\,]\\ &\times \mathcal{O}_n(p_1,\ldots,p_n)\,.\end{aligned} \tag{9.18}$$

Relative to LO calculations, two important issues appear in the NLO calculations. Firstly, the extra complexity of loop-calculations relative to tree-level calculations means that automated calculations started to appear only about fifteen years ago (see below). Secondly, loop amplitudes are infinite in 4 dimensions, while tree-level amplitudes are finite, but their *integrals* are infinite, due to the divergences of Eq. (9.16). These two sources of infinities have the same soft and collinear origins and cancel after the integration only if the observable $\mathcal{O}$ satisfies the property of infrared and collinear safety, which means that the observable is non-sensitive to soft emissions or to collinear splittings, *i.e.*

$$\begin{aligned}\mathcal{O}_{n+1}(p_1,\ldots,p_s,\ldots,p_n) &\to \mathcal{O}_n(p_1,\ldots,p_{s-1},p_{s+1},\ldots,p_n)\\ &\quad \text{if } p_s \to 0\\ \mathcal{O}_{n+1}(p_1,\ldots,p_a,p_b,\ldots,p_n) &\to \mathcal{O}_n(p_1,\ldots,p_a+p_b,\ldots,p_n)\\ &\quad \text{if } p_a \,||\, p_b\,.\end{aligned} \tag{9.19}$$

Examples of infrared-safe quantities include event-shape distributions and jet cross sections (with appropriate jet algorithms, see below). Unsafe quantities include the distribution of the momentum of the hardest QCD particle (which is not conserved under collinear splitting), observables that require the complete absence of radiation in some region of phase space (*e.g.* rapidity gaps or 100% isolation cuts, which are affected by soft emissions), or the particle multiplicity (affected by both soft and collinear emissions). The non-cancellation of divergences at NLO due to infrared or collinear unsafety compromises the usefulness not only of the NLO calculation, but also that of a LO calculation, since LO is only an acceptable approximation if one can prove that higher-order terms are smaller. Infrared and collinear unsafety usually also imply large non-perturbative effects.

As with LO calculations, the phase-space integrals in Eq. (9.18) are usually carried out by Monte Carlo integration, so as to facilitate the study of arbitrary observables. Various methods exist to obtain numerically efficient cancellation among the different infinities. These include notably dipole [117], FKS [118] and antenna [119] subtraction.

Thanks to new ideas like the OPP method [120], generalised [121] and D-dimensional [122] unitarity, onshell methods [123], and on the fly reduction algorithms [124], recent years have seen a breakthrough in the calculation of one-loop matrix elements (for reviews on unitarity based method see Ref. [125,126]). Thanks to these innovative methods, automated NLO calculations tools have been developed and a number of programs are available publicly: Madgraph5_aMC@NLO [108] and Helac-NLO [127] provide full frameworks for NLO calculations; GoSam [128], Njet [129], OpenLoops [130] and Recola [131] calculate just the 1-loop part and are typically interfaced with an external tool such as Sherpa [132] for a combination with the appropriate tree-level amplitudes. Other tools such as NLOJet++ [133], MCFM [134], VBFNLO [135], the Phox family [136] or BlackHat [137] implement analytic calculations for a selected class of processes. Given that NLO computation for high-multiplicity final states is numerically demanding, procedures [138–141] have been developed for *a posteriori* PDF and scale change. These methods represent NLO (or NNLO) results, for a given set of cuts and binning, as an effective coefficient function on a grid in parton momentum fractions and factorization scales.

Recently, a lot of attention has also been paid to the calculation of NLO electroweak corrections. Electroweak corrections are especially important for transverse momenta significantly above the W and Z masses, because they are enhanced by two powers of $\ln p_t/M_W$ for each power of the electroweak coupling, and close to Sudakov peaks, where most of the data lie and the best experimental precision can be achieved. In some cases the above programs (or development versions of them) can be used to calculate also NLO electroweak or beyond-standard-model corrections [142–148].

Given the progress in QCD and EW fixed-order computations, the largest unknown from fixed-order corrections is often given by the mixed QCD-electroweak corrections of $\mathcal{O}(\alpha_s\alpha)$. These mixed two-loop corrections are often available only in an approximate form [149–154] and first three-loop results $\mathcal{O}(\alpha_s^2\alpha)$ in the case of Higgs productions started to appear recently [155].

NNLO. Conceptually, NNLO and NLO calculations are similar, except that one must add a further order in α_s, consisting of: the squared $(n+2)$-parton tree-level amplitude, the interference of the $(n+1)$-parton tree-level and 1-loop amplitudes, the interference of the n-parton tree-level and 2-loop amplitudes, and the squared n-parton 1-loop amplitude.

Each of these elements involves large numbers of soft and collinear divergences, satisfying relations analogous to Eq. (9.16) which now involve multiple collinear or soft particles and higher loop orders (see *e.g.* Refs. [156–158]). Arranging for the cancellation of the divergences after numerical Monte Carlo integration has been one of the significant challenges of NNLO calculations, as has been the determination of the relevant 2-loop amplitudes. For the cancellations of divergences a wide range of methods has been developed. Some of them [159–163] retain the approach, inherent in NLO methods, of directly combining the separate loop and tree-level amplitudes. Others combine a suitably chosen, partially inclusive $2 \to n$ NNLO calculation with a fully differential $2 \to n+1$ NLO calculation [164–167].

Quite a number of processes have been calculated differentially at NNLO so far. The state of the art for e^+e^- collisions is $e^+e^- \to$ 3 jets [168–170]. For DIS, dijet production is known at NNLO [171] and the description jet production has been recently pushed even to N^{3}LO using the Projection-to-Born method [172,173]. For hadron colliders, all $2 \to 1$ processes are known, specifically vector boson [174,175] and Higgs boson production [164,176]. For most of the above calculations there exist public codes (EERAD3 for e^+e^-, DYNNLO, FEWZ and MATRIX for W and Z production, Fehipro and HNNLO for Higgs production), links to which are to be found among the above references. Substantial progress has been made in the past couple of years for hadron-collider $2 \to 2$ processes, with calculations having been performed for nearly all relevant processes: ZZ [86] WW [85] and WZ [177], $\gamma\gamma$ [178,179], $Z\gamma$ [180] and $W\gamma$ [181] (many of these colour singlet processes are available also in MCFM [182] or MATRIX [87]), inclusive photon [183,184], $\gamma+$jet [184,185], $W+$jet [165], $Z+$jet [185–187] $H+$jet [188–191], WH [192] and ZH [193], t-channel single-top [194,195], $t\bar{t}$ production [196], dijet production [197], and HH [198] (in large-top-mass approximation, see also the exact (two-loop) NLO result [83]). One $2 \to 3$ process is known at NNLO, Higgs production through vector-boson fusion, using an approximation in which the two underlying DIS-like $q \to qV$ scatterings are factorised, the so-called structure function approximation [167, 199]. Corrections beyond the structure function approximation are expected to be small, on the order of a percent or less [200].

The Les Houches precision wishlist compiles predictions needed to fully exploit the data that will be taken at the High Luminosity LHC [201]. Most of the needed calculations require accuracy of at least NNLO QCD and NLO EW, and many require the prediction of $2 \to 3$ processes, such as $W/Z+ \geq 2$ jets, $H+ \geq 2$ jets, and ttH to NNLO.

As discussed in this section, calculations at NLO can now be relatively easily generated by non-experts using the programs described. However, many NNLO calculations can be too complex and CPU-intensive to allow such an approach. In these cases, the relevant matrix element information can be stored in a grid format (or in ROOT ntuples) allowing predictions to be generated on-the-fly, similar to what has been available at NLO.

9.2.3.3 *Resummation*

Many experimental measurements place tight constraints on emissions in the final state. For example, in e^+e^- events, that (one minus) the Thrust should be less than some value $\tau \ll 1$, or, in $pp \to Z$, events that the Z-boson transverse momentum or the transverse momentum of the accompanying jet should be much smaller than the Z-boson mass. A further example is the production of heavy particles or jets near threshold (so that little energy is left over for real emissions) in DIS and pp collisions.

In such cases, the constraint vetoes a significant part of the integral over the soft and collinear divergence of Eq. (9.16). As a result, there is only a partial cancellation between real emission terms (subject to the constraint) and loop (virtual) contributions (not subject to the constraint), causing each order of α_s to be accompanied by a large coefficient $\sim L^2$, where *e.g.* $L = \ln \tau$ or $L = \ln(M_Z/p_t^Z)$. One ends up with a perturbative series, whose terms go as $\sim (\alpha_s L^2)^n$. It is not uncommon that $\alpha_s L^2 \gg 1$, so that the perturbative series converges very poorly if at all.[5] In such cases one may carry out a "resummation", which accounts for the dominant logarithmically enhanced terms to all orders in α_s, by making use of known properties of matrix elements for multiple soft and collinear emissions, and of the all-orders properties of the divergent parts of virtual corrections, following original works such as Refs. [202–211] and also through soft-collinear effective theory [212, 213] (*cf.* also the section on "Heavy-Quark and Soft-Collinear Effective Theory" in this *Review*, as well as Ref. [214]).

For cases with double logarithmic enhancements (two powers of logarithm per power of α_s), there are two classification schemes for resummation accuracy. Writing the cross section including the constraint as $\sigma(L)$ and the unconstrained (total) cross section as σ_{tot}, the series expansion takes the form

$$\sigma(L) \simeq \sigma_{\text{tot}} \sum_{n=0}^{\infty} \sum_{k=0}^{2n} R_{nk} \alpha_s^n(\mu_R^2) L^k, \qquad L \gg 1\,, \tag{9.20}$$

and leading log (LL) resummation means that one accounts for all terms with $k = 2n$, next-to-leading-log (NLL) includes additionally all terms with $k = 2n-1$, *etc.* Often $\sigma(L)$ (or its Fourier or Mellin transform) *exponentiates* [6],

$$\sigma(L) \simeq \sigma_{\text{tot}} \exp\left[\sum_{n=1}^{\infty} \sum_{k=0}^{n+1} G_{nk} \alpha_s^n(\mu_R^2) L^k\right], \qquad L \gg 1\,, \tag{9.21}$$

where one notes the different upper limit on k ($\leq n+1$) compared to Eq. (9.20). This is a more powerful form of resummation: the G_{12} term alone reproduces the full LL series in Eq. (9.20). With the form Eq. (9.21) one still uses the nomenclature LL, but this now means that all terms with $k = n+1$ are included, and NLL implies all terms with $k = n$, *etc.*

For a large number of observables, NLL resummations are available in the sense of Eq. (9.21) (see Refs. [218–220] and references therein). NNLL has been achieved for the DY and Higgs-boson p_t distributions [221–224] (also available in the CuTe [225], HRes [226] and ResBos [227] families of programs and also differentially in vector-boson decay products [228]) and related variables [229], for the p_t of vector-boson pairs [230], for the back-to-back energy-energy correlation in e^+e^- [231], the jet broadening

[5] To be precise one should be aware of two causes of the divergence of perturbative series. That which interests us here is associated with the presence of a new large parameter (*e.g.* ratio of scales). It is distinct from the "renormalon" induced factorial divergences of perturbation theory which were discussed above.

[6] Whether or not this happens depends on the quantity being resummed. A classic example involves two-jet rate in e^+e^- collisions as a function of a jet-resolution parameter y_{cut}. The logarithms of $1/y_{\text{cut}}$ exponentiate for the k_t (Durham) jet algorithm [215], but not [216] for the JADE algorithm [217] (both are discussed below in Sec. 9.3.1.1).

in e^+e^- collisions [232], the jet-veto survival probability in Higgs and Z boson production in pp collisions [233, 234] [7], an event-shape type observable known as the beam Thrust [235], hadron-collider jet masses in specific limits [236] (see also Ref. [237]), the production of top anti-top pairs near threshold [238–240] (and references therein), and high-p_t W and Z production [241]. Automation of NNLL jet-veto resummations for different processes has been achieved in Ref. [242] (*cf.* also the NLL automation in Ref. [243]), while automation for a certain class of e^+e^- observables has been achieved in Ref. [244]. N^{3}LL resummations are available for the Thrust variable, C-parameter and heavy-jet mass in e^+e^- annihilations [245–247] (confirmed for Thrust at NNLL in Ref. [248]), for p_t distribution of the Higgs boson [249] and weak gauge bosons [250] and for Higgs- and vector-boson production near threshold [251]. An extensive discussion of jet masses for heavy-quark induced jets has been given in Ref. [252] (see also Ref. [253]). In order to make better contact with experimental measurements, recent years have seen an increasing interest in resummations in exclusive phase-space regions and joint resummations [254–260]. Finally, there has also been considerable progress in resummed calculations for jet substructure, whose observables involve more complicated definitions than is the case for standard resummations [261–267], see also Refs. [268, 269]. The inputs and methods involved in these various calculations are somewhat too diverse to discuss in detail here, so we recommend that the interested reader consult the original references for further details.

9.2.3.4 *Fragmentation functions*

Since the parton-hadron transition is non-perturbative, it is not possible to perturbatively calculate quantities such as the energy-spectra of specific hadrons in high-energy collisions. However, one can factorize perturbative and non-perturbative contributions via the concept of fragmentation functions. These are the final-state analogue of the parton distribution functions which are used for initial-state hadrons. Like parton distribution functions, they depend on a (fragmentation) factorization scale and satisfy a DGLAP evolution equation.

It should be added that if one ignores the non-perturbative difficulties and just calculates the energy and angular spectrum of partons in perturbative QCD with some low cutoff scale $\sim \Lambda$ (using resummation to sum large logarithms of $\sqrt{s}/\Lambda$), then this reproduces many features of the corresponding hadron spectra [270]. This is often taken to suggest that hadronization is "local", in this sense it mainly involves partons that are close both in position and in momentum.

Section 19 of this *Review* provides further information (and references) on these topics, including also the question of heavy-quark fragmentation.

9.2.3.5 *Parton-shower Monte Carlo generators*

Parton-shower Monte Carlo (MC) event generators like PYTHIA [271–273], HERWIG [274–276] and SHERPA [132] provide fully exclusive simulations of QCD events.[8] Because they provide access to "hadron-level" events, they are a crucial tool for all applications that involve simulating the response of detectors to QCD events. Here we give only a brief outline of how they work and refer the reader to Sec. 41 and Ref. [278] for a full overview.

The MC generation of an event involves several stages. It starts with the random generation of the kinematics and partonic channels of whatever *hard scattering process* the user has requested at some high scale Q_0 (for complex processes, this may be carried out by an external program). This is followed by a *parton shower*, usually based on the successive random generation of gluon emissions (or $g \to q\bar{q}$ splittings). Emissions are ordered according to some ordering variable. Common choices of scale for the ordering of emissions are virtuality, transverse momentum or angle. Each emission is generated at a scale lower than the previous emission, following a (soft and collinear resummed) perturbative QCD distribution, which depends on the momenta of all previous emissions. Parton showering stops at a scale of order 1 GeV, at which point a *hadronization model* is used to convert the resulting partons into hadrons. One widely-used model involves stretching a color "string" across quarks and gluons, and breaking it up into hadrons [279, 280]. Another breaks each gluon into a $q\bar{q}$ pair and then groups quarks and anti-quarks into colorless "clusters", which then give the hadrons [274]. As both models are tuned primarily to LEP data, the cluster and string models provide similar results for most observables [281]. For pp and γp processes, modeling is also needed to treat the collision between the two hadron remnants, which generates an *underlying event* (UE), usually implemented via additional $2 \to 2$ scatterings ("multiple parton interactions") at a scale of a few GeV, following Ref. [282]. The parameter values for the multiple parton interaction models must be determined from fits to the underlying event levels from LHC collision data. As the different Monte Carlo programs fit to essentially the same data, there should be similar results for each program. One complication, however, is the non-universality of the underlying event for different physics processes.

A deficiency of the soft and collinear approximations that underlie parton showers is that they may fail to reproduce the full pattern of hard wide-angle emissions, important, for example, in many new physics searches. It is therefore common to use LO multi-parton matrix elements to generate hard high-multiplicity partonic configurations as additional starting points for the showering, supplemented with some prescription (CKKW [283], MLM [284]) for consistently merging samples with different initial multiplicities. Monte Carlo generators, as described above, compute cross sections for the requested hard process that are correct at LO.

A wide variety of processes are available in MC implementations that are correct also to NLO, using the MC@NLO [285] or POWHEG [286] prescriptions, notably through the Madgraph5_aMC@NLO [108], POWHEGBox [287] and Sherpa [110] programs. Techniques have also been developed to combine NLO plus shower accuracy for different multiplicities of final-state jets [288]. Building in part on some of that work, several groups have also obtained NNLO plus shower accuracy for Drell-Yan and Higgs production [289], as well as for a handful of $2 \to 2$ processes [290–292].

In general, we expect parton-shower matched predictions to differ from the underlying fixed-order results in regions where (1) there is a large sensitivity to jet shapes (for instance small R jets), (2) there is a restriction in phase space such that soft gluon resummation effects become important, (3) the observable contains multiple disparate scales, (4) there are perturbative instabilities at fixed order, *e.g.* related to kinematical cuts, and (5) the observable is sensitive to higher multiplicity states than those described by the fixed-order calculation [281].

9.2.4 *Accuracy of predictions*

Estimating the accuracy of perturbative QCD predictions is not an exact science. It is often said that LO calculations are accurate to within a factor of two. This is based on experience with NLO corrections in the cases where these are available. In processes involving new partonic scattering channels at NLO and/or large ratios of scales (such as jet observables in processes with vector bosons, or the production of high-p_t jets containing B-hadrons), the ratio of the NLO to LO predictions, commonly called the "K-factor", can be substantially larger than two. NLO corrections tend to be large for processes for which there is a great deal of color annihilation in the interaction. In addition, NLO corrections tend to decrease as more final state legs are added.

For calculations beyond LO, a conservative approach to estimate the perturbative uncertainty is to take it to be the last known perturbative correction; a more widely used method is to estimate it from the change in the prediction when varying the renormalization and factorization scales around a central value Q that is taken close to the physical scale of the process. A conventional range of variation is $Q/2 < \mu_R, \mu_F < 2Q$, varying the two scales independently with the restriction $\frac{1}{2}\mu_R < \mu_F < 2\mu_R$ [293]. This constraint limits the risk of misleadingly small uncertainties due

[7] A veto on the jet phase space can be severe, for example by requiring exactly zero jets above a given transverse momentum cut accompanying a Higgs boson, or relatively mild, for example by placing a transverse momentum cut of 30 GeV on the measurement of the production of a Higgs boson with one or more jets. In general, inclusive cross sections are preferable, as uncertainties on both the theoretical and experimental sides are smaller.

[8] The program ARIADNE [277] has also been widely used for simulating e^+e^- and DIS collisions.

to fortuitous cancellations between the μ_F and μ_R dependence when both are varied together, while avoiding the appearance of large logarithms of μ_R^2/μ_F^2 when both are varied completely independently. Where possible, it can be instructive to examine the two-dimensional scale distributions (μ_R *vs.* μ_F) to obtain a better understanding of the interplay between μ_R and μ_F. This procedure should not be assumed to always estimate the full uncertainty from missing higher orders, but it does indicate the size of one important known source of higher-order ambiguity.[9]

For processes involving jets in the final state, estimates of the uncertainties at NNLO, along the lines described above, can be misleading for jets of smaller radii, due to accidental cancellations. Procedures are available to provide more reasonable estimates of the uncertainties in those cases [281, 302]. In addition, care must be taken as to the form of the central scale [303].

Calculations that involve resummations usually have an additional source of uncertainty associated with the choice of argument of the logarithms being resummed, *e.g.* $\ln(2\frac{p_t^Z}{M_Z})$ as opposed to $\ln(\frac{1}{2}\frac{p_t^Z}{M_Z})$. In addition to varying renormalization and factorization scales, it is therefore also advisable to vary the argument of the logarithm by a suitable factor in either direction with respect to the "natural" argument.

The accuracy of QCD predictions is limited also by non-perturbative corrections, which typically scale as a power of Λ/Q.[10] For measurements that are directly sensitive to the structure of the hadronic final state, the corrections are usually linear in Λ/Q. The non-perturbative corrections are further enhanced in processes with a significant underlying event (*i.e.* in pp and $p\bar{p}$ collisions) and in cases where the perturbative cross sections fall steeply as a function of p_t or some other kinematic variable, for example in inclusive jet spectra or dijet mass spectra. In general, the underlying event for a hard scattering process, such as dijet production, is of a similar order, but somewhat harder, than the average energy density in a minimum-bias event. Under high-luminosity running conditions, such as 13 TeV at the LHC, there can be on the order of 50 minimum-bias interactions occurring at each beam-beam crossing. This additional energy needs to be corrected for, and is typically removed by subtracting a rapidity-dependent transverse energy density determined on an event-by-event basis [304]. This subtraction, of necessity, also removes the underlying event, which must be added back in to restore the measured event to the hadron level.

Non-perturbative corrections are commonly estimated from the difference between Monte Carlo events at the parton level and after hadronization. An issue to be aware of with this procedure is that "parton level" is not a uniquely defined concept. For example, in an event generator it depends on a (somewhat arbitrary and tunable) internal cutoff scale that separates the parton showering from the hadronization. In contrast, no such cutoff scale exists in an NLO or NNLO partonic calculation. There exist alternative methods for estimating hadronization corrections, that attempt to analytically deduce non-perturbative effects in one observable based on measurements of other observables (see the reviews [28, 305]). While they directly address the problem of different possible definitions of parton level, it should also be said that they are far less flexible than Monte Carlo programs and not always able to provide equally good descriptions of the data.

One of the main issues is whether the fixed partonic final state of a NLO or NNLO prediction can match the parton shower in its ability to describe the experimental jet shape (minus any underlying event). NNLO calculations provide a better match to the parton shower predictions than do NLO ones, as might be expected from the additional gluon available to describe the jet shape. The hadronization predictions appear to work for both orders, but at an unknown accuracy. The impact of any error should fall as a power correction.

[9] A number of prescriptions also exist for setting the scale automatically, *e.g.* Refs. [294–298], eliminating uncertainties from scale variation, though not from the truncation of the perturbative series itself. Recently, there have also been studies of how to estimate uncertainties from missing higher orders that go beyond scale variations [299–301].

[10] In some circumstances, the scale in the denominator could be a smaller kinematic or physical scale that depends on the observable.

9.3 Experimental studies of QCD

Since we are not able to directly measure partons (quarks or gluons), but only hadrons and their decay products, a central issue for every experimental study of perturbative QCD is establishing a correspondence between observables obtained at the partonic and the hadronic level. The only theoretically sound correspondence is achieved by means of *infrared and collinear safe* quantities, which allow one to obtain finite predictions at any order of perturbative QCD.

As stated above, the simplest case of infrared- and collinear-safe observables are total cross sections. More generally, when measuring fully inclusive observables, the final state is not analyzed at all regarding its (topological, kinematical) structure or its composition. Basically the relevant information consists in the rate of a process ending up in a partonic or hadronic final state. In e^+e^- annihilation, widely used examples are the ratios of partial widths or branching ratios for the electroweak decay of particles into hadrons or leptons, such as Z or τ decays, (*cf.* Sec. 9.2.1). Such ratios are often favored over absolute cross sections or partial widths because of large cancellations of experimental and theoretical systematic uncertainties. The strong suppression of non-perturbative effects, $\mathcal{O}(\Lambda^4/Q^4)$, is one of the attractive features of such observables, however, at the same time, the sensitivity to radiative QCD corrections is small, which for example affects the statistical uncertainty when using them for the determination of the strong coupling constant. In the case of τ decays not only the hadronic branching ratio is of interest, but also moments of the spectral functions of hadronic tau decays, which sample different parts of the decay spectrum and thus provide additional information. Other examples of fully inclusive observables are structure functions (and related sum rules) in DIS. These are extensively discussed in Sec. 18 of this *Review*.

On the other hand, often the structure or composition of the final state are analyzed and cross sections differential in one or more variables characterizing this structure are of interest. Examples are jet rates, jet substructure, event shapes or transverse momentum distributions of jets or vector bosons in hadron collisions. The case of fragmentation functions, *i.e.* the measurement of hadron production as a function of the hadron momentum relative to some hard scattering scale, is discussed in Sec. 19 of this *Review*.

It is worth mentioning that, besides the correspondence between the parton and hadron level, also a correspondence between the hadron level and the actually measured quantities in the detector has to be established. The simplest examples are corrections for finite experimental acceptance and efficiencies. Whereas acceptance corrections essentially are of theoretical nature, since they involve extrapolations from the measurable (partial) to the full phase space, other corrections such as for efficiency, resolution and response are of experimental nature. For example, measurements of differential cross sections such as jet rates require corrections in order to relate, *e.g.*, the energy deposits in a calorimeter to the jets at the hadron level. Typically detector simulations and/or data-driven methods are used in order to obtain these corrections. Care should be taken here in order to have a clear separation between the parton-to-hadron level and hadron-to-detector level corrections. Finally, for the sake of an easy comparison to the results of other experiments and/or theoretical calculations, it is suggested to provide, whenever possible, measurements corrected for detector effects and/or all necessary information related to the detector response (*e.g.*, the detector response matrix).

9.3.1 *Hadronic final-state observables*

9.3.1.1 *Jets*

In hard interactions, final-state partons and hadrons appear predominantly in collimated bunches, which are generically called *jets*. To a first approximation, a jet can be thought of as a hard parton that has undergone soft and collinear showering and then hadronization. Jets are used both for testing our understanding and predictions of high-energy QCD processes, and also for identifying the hard partonic structure of decays of massive particles such as top quarks and W, Z and Higgs bosons.

In order to map observed hadrons onto a set of jets, one uses a *jet definition*. The mapping involves explicit choices: for example when a gluon is radiated from a quark, for what range of kinematics should the gluon be part of the quark jet, or instead form a separate jet? Good jet definitions are infrared and collinear safe, simple to use in theoretical and experimental contexts, applicable to any type of inputs (parton or hadron momenta, charged particle tracks, and/or energy deposits in the detectors) and lead to jets that are not too sensitive to non-perturbative effects.

An extensive treatment of the topic of jet definitions is given in Ref. [306] (for e^+e^- collisions) and Refs. [307–309]. Here we briefly review the two main classes: cone algorithms, extensively used at older hadron colliders, and sequential recombination algorithms, more widespread in e^+e^- and ep colliders and at the LHC.

Very generically, most (iterative) cone algorithms start with some seed particle i, sum the momenta of all particles j within a cone of opening-angle R, typically defined in terms of rapidity and azimuthal angle. They then take the direction of this sum as a new seed and repeat until the direction of the cone is stable, and call the contents of the resulting stable cone a jet if its transverse momentum is above some threshold $p_{t,\min}$. The parameters R and $p_{t,\min}$ should be chosen according to the needs of a given analysis.

There are many variants of the cone algorithm, and they differ in the set of seeds they use and the manner in which they ensure a one-to-one mapping of particles to jets, given that two stable cones may share particles ("overlap"). The use of seed particles is a problem w.r.t. infrared and collinear safety. Seeded algorithms are generally not compatible with higher-order (or sometimes even leading-order) QCD calculations, especially in multi-jet contexts, as well as potentially subject to large non-perturbative corrections and instabilities. Seeded algorithms (JetCLU, MidPoint, and various other experiment-specific iterative cone algorithms) are therefore to be deprecated. Such algorithms are not used at the LHC, but were at the Fermilab Tevatron, where data still provide useful information, for example for global PDF fits. A modern alternative is to use a seedless variant, SISCone [310].

Sequential recombination algorithms at hadron colliders (and in DIS) are characterized by a distance $d_{ij} = \min(k_{t,i}^{2p}, k_{t,j}^{2p})\Delta_{ij}^2/R^2$ between all pairs of particles i, j, where Δ_{ij} is their separation in the rapidity-azimuthal plane, $k_{t,i}$ is the transverse momentum w.r.t. the incoming beams, and R is a free parameter. At the LHC, R is typically in the range from 0.4 to 0.7. They also involve a "beam" distance $d_{iB} = k_{t,i}^{2p}$. One identifies the smallest of all the d_{ij} and d_{iB}, and if it is a d_{ij}, then i and j are merged into a new pseudo-particle (with some prescription, a recombination scheme, for the definition of the merged four-momentum). If the smallest distance is a d_{iB}, then i is removed from the list of particles and called a jet. As with cone algorithms, one usually considers only jets above some transverse-momentum threshold $p_{t,\min}$. The parameter p determines the kind of algorithm: $p = 1$ corresponds to the (*inclusive*-)k_t algorithm [215, 311, 312], $p = 0$ defines the *Cambridge-Aachen* algorithm [313, 314], while for the *anti-k_t* algorithm $p = -1$ [315]. All these variants are infrared and collinear safe. Whereas the former two lead to irregularly shaped jet boundaries, the latter results in cone-like boundaries. The *anti-k_t* algorithm has become the de-facto standard for the LHC experiments.

In e^+e^- annihilation the k_t algorithm [215] uses $y_{ij} = 2\min(E_i^2, E_j^2)(1 - \cos\theta_{ij})/Q^2$ as distance measure between two particles/partons i and j and repeatedly merges the pair with smallest y_{ij}, until all y_{ij} distances are above some threshold $y_{\rm cut}$, the jet resolution parameter. Q is a measure of the overall hardness of the event. The (pseudo)-particles that remain at this point are called the jets. Here it is $y_{\rm cut}$ (rather than R and $p_{t,\min}$) that should be chosen according to the needs of the analysis. The two-jet rate in the k_t algorithm has the property that logarithms $\ln(1/y_{\rm cut})$ exponentiate. This is one reason why it is preferred over the earlier JADE algorithm [217], which uses the distance measure $y_{ij} = 2\,E_i\,E_j\,(1 - \cos\theta_{ij})/Q^2$. Note that other variants of sequential recombination algorithms for e^+e^- annihilations, using different definitions of the resolution measure y_{ij}, exhibit much larger sensitivities to fragmentation and hadronization effects than the k_t and JADE algorithms [316]. Efficient implementations of the above algorithms are available through the *FastJet* package [317].

9.3.1.2 *Event Shapes*

Event-shape variables are functions of the four momenta of the particles in the final state and characterize the topology of an event's energy flow. They are sensitive to QCD radiation (and correspondingly to the strong coupling) insofar as gluon emission changes the shape of the energy flow.

The classic example of an event shape is the *Thrust* [318, 319] in e^+e^- annihilations, defined as

$$\hat{\tau} = \max_{\vec{n}_\tau} \frac{\sum_i |\vec{p}_i \cdot \vec{n}_\tau|}{\sum_i |\vec{p}_i|}\,, \tag{9.22}$$

where $\vec{p}_i$ are the momenta of the particles or the jets in the final-state and the maximum is obtained for the Thrust axis $\vec{n}_\tau$. In the Born limit of the production of a perfect back-to-back $q\bar{q}$ pair, the limit $\hat{\tau} \to 1$ is obtained, whereas a perfectly spherical many-particle configuration leads to $\hat{\tau} \to 1/2$. Further event shapes of similar nature have been extensively measured at LEP and at HERA, and for their definitions and reviews we refer to Refs. [1, 7, 305, 320, 321]. The energy-energy correlation function [322], namely the energy-weighted angular distribution of produced hadron pairs, and its associated asymmetry are further shape variables which have been studied in detail at e^+e^- colliders. For hadron colliders the appropriate modification consists in only taking the transverse momentum component [323]. More recently, the event shape *N-jettiness* has been proposed [324], that measures the degree to which the hadrons in the final state are aligned along N jet axes or the beam direction. It vanishes in the limit of exactly N infinitely narrow jets.

Phenomenological discussions of event shapes at hadron colliders can be found in Refs. [324–328]. Measurements of hadronic event-shape distributions have been published by CDF [329], ATLAS [330–335] and CMS [336–339].

Event shapes are used for many purposes. These include measuring the strong coupling, tuning the parameters of Monte Carlo programs, investigating analytical models of hadronization and distinguishing QCD events from events that might involve decays of new particles (giving event-shape values closer to the spherical limit).

9.3.1.3 *Jet substructure, quark vs. gluon jets*

Jet substructure, which can be resolved by finding subjets or by measuring jet shapes, is sensitive to the details of QCD radiation in the shower development inside a jet and has been extensively used to study differences in the properties of quark and gluon induced jets, strongly related to their different color charges. In general, there is clear experimental evidence that gluon jets have a softer particle spectrum and are "broader" than (light-) quark jets (as expected from perturbative QCD) when looking at observables such as the jet shape $\Psi(r/R)$. This is the fractional transverse momentum contained within a sub-cone of cone-size r for jets of cone-size R. It is sensitive to the relative fractions of quark and gluon jets in an inclusive jet sample and receives contributions from soft-gluon initial-state radiation and the underlying event. Therefore, it has been widely employed for validation and tuning of Monte Carlo parton-shower models. Furthermore, this quantity turns out to be sensitive to the modification of the gluon radiation pattern in heavy ion collisions (see *e.g.* Ref. [340]).

The most recent jet shape measurements using proton-proton collision data have been presented for inclusive jet samples [341–343] and for top-quark production [344]. Further discussions, references and summaries can be found in Refs. [321, 345, 346] and Sec. 4 of Ref. [347].

The use of jet substructure has also been investigated in order to distinguish QCD jets from jets that originate from hadronic decays of boosted massive particles (high-p_t electroweak bosons, top quarks and hypothesized new particles). A considerable number of experimental studies have been carried out with Tevatron and LHC data, in order to investigate on the performance of the proposed algorithms for resolving jet substructure and to apply them to searches for new physics, as well as to the reconstruction of boosted top quarks, vector bosons and the Higgs boson. For reviews of this rapidly growing field, see sec. 5.3 of Ref. [307], Ref. [348] and Refs. [347,349–352]. Perhaps no other sub-field has benefited as much from machine learning techniques as the study of jet substructure. As a jet can have O(100) constituents each with kinematic and other information, jet substructure analysis is naturally a highly multivariate problem. Deep learning techniques can use all of the available information to study jets in their natural high dimensionality. Such techniques have not only improved discrimination between different final states/types of jets, but have also improved our understanding of perturbative QCD. See for example the review in Ref. [268].

9.3.2 *QCD measurements at colliders*

There exists a wealth of data on QCD-related measurements in e^+e^-, ep, pp, and $p\bar{p}$ collisions, to which a short overview like this would not be able to do any justice. Extensive reviews of the subject have been published in Refs. [320, 321] for e^+e^- colliders and in Ref. [353] for ep scattering, whereas for hadron colliders comprehensive overviews are given in, *e.g.*, Refs. [308, 346] and Refs. [2, 354–356].

Below we concentrate our discussion on measurements that are most sensitive to hard QCD processes with focus on jet production.

9.3.2.1 e^+e^- *colliders*

Analyses of jet production in e^+e^- collisions are mostly based on data from the JADE experiment at center-of-mass energies between 14 and 44 GeV, as well as on LEP collider data at the Z resonance and up to 209 GeV. The analyses cover the measurements of (differential or exclusive) jet rates (with multiplicities typically up to 4, 5 or 6 jets), the study of 3-jet events and particle production between the jets, as well as 4-jet production and angular correlations in 4-jet events.

Event-shape distributions from e^+e^- data have been an important input to the tuning of parton shower MC models, typically matched to matrix elements for 3-jet production. In general these models provide good descriptions of the available, highly precise data. Especially for the large LEP data sample at the Z peak, the statistical uncertainties are mostly negligible and the experimental systematic uncertainties are at the percent level or even below. These are usually dominated by the uncertainties related to the MC model dependence of the efficiency and acceptance corrections (often referred to as "detector corrections").

Observables measured in e^+e^- collisions have been used for determinations of the strong coupling constant (*cf.* Section 9.4 below) and for putting constraints on the QCD color factors (*cf.* Sec. 9.1 for their definitions), thus probing the non-Abelian nature of QCD. Typically, cross sections can be expressed as functions of these color factors, for example $\sigma = f(\alpha_s C_F, C_A/C_F, n_f T_R/C_F)$. Angular correlations in 4-jet events give sensitivity at leading order. Some sensitivity to these color factors, although only at NLO, is also obtained from event-shape distributions. Scaling violations of fragmentation functions and the different subjet structure in quark and gluon induced jets also give access to these color factors. In order to extract absolute values, *e.g.* for C_F and C_A, certain assumptions have to be made for other parameters, such as T_R, n_f or α_s, since typically only combinations (ratios, products) of all the relevant parameters appear in the perturbative predictions. A compilation of results [321] quotes world average values of $C_A = 2.89 \pm 0.03(\text{stat}) \pm 0.21(\text{syst})$ and $C_F = 1.30 \pm 0.01(\text{stat}) \pm 0.09(\text{syst})$, with a correlation coefficient of 82%. These results are in perfect agreement with the expectations from SU(3) of $C_A = 3$ and $C_F = 4/3$.

9.3.2.2 *DIS and photoproduction*

Jet measurements in ep collisions, both in the DIS and photoproduction regimes, allow for tests of QCD factorization (as they involve only one initial state proton and thus one PDF function), and provide sensitivity to both the gluon distribution and to the strong coupling constant. Calculations are available at NNLO in both regimes [357, 358]. Experimental uncertainties of the order of 5–10% have been achieved, mostly dominated by the jet energy scale, whereas statistical uncertainties are negligible to a large extent. For comparison to theoretical predictions, at large jet p_t the PDF uncertainty dominates the theoretical uncertainty (typically of order 5–10%, in some regions of phase space up to 20%), therefore jet observables become useful inputs for PDF fits.

In general, the data are well described by the NLO and NNLO matrix-element calculations, combined with DGLAP evolution equations, in particular at large Q^2 and central values of jet pseudo-rapidity. At low values of Q^2 and x, in particular for large jet pseudo-rapidities, certain features of the data have been interpreted as requiring BFKL-type evolution, though the predictions for such schemes are still limited. It is worth noting that there is lack of consensus throughout the community regarding this need of BFKL-evolution at currently probed x, Q^2 values, and an alternative approach [359], which implements the merging of LO matrix-element based event generation with a parton shower (using the SHERPA framework), successfully describes the data in all kinematical regions, including the low Q^2, low x domain. At moderately small x values, it should perhaps not be surprising that the BFKL approach and fixed-order matrix-element merging with parton showers may both provide adequate descriptions of the data, because some part of the multi-parton phase space that they model is common to both approaches.

In the case of photoproduction, a wealth of measurements with low p_t jets were performed in order to constrain the photon content of the proton. The uncertainties related to such photon PDFs play a minor role at high jet p_t, which has allowed for precise tests of pQCD calculations.

A few examples of recent measurements can be found in Refs. [360–364] for photoproduction and in Refs. [365–374] for DIS.

9.3.2.3 *Hadron-hadron colliders*

The spectrum of observables and the number of measurements performed at hadron colliders is enormous, probing many regions of phase space and covering a huge range of cross sections, as illustrated in Fig. 9.1 for the case of the ATLAS and CMS experiments at the LHC. In general, the theory agreement with data is excellent for a wide variety of processes, indicating the success of perturbative QCD with the PDF and strong coupling inputs. For the sake of brevity, in the following only certain classes of those measurements will be discussed, which allow addressing particular aspects of the various QCD studies performed. Most of our discussion will focus on LHC results, which are available for center-of-mass energies of 2.76, 5, 7, 8 and 13 TeV with integrated luminosities of up to 140 fb^{-1}. Generally speaking, besides representing a general test of the standard model and QCD in particular, these measurements serve several purposes, such as: (i) probing pQCD and its various approximations and implementations in MC models, in order to quantify the order of magnitude of not yet calculated contributions and to gauge their precision when used as background predictions, or (ii) extracting/constraining model parameters such as the strong coupling constant or PDFs. Indeed, data from the LHC is becoming increasingly important for the determination of both, PDFs and the strong coupling constant.

The final states measured at the LHC include single, double and triple gauge boson production, top production (single top, top pair and four top production), Higgs boson production, alone and in conjunction with a W or Z boson, and with a top quark pair. Many/most of these events are accompanied by additional jets. So far only relatively loose limits have been placed on double Higgs production. The volume of LHC results prohibits a comprehensive description in this *Review*; hence, only a few highlights will be presented.

Among the most important cross sections measured, and the one with the largest dynamic range, is the inclusive jet spectrum as a function of the jet transverse momentum (p_t), for several rapidity regions and for p_t up to 700 GeV at the Tevatron and ~ 3.5 TeV at the LHC. It is worth noting that this upper limit in p_t corresponds to a distance scale of $\sim 10^{-19}$ m: no other experiment so far is able to directly probe smaller distance scales of nature than this measurement. The Tevatron inclusive jet measurements in Run 2 (Refs. [377–380]) were carried out with the MidPoint jet clustering algorithm (or its equivalent) and with the k_t jet

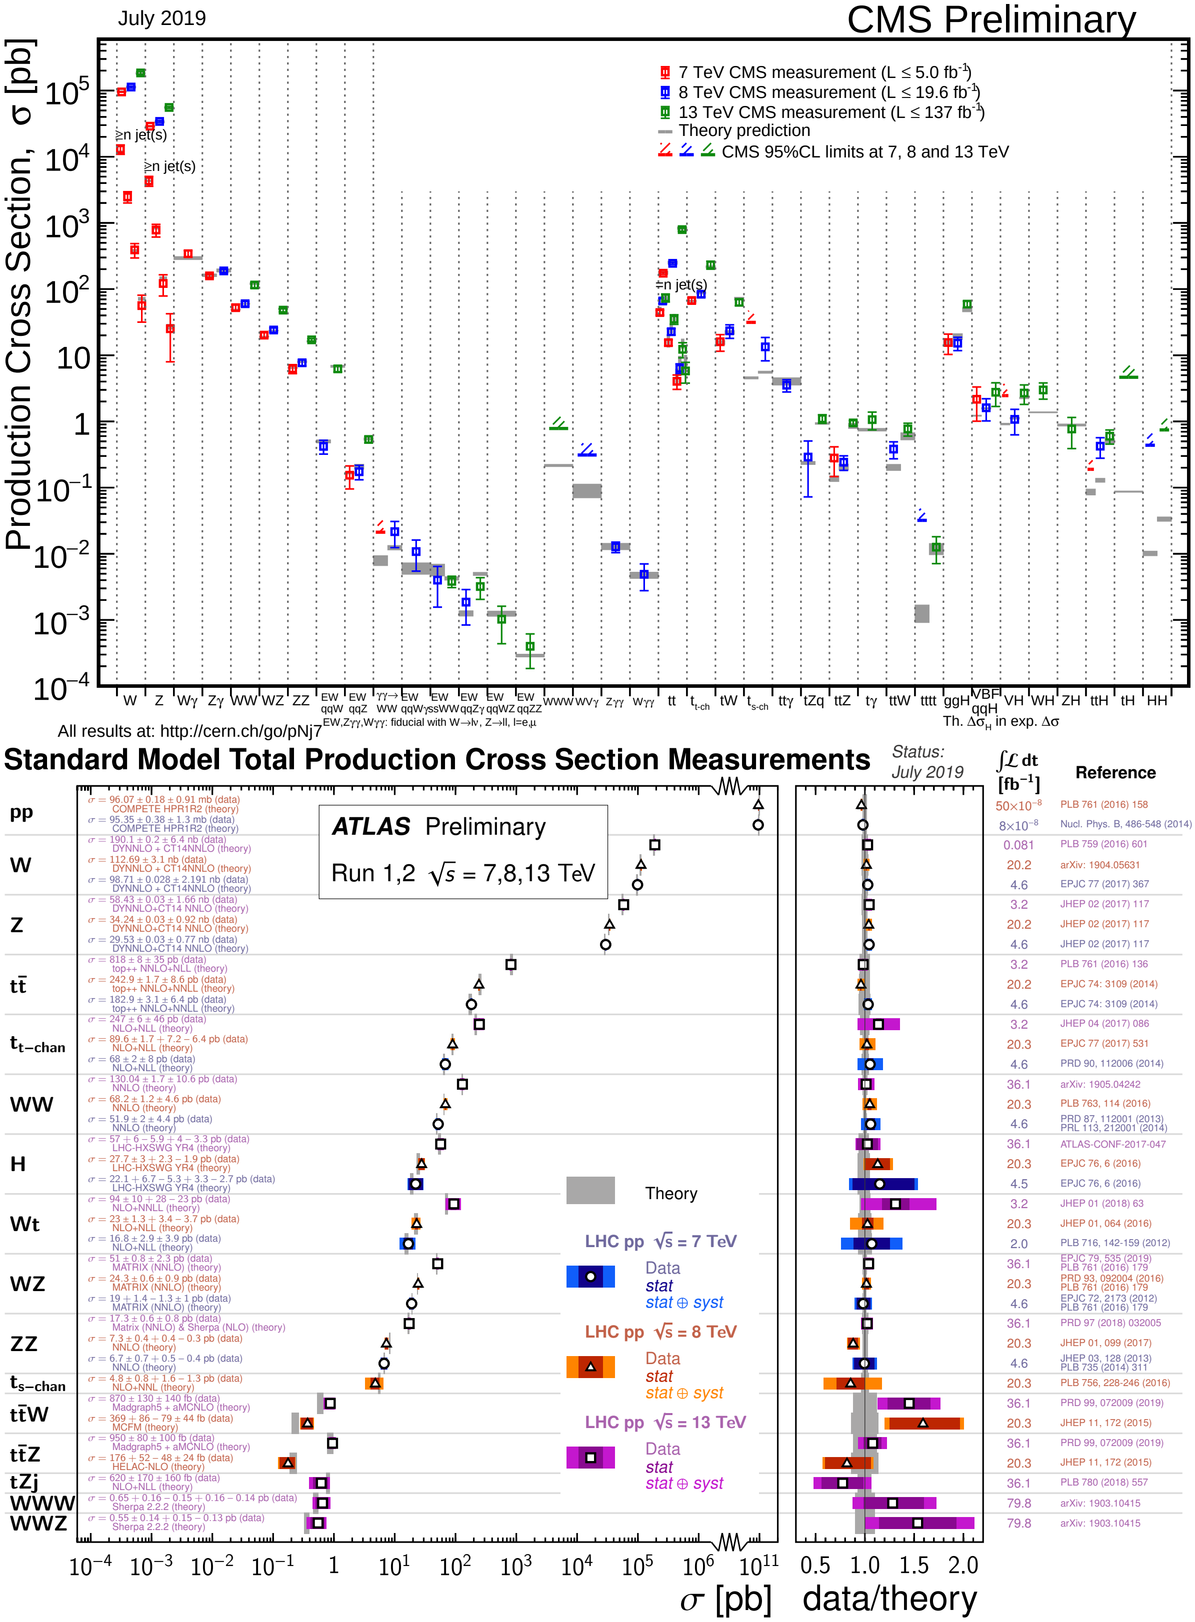

Figure 9.1: Overview of cross section measurements for a wide class of processes and observables, as obtained by the CMS [375] and ATLAS [376] experiments at the LHC, for centre-of-mass energies of 7, 8 and 13 TeV. Also shown are the theoretical predictions and their uncertainties.

clustering algorithm. Most of the LHC measurements use the *anti-*k_t algorithm, with a variety of jet radii. The use of multiple jet radii in the same analysis allows a better understanding of the underlying QCD dynamics. Measurements by ALICE, ATLAS and CMS have been published in Refs. [381–389].

In general, we observe a good description of the data by the NLO and NNLO QCD predictions over about 11 orders of magnitude in cross section. as long as care is taken for the form of the central scale choice [303]. The experimental systematic uncertainties are dominated by the jet energy scale uncertainty, quoted to be in the range of a few percent (see for instance the review in Ref. [390]), leading to uncertainties of $\sim 5-30\%$ on the cross section, increasing with p_t and rapidity. The PDF uncertainties dominate the theoretical uncertainty at large p_t and rapidity. In fact, inclusive jet data are one of the most important inputs to global PDF fits, in particular for constraining the high-x gluon PDF [77, 391]. Constraints on the PDFs can also be obtained from ratios of inclusive cross sections at different center-of-mass energies [382, 387]. In general, ratios of jet cross sections are a means to (at least partially) cancel the jet energy scale uncertainties and thus provide jet observables with significantly improved precision.

Dijet events are analyzed in terms of their invariant mass or average dijet p_t and angular distributions, which allows for tests of NLO and NNLO QCD predictions (see *e.g.* Refs. [386,392,393] for recent LHC results), and for setting stringent limits on deviations from the Standard Model, such as quark compositeness or contact interactions (some examples can be found in Refs. [389,394–400]). Furthermore, dijet azimuthal correlations between the two leading jets, normalized to the total dijet cross section, are an extremely valuable tool for studying the spectrum of gluon radiation in the event. The azimuthal separation of the two leading jets is sensitive to multi-jet production, avoiding at the same time large systematic uncertainties from the jet energy calibration. For example, results from the Tevatron [401, 402] and the LHC [335, 403–407] show that the LO (non-trivial) prediction for this observable, with at most three partons in the final state, is not able to describe the data for an azimuthal separation below $2\pi/3$, where NLO contributions (with 4 partons) restore the agreement with data. In addition, this observable can be employed to tune Monte Carlo predictions of soft gluon radiation. Further examples of dijet observables that probe special corners of phase space are those that involve forward (large rapidity) jets and where a large rapidity separation, possibly also a rapidity gap, is required between the two jets. Reviews of such measurements can be found in Ref. [346], showing that no single prediction is capable of describing the data in all phase-space regions. In particular, no conclusive evidence for BFKL effects in these observables has been established so far.

Beyond dijet final states, measurements of the production of three or more jets, including cross section ratios, have been performed (see Refs. [346,408] for recent reviews), as a means of testing perturbative QCD predictions, determining the strong coupling constant (at NLO precision so far), and probing/tuning MC models, in particular those combining multi-parton matrix elements with parton showers.

W and Z production serve as benchmark cross sections at the LHC. The large boson mass provides a stability for the perturbative predictions which results in better theoretical precision. In terms of experimental precision, measurements of inclusive vector boson (W, Z) production provide the most precisely determined observables at hadron colliders so far. This is because the experimental signatures are based on leptons which are measured much more accurately than jets or photons. At the LHC [409–416], the dominant uncertainty stems from the luminosity determination ($\lesssim$2–4%), while other uncertainties (*e.g.* statistics, lepton efficiencies) are controlled at the $\sim$0.5–3% level. The uncertainty from the acceptance correction of about $\sim$1–2% can be reduced by measuring so-called fiducial cross sections, ie. by applying kinematic cuts also to the particle level of the theoretical predictions. A further reduction or even complete elimination of particular uncertainties (*e.g.* luminosity) is achieved by measuring cross section ratios (W/Z or W^+/W^-) or differential distributions that are normalised to the inclusive cross section. On the theory side, as discussed earlier in this *Review*, the production of these color-singlet states has been calculated up to NNLO accuracy, with some progress towards N^{3}LO. Since the dominant theoretical uncertainty is related to the choice of PDFs, these high-precision data provide useful handles for PDF determinations.

Further insights are obtained from measurements of differential vector boson production, as a function of the invariant dilepton mass, the boson's rapidity or its transverse momentum. For example, the dilepton invariant mass distribution has been measured [417–422] for masses between 15 and 3000 GeV, covering more than 8 orders of magnitude in cross section. NNLO QCD predictions, together with modern PDF sets and including higher-order electroweak and QED final-state radiation corrections, describe the data to within 5–10% over this large range, whereas NLO predictions show larger deviations, unless matched to a parton shower.

Similar conclusions can be drawn from the observed rapidity distribution of the dilepton system (see *e.g.* Refs. [409, 418, 423]) or, in the case of W production, from the observed charged lepton rapidity distribution and its charge asymmetry. The latter is particularly sensitive to differences among PDF sets [409, 424–426], also thanks to the high precision achieved by the ATLAS and CMS experiments for central rapidity ranges. These measurements are nicely extended to the very forward region, up to 4.5 in lepton rapidity, by the LHCb experiment.

An overview of this kind of measurements can be found in Ref. [346]. There one can also find a discussion of and references to LHC results from studies of the vector boson's transverse momentum distribution, p_t^V (see also Refs. [427–429]). This observable covers a wide kinematic range and probes different aspects of higher-order QCD effects. It is sensitive to jet production in association with the vector boson, without suffering from the large jet energy scale uncertainties. In the p_t^V region of several tens of GeV to over 1 TeV, the NNLO predictions for V+jet [11] can be used to predict the high p_t boson transverse cross section. The NNLO predictions agree with the data to within about 10%, and agree somewhat better at high transverse momentum than do the NLO predictions [430]. At transverse momenta below $\sim$20 GeV, the fixed-order predictions fail and soft-gluon resummation is needed to restore the agreement with data. The soft gluon resummation can either be performed analytically, or effectively using parton showering implemented in Monte Carlo programs.

The addition of jets to the final state extends the kinematic range as well as increasing the complexity of the calculation/measurements.[12] The number of results obtained both at the Tevatron and at the LHC is extensive. Recent summaries can be found in Refs. [346, 432]. Some more recent results can be found in Refs. [430, 433–436].

The measurements cover a very large phase space, *e.g.* with jet transverse momenta between 30 GeV and $\sim$ 1.5 TeV and jet rapidities up to $|y| < 4.4$ [430]. Jet multiplicities as high as seven jets accompanying the vector boson have already been probed at the LHC, together with a substantial number of other kinematical observables, such as angular correlations among the various jets or among the jets and the vector boson, or the sum of jet transverse momenta, H_T. Whereas the jet p_t and H_T distributions are dominated by jet energy scale uncertainties at levels similar to those discussed above for inclusive jet production, angular correlations and jet multiplicity ratios have been measured with a precision of $\sim$ 10%, see *e.g.* Refs. [337, 437].

NLO calculations for up to five jets [438] in addition to the vector boson are in good agreement with the data over that phase space, where the calculations are applicable; that is, one can not expect such predictions to work for *e.g.* the p_t distribution of the $n+1$st jet with $V+n$ jets calculated at NLO. However, with the higher kinematic reach achieved by the LHC experiments, some more detailed observations can be made. NLO fixed-order predictions describe the W boson p_t distribution and the lead jet p_t distribution reasonably well at transverse momenta below around 500 GeV, but predict smaller cross sections than the data at higher transverse momenta. Predictions for V+jet at NNLO improve the description of the data. MC models that implement parton shower matching to matrix elements (either at LO or NLO) have mixed results.

The challenges get even more severe in the case of vector boson plus heavy quark (b, c) production, both because of theoretical

[11] For these calculations, there is a requirement of the presence of a jet, but the p_t cut is typically small (30 GeV) compared to the high p_t region being discussed here.

[12] For reliable predictions, the scale used in the higher order calculations should be proportional to the sum of the transverse momenta of all of the objects in the final state [431].

issues (an additional scale is introduced by the heavy quark mass and different schemes exist for the handling of heavy quarks and their mass effects in the initial and/or final state) and because of additional experimental uncertainties related to the heavy-flavour tagging. A review of heavy quark production at the LHC can be found in Ref. [439]. There it is stated that studies of b-jet production with or without associated W and Z bosons reveal the di-b-jet p_t and mass spectra to be well modelled, within experimental and theoretical uncertainties, by most generators on the market. However, sizable differences between data and predictions are seen in the modelling of events with single b jets, particularly at large b-jet p_t, where gluon splitting processes become dominant, as also confirmed by studies of b-hadron and b-jet angular correlations.

The precision reached in photon measurements is in between that for lepton and jet measurements. The photon 4-vectors can be measured at about the same precision as the lepton 4-vectors in Drell-Yan production, but there are greater challenges encountered in photon reconstruction (for example isolation) and in purity determination. Note, though, that the photon purity approaches unity as the photon p_t increases. At high p_t, it becomes increasingly difficult for a jet to fragment into an isolated neutral electromagnetic cluster which mimics the photon signature. The inclusive photon cross section can be measured [392, 440–443], as well as the production of a photon accompanied by one or more jets [443–445, 445–448]. The kinematic range for photon production is less than that for jet production because of the presence of the electromagnetic coupling, but still reaches about 2 TeV. Better agreement is obtained with NNLO predictions for photon production than for NLO predictions, except when the latter are matched to matrix element plus parton shower predictions. Photon production in association with a heavy-flavor jet is a useful input for the determination of the b and c quark PDFs [449].

Electroweak corrections are expected to become more and more relevant now that the TeV energy range starts to be explored. For example, such corrections were found [450] to be sizable (tens of percent) when studying the ratio $(d\sigma^{\gamma}/dp_t)/(d\sigma^{Z}/dp_t)$ in $\gamma\,(Z)$+jet production, p_t being the boson's transverse momentum, and might account for (some of) the differences observed in a CMS measurement [451] of this quantity.

A number of interesting developments, in terms of probing higher-order QCD effects, have occurred in the sector of diboson production, in particular for the WW and $\gamma\gamma$ cases. Regarding the former, an early disagreement of about 10% between the LHC measurements and the NLO predictions had led to a number of speculations of possible new physics effects in this channel. However, more recent ATLAS and CMS measurements [452–455] are in agreement with the NNLO prediction [85]. The statistical reach of the LHC has resulted in evidence for triple massive gauge boson production [456].

In the case of diphoton production, ATLAS [457, 458] and CMS [459] have provided accurate measurements, in particular for phase-space regions that are sensitive to radiative QCD corrections (multi-jet production), such as small azimuthal photon separation. While there are large deviations between data and NLO predictions in this region, a calculation [178] at NNLO accuracy manages to mostly fill this gap. This is an interesting example where scale variations can not provide a reliable estimate of missing contributions beyond NLO, since at NNLO new channels appear in the initial state (gluon fusion in this case). These missing channels can be included in a matrix element plus parton shower calculation in which two additional jets are included at NLO. The result is a similar level of agreement as that obtained at NNLO. Three photon production has also been measured [460].

In terms of heaviest particle involved, top-quark production at the LHC has become an important tool for probing higher-order QCD calculations, thanks to very impressive achievements both on the experimental and theoretical side, as extensively summarised in Ref. [461]. Regarding $t\bar{t}$ production, the most precise inclusive cross section measurements are achieved using the dilepton $(e\,\mu)$ final state, with a total uncertainty of 4% [462–465]. This is of about the same size as the uncertainty on the most advanced theoretical predictions [84, 466–468], obtained at NNLO with additional soft-gluon resummation at NNLL accuracy [469]. There is excellent agreement between data and the QCD predictions.

The $t\bar{t}$ final state allows multiple observables to be measured. A large number of differential cross section measurements have been performed at 7, 8 and 13 TeV centre-of-mass energy, studying distributions such as the top-quark p_t and rapidity, the transverse momentum and invariant mass of the $t\bar{t}$ system (probing scales up to the TeV range), or the number of additional jets. These measurements have been compared to a wide range of predictions, at fixed order up to NNLO as well as using LO or NLO matrix elements matched to parton showers. Each of the observables provides information on the high x gluon and have been used in global PDF fits. While in general there is reasonable agreement observed with data, most MC simulations predict a somewhat harder top-quark p_t distribution than seen in data.

Thanks to both the precise measurements of, and predictions for, the inclusive top-pair cross section, which is sensitive to the strong coupling constant and the top-quark mass, this observable has been used to measure the strong coupling constant at NNLO accuracy from hadron collider data [470, 471] (*cf.* Section 9.4 below), as well as to obtain a measurement of the top-quark's pole mass without employing direct reconstruction methods [470, 472, 473].

The Higgs boson lends itself to being a tool for QCD studies, especially as the dominant production mechanism is gg fusion, which is subject to very large QCD corrections. Higgs boson production has been measured in the ZZ, $\gamma\gamma$, WW and $\tau\tau$ decay channels. The experimental cross section is now known with a precision approaching 10% [474, 475], similar to the size of the theoretical uncertainty [92], of which the PDF+α_s uncertainty is the largest component. The experimental precision has allowed detailed fiducial and differential cross section measurements. For example, with the diphoton final state, the transverse momentum of the Higgs boson can be measured out to 350-400 GeV [476, 477], where top quark mass effects become important. The production of a Higgs boson with up to 4 jets has been measured [476, 478]. The experimental cross sections have been compared to NNLO predictions (for $H+\geq 1$ jet), NLO for 2 and 3 jets, and NNLO+NNLL for the transverse momentum distribution. In addition, finite top quark mass effects have been taken into account at NLO. The use of the boosted $H \to b\bar{b}$ topology allows probes of Higgs boson transverse momenta on the order of 600 GeV [478]. So far the agreement with the perturbative QCD corrections is good.

9.4 Determinations of the strong coupling constant

Beside the quark masses, the only free parameter in the QCD Lagrangian is the strong coupling constant α_s. The coupling constant in itself is not a physical observable, but rather a quantity defined in the context of perturbation theory, which enters predictions for experimentally measurable observables, such as R in Eq. (9.7). The value of the strong coupling constant must be inferred from such measurements and is subject to experimental and theoretical uncertainties. The incomplete knowledge of α_s propagates into uncertainties in numerous precision tests of the Standard Model. Here we present an update of the 2016 PDG average value of $\alpha_s(M_Z^2)$ and its uncertainty [479], which were retained in the 2018 edition of this *Review* [480].[13]

Many experimental observables are used to determine α_s. A number of recent determinations are collected in Ref. [484]. Further discussions and considerations on determinations of α_s can also be found in Refs. [485, 486]. Such considerations include:

- The observable's sensitivity to α_s as compared to the experimental precision. For example, for the e^+e^- cross section to hadrons (*cf.* R in Sec. 9.2.1), QCD effects are only a small correction, since the perturbative series starts at order α_s^0; 3-jet production or event shapes in e^+e^- annihilations are directly sensitive to α_s since they start at order α_s; the hadronic decay width of heavy quarkonia, $\Gamma(\Upsilon \to \text{hadrons})$, is very sensitive to α_s since its leading order term is $\propto \alpha_s^3$.

[13]♯ The time evolution of α_s combinations can be followed by consulting Refs. [481–483] as well as earlier editions of this *Review*.

- The accuracy of the perturbative prediction, or equivalently of the relation between α_s and the value of the observable. The minimal requirement is generally considered to be an NLO prediction. Some observables (many inclusive ones as well as 3-jet rates and event shapes in e^+e^- collisions) are known to NNLO since quite some time. Recent additions to the list of processes calculated up to NNLO comprise inclusive jet and dijet production in DIS and pp or $p\bar{p}$ collisions. Likewise, $t\bar{t}$ and W/Z+jet production cross sections have been computed up to NNLO for pp and $p\bar{p}$ scattering. The e^+e^- hadronic cross section and τ branching fraction to hadrons are even known to N^{3}LO, where one denotes the LO as the first non-trivial term. In certain cases, fixed-order predictions are supplemented with resummation. The precise magnitude of the associated theory uncertainties usually is estimated as discussed in Sec. 9.2.4.
- The size of non-perturbative effects. Sufficiently inclusive quantities, like the e^+e^- cross section to hadrons, have small non-perturbative contributions $\sim \Lambda^4/Q^4$. Others, such as event-shape distributions, have typically contributions $\sim \Lambda/Q$.
- The scale at which the measurement is performed. An uncertainty δ on a measurement of $\alpha_s(Q^2)$, at a scale Q, translates to an uncertainty $\delta' = (\alpha_s^2(M_Z^2)/\alpha_s^2(Q^2)) \cdot \delta$ on $\alpha_s(M_Z^2)$. For example, this enhances the already important impact of precise low-Q measurements, such as from τ decays, in combinations performed at the M_Z scale.

The selection of results from which to determine the world average value of $\alpha_s(M_Z^2)$ is restricted to those that are

- published in a peer-reviewed journal at the time of writing this report,
- based on the most complete perturbative QCD predictions of at least NNLO accuracy,
- accompanied by reliable estimates of all experimental and theoretical uncertainties.

We note that all determinations of $\alpha_s(M_Z^2)$ entering the average of the lattice gauge community as summarised comprehensively in the FLAG2019 report [487] are published in peer-reviewed journals, although the FLAG report itself that only describes the averaging procedure is not.

We also note that a prediction in perturbative QCD for the determination of $\alpha_s(M_Z^2)$ at NNLO accuracy requires the calculation of at least three consecutive terms in powers $p > 0$ of α_s^p. Although this condition is fulfilled, measurements from jet production in DIS and at hadron colliders (with one exception) are still excluded, because the determination of $\alpha_s(M_Z^2)$ has not yet been upgraded to NNLO. Nevertheless, the NLO analyses will be discussed in this *Review*, as they are important ingredients for the experimental evidence of the energy dependence of α_s, *i.e.* for Asymptotic Freedom, one of the key features of QCD.

In order to calculate the world average value of $\alpha_s(M_Z^2)$, as in earlier editions we apply an intermediate step of pre-averaging results within the sub-fields now labelled "Hadronic τ decays and low Q^2 continuum" (τ decays and low Q^2), "Heavy quarkonia decays" ($Q\bar{Q}$ bound states), "Deep-inelastic scattering and global PDF fits" (DIS & PDF fits), "Hadronic final states of e^+e^- annihilations" (e^+e^- jets & shapes), "Hadron collider results" (hadron collider), and "Electroweak precision fit" (electroweak) as explained in the following sections. For each sub-field, the *unweighted average* of all selected results is taken as the pre-average value of $\alpha_s(M_Z^2)$, and the unweighted average of the quoted uncertainties is assigned to be the respective overall error of this pre-average.[14] At variance with previous reviews, for the "Lattice QCD" (lattice) sub-field we do not perform a pre-averaging; instead, we adopt for this sub-field the FLAG2019 average value and uncertainty derived in Ref. [487].

Assuming that the six sub-fields (excluding lattice) are largely independent of each other, we determine a non-lattice world average value using a 'χ^2 *averaging*' method. In a last step we perform an unweighted average of the values and uncertainties of $\alpha_s(M_Z^2)$ from our non-lattice result and the lattice result presented in the FLAG 2019 report [487].

9.4.1 *Hadronic τ decays and low Q^2 continuum:*

Based on complete N^{3}LO predictions [36], analyses of the τ hadronic decay width and spectral functions have been performed, *e.g.* in Refs. [36,488–493], and lead to precise determinations of α_s at the energy scale of M_τ^2. They are based on different approaches to treat perturbative and non-perturbative contributions, the impacts of which have been a matter of intense discussions since a long time, see *e.g.* Refs. [492–495]. In particular, in τ decays there is a significant difference between results obtained using fixed-order (FOPT) or contour improved perturbation theory (CIPT), such that analyses based on CIPT generally arrive at larger values of $\alpha_s(M_\tau^2)$ than those based on FOPT. In addition, some results show differences in $\alpha_s(M_\tau^2)$ between different groups using the same data sets and perturbative calculations, most likely due to different treatments of the non-perturbative contributions, *cf.* Ref. [493] with Refs. [492, 496].

Here, we largely keep the same input calculations as in the previous review, with only the following changes. The result of Ref. [492] has been replaced by the one of Ref. [495]. From Ref. [493] we use the values resulting from a combination of ALEPH and OPAL data instead of ALEPH data alone. Moreover, we include the new α_s determination obtained from $R(s)$ below the charm threshold [497]. Here, the average from the FOPT and CIPT results gives $\alpha_s(M_\tau^2) = 0.301 \pm 0.019$, where the difference between the two amounts to 2% at m_τ. This corresponds to $\alpha_s(M_Z^2) = 0.1162 \pm 0.0025$.

In summary, we determine the pre-average value of $\alpha_s(M_Z^2)$ for this sub-field from studies that employ both FOPT and CIPT expansions, and that account for the difference among these in the quoted overall uncertainty: $\alpha_s(M_Z^2) = 0.1202 \pm 0.0019$ [36], $\alpha_s(M_Z^2) = 0.1199 \pm 0.0015$ [496], $\alpha_s(M_Z^2) = 0.1175 \pm 0.0017$ [493], $\alpha_s(M_Z^2) = 0.1197 \pm 0.0015$ [495], and $\alpha_s(M_Z^2) = 0.1162 \pm 0.0025$ [497]. Additionally, we include the result from τ decay and lifetime measurements, obtained in Sec. *Electroweak Model and constraints on New Physics* of the 2018 edition of this *Review*, $\alpha_s(M_Z^2) = 0.1184 \pm 0.0019$. The latter result, being a global fit of τ data, involve some correlations with the other extractions of this category. However, since we perform an unweighted average of the central value and uncertainty, we do not need to worry about double counting.

All these results are summarised in Fig. 9.2. Determining the unweighted average of the central values and their overall uncertainties, we arrive at $\alpha_s(M_Z^2) = 0.1187 \pm 0.0018$, which we will use as the first input for determining the world average value of $\alpha_s(M_Z^2)$. This corresponds to $\alpha_s(M_\tau^2) = 0.325 \pm 0.016$.

9.4.2 *Heavy quarkonia decays:*

For a long time, the best determination of the strong coupling constant from radiative Υ decays was the one of Ref. [498], which resulted in $\alpha_s(M_Z^2) = 0.119^{+0.006}_{-0.005}$. This determination is based on QCD at NLO only, so it will not be considered for the final extraction of the world average value of α_s; it is, however, an important ingredient for the demonstration of Asymptotic Freedom as given in Fig. 9.3. More recently, two determinations have been performed [499, 500] that are based on N^{3}LO accurate predictions. Reference [499] performs a simultaneous fit of the strong coupling and the bottom mass $\overline{m_b}$, including states with principal quantum number up to $n \leq 2$ in order to break the degeneracy between α_s and $\overline{m_b}$, finding $\alpha_s(M_Z^2) = 0.1178 \pm 0.0051$. Reference [500] instead uses as input of the fit the renormalon-free energy combination of B_c and bottomonium η_b and charmonium η_c, $M_{B_c} - M_{\eta_b}/2 - M_{\eta_c}/2$, which is weakly dependent on the heavy quark masses, but shows a good dependence on α_s. Using this observable, they obtain $\alpha_s(M_Z^2) = 0.1178 \pm 0.0051$. These two determinations satisfy our criteria to be included in the world

[14] In the previous review, if this error appeared to be smaller than the unweighted standard deviation - *i.e.* the *spread* - of the results, the standard deviation was taken as the overall uncertainty instead. This was done in order to arrive at an unbiased estimator of the average value of $\alpha_s(M_Z^2)$ from a given sub-field, and to avoid that singular, optimistic estimates of systematic uncertainties unduly bias the uncertainty of the sub-field average. Here we find that, for all six sub-fields, the quoted error is larger than the standard deviation.

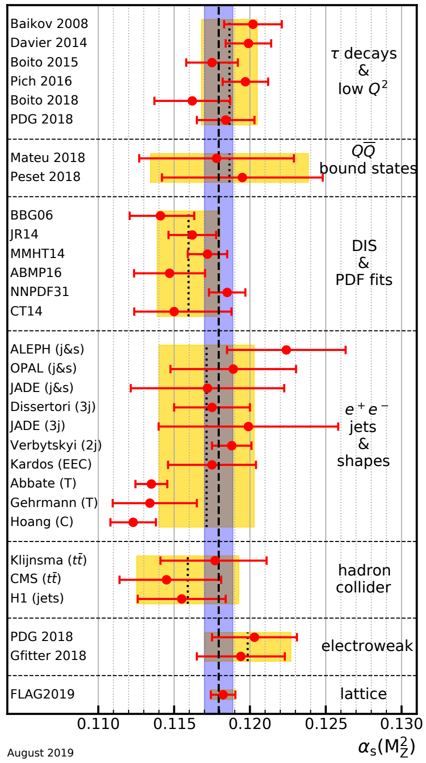

Figure 9.2: Summary of determinations of $\alpha_s(M_Z^2)$ from the seven sub-fields discussed in the text. The yellow (light shaded) bands and dotted lines indicate the pre-average values of each sub-field. The dashed line and blue (dark shaded) band represent the final world average value of $\alpha_s(M_Z^2)$.

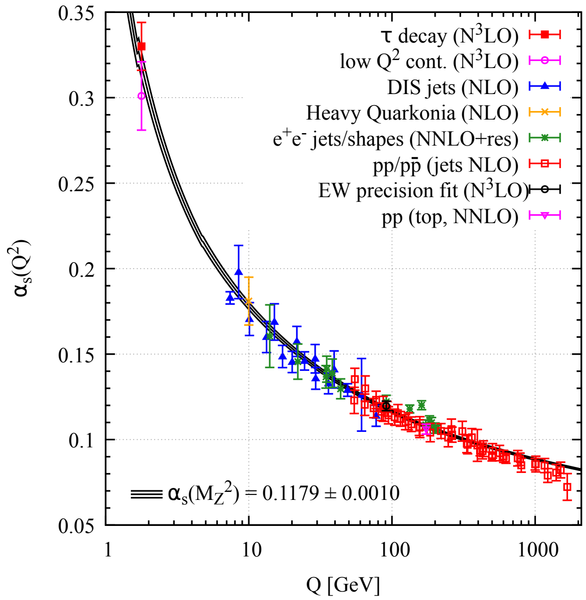

Figure 9.3: Summary of measurements of α_s as a function of the energy scale Q. The respective degree of QCD perturbation theory used in the extraction of α_s is indicated in brackets (NLO: next-to-leading order; NNLO: next-to-next-to-leading order; NNLO+res.: NNLO matched to a resummed calculation; N^{3}LO: next-to-NNLO).

average and are at the moment the only input values in the Heavy-quarkonia category. Their unweighted combination leads to the pre-average for this category of $\alpha_s(M_Z^2) = 0.1187 \pm 0.0052$. We note that, while we include this result in our final average, because of the large uncertainty of the two determinations in this category, removing this pre-average would not change the final result within the quoted uncertainty.

9.4.3 *Deep-inelastic scattering and global PDF fits:*

Studies of DIS final states have led to a number of precise determinations of α_s: a combination [501] of precision measurements at HERA, based on NLO fits to inclusive jet cross sections in neutral current DIS at high Q^2, provides combined values of α_s at different energy scales Q, as shown in Fig. 9.3, and quotes a combined result of $\alpha_s(M_Z^2) = 0.1198 \pm 0.0032$. A more recent study of multijet production [373], based on improved reconstruction and data calibration, confirms the general picture, albeit with a somewhat smaller value of $\alpha_s(M_Z^2) = 0.1165 \pm 0.0039$, still at NLO. An evaluation of inclusive jet production, including *approximate* NNLO contributions [502], reduces the theoretical prediction for jet production in DIS, improves the description of the final HERA data in particular at high photon virtuality Q^2 and increases the central fit value of the strong coupling constant.

Another class of studies, analyzing structure functions at NNLO QCD (and partly beyond), provide results that serve as relevant inputs for the world average of α_s. Most of these studies do *not*, however, explicitly include estimates of theoretical uncertainties when quoting fit results of α_s. In such cases we add, in quadrature, half of the difference between the results obtained in NNLO and NLO to the quoted errors: a combined analysis of non-singlet structure functions from DIS [503], based on QCD predictions up to N^{3}LO in some of its parts, results in $\alpha_s(M_Z^2) = 0.1141 \pm 0.0022$ (BBG). Studies of singlet and non-singlet structure functions, based on NNLO predictions, result in $\alpha_s(M_Z^2) = 0.1162 \pm 0.0017$ [504] (JR14). The AMBP group [505, 506] determined a set of parton distribution functions using data from HERA, NOMAD, CHORUS, from Tevatron and the LHC for the Drell-Yan process and the hadro-production of single-top and top-quark pairs and determined $\alpha_s(M_Z^2) = 0.1147 \pm 0.0024$ [505]. The MMHT group [507], also including hadron collider data, determined a new set of parton density functions (MMHT2014) together with $\alpha_s(M_Z^2) = 0.1172 \pm 0.0013$. Similarly, the CT group [508] determined the CT14 parton density set together with $\alpha_s(M_Z^2) = 0.1150^{+0.0036}_{-0.0024}$. The NNPDF group [509] presented NNPDF3.1 parton distribution functions together with $\alpha_s(M_Z^2) = 0.1185 \pm 0.0012$.

We note that criticism has been expressed on some of the above extractions. Among the issues raised, we mention the neglect of singlet contributions at $x \geq 0.3$ in pure non-singlet fits [510], the impact and detailed treatment of particular classes of data in the fits [510, 511], possible biases due to insufficiently flexible parametrizations of the PDFs [512] and the use of a fixed-flavor number scheme [513, 514].

Summarizing the results from world data on structure functions, taking the *unweighted average* of the central values and errors of all selected results, leads to a pre-average value of $\alpha_s(M_Z^2) = 0.1161 \pm 0.0018$, see Fig. 9.2.

9.4.4 *Hadronic final states of e^+e^- annihilations:*

Re-analyses of event shapes in e^+e^- annihilation (j&s), measured around the Z peak and at LEP2 center-of-mass energies up to 209 GeV, using NNLO predictions matched to NLL resummation and Monte Carlo models to correct for hadronization effects, resulted in $\alpha_s(M_Z^2) = 0.1224 \pm 0.0039$ (ALEPH) [515], with a dominant theoretical uncertainty of 0.0035, and in $\alpha_s(M_Z^2) = 0.1189 \pm 0.0043$ (OPAL) [516]. Similarly, an analysis of JADE data [517] at center-of-mass energies between 14 and 46 GeV gives $\alpha_s(M_Z^2) = 0.1172 \pm 0.0051$, with contributions from the hadronization model and from perturbative QCD uncertainties of 0.0035 and 0.0030, respectively. Precise determinations of α_s from 3-jet production alone (3j), at NNLO, resulted in $\alpha_s(M_Z^2) = 0.1175 \pm 0.0025$ [518] from ALEPH data and in $\alpha_s(M_Z^2) = 0.1199 \pm 0.0059$ [519] from JADE. A recent determination is based on an NNLO+NNLL accurate calculation that allows to fit the region of lower 3-jet rate (2j) using data collected at LEP and PETRA at different energies. This fit gives $\alpha_s(M_Z^2) = 0.1188 \pm 0.0013$ [520], where the dominant uncertainty is the hadronization uncertainty, which is estimated from Monte Carlo simulations. A fit of energy-energy-correlation (EEC) also based on an NNLO+NNLL calculation together with a Monte Carlo based modelling of hadronization corrections gives $\alpha_s(M_Z^2) = 0.1175 \pm 0.0029$ [521]. These results are summarized in the upper seven rows of the e^+e^- sector of Fig. 9.2.

Another class of α_s determinations is based on analytic modelling of non-perturbative and hadronization effects, rather than on Monte Carlo models [522–525], using methods like power corrections, factorization of soft-collinear effective field theory, dispersive models and low scale QCD effective couplings. In these studies, the world data on Thrust distributions (T), or - most recently - C-parameter distributions (C), are analysed and fitted to perturbative QCD predictions at NNLO matched with resummation of leading logs up to N^{3}LL accuracy, see Sec. 9.2.3.3. The results are $\alpha_s(M_Z^2) = 0.1135 \pm 0.0011$ [523] and $\alpha_s(M_Z^2) = 0.1134^{+0.0031}_{-0.0025}$ [524] from Thrust, and $\alpha_s(M_Z^2) = 0.1123 \pm 0.0015$ [525] from C-parameter. They are displayed in the lower three rows of the e^+e^- sector of Fig. 9.2.

The determination of Ref. [522], $\alpha_s(M_Z^2) = 0.1164^{+0.0028}_{-0.0024}$, is no longer included in the average as it is superseded by other determinations that use the same Thrust data but rely on more accurate theoretical predictions. Not included in the computation of the world average but worth mentioning are a computation of the NLO corrections to 5-jet production and comparison to the measured 5-jet rates at LEP [526], giving $\alpha_s(M_Z^2) = 0.1156^{+0.0041}_{-0.0034}$, and a computation of non-perturbative and perturbative QCD contributions to the scale evolution of quark and gluon jet multiplicities, including resummation, resulting in $\alpha_s(M_Z^2) = 0.1199 \pm 0.0026$ [527].

We note that there is criticism on both classes of α_s extractions described above: those based on corrections of non-perturbative hadronization effects using QCD-inspired Monte Carlo generators (since the parton level of a Monte Carlo simulation is not defined in a manner equivalent to that of a fixed-order calculation), as well as studies based on non-perturbative analytic modelling, as their systematics have not yet been fully verified. For the latter case, Refs. [523, 525] quote surprisingly small overall experimental, hadronization, and theoretical uncertainties of only 2, 5, and 9 per-mille, respectively, which calls for an independent confirmation.

In view of these open questions, the determination of the *unweighted average* and uncertainties is intended to provide the most appropriate and unbiased estimate of the average value of $\alpha_s(M_Z^2)$ for this sub-field, which results in $\alpha_s(M_Z^2) = 0.1171 \pm 0.0031$.

9.4.5 *Hadron collider results:*

Until recently, determinations of α_s using hadron collider data, mostly from jet or $t\bar{t}$ production processes, could be performed at NLO only. In the meantime, NNLO calculations have become available for $t\bar{t}$ [84, 466, 468] and for inclusive jet and dijet production [197, 528, 529]. Both can be supplemented by electroweak corrections [530–532], which become important for high-p_{T} collisions at the LHC; for $t\bar{t}$ logarithms have been resummed [469]. Z+jet production, studied with respect to an α_s determination at NLO from multi-jet events in Ref. [533], is also known at NNLO for the 1-jet case [187, 534].

The first determination of α_s at NNLO accuracy in QCD has been reported by CMS [470] from the $t\bar{t}$ production cross section at $\sqrt{s} = 7\,$TeV: $\alpha_s(M_Z^2) = 0.1151^{+0.0028}_{-0.0027}$, whereby the dominating contributions to the overall uncertainty are experimental ($^{+0.0017}_{-0.0018}$), from parton density functions ($^{+0.0013}_{-0.0011}$) and the value of the top quark pole mass (± 0.0013). In the last *Review* this opened up a new sub-field on its own. In the meantime, multiple datasets on $t\bar{t}$ production from Tevatron at $\sqrt{s} = 1.96\,$TeV and from LHC at $\sqrt{s} = 7$, 8, and 13 TeV have been analyzed simultaneously to determine α_s [471] to

$$\alpha_s(M_Z^2) = 0.1177^{+0.0034}_{-0.0036}\,,$$

where the largest uncertainties are associated with missing higher orders and with PDFs. Since this combined analysis contains among other things an updated measurement as compared to the dataset used by CMS, the latter is replaced in the averaging by the new combined result. A second entry into this sub-field is given by an analysis of new $t\bar{t}$ production data at $\sqrt{s} = 13\,$TeV from the CMS collaboration [464]. From the four values presented for the chosen PDF sets, the unweighted average is taken:

$$\alpha_s(M_Z^2) = 0.1145^{+0.0036}_{-0.0031}.$$

From jet production only one α_s determination has been performed yet at NNLO using DIS data of the H1 Collaboration [374]. Two strategies are pursued for the extraction of α_s, one using predetermined PDFs as input and a second strategy fitting the proton PDFs together with the strong coupling constant. From the first approach we choose the result with the smallest total uncertainty, $\alpha_s(M_Z^2) = 0.1168 \pm 0.0030$, where the analysis is restricted to the phase space with the most precise theoretical prediction at the cost of excluding numerous data points at lower scale values. The second approach gives $\alpha_s(M_Z^2) = 0.1142 \pm 0.0028$, which we combine with the first result to our unweighted input average:

$$\alpha_s(M_Z^2) = 0.1155 \pm 0.0029.$$

As unweighted pre-average for this sub-field we obtain: $\alpha_s(M_Z^2) = 0.1159 \pm 0.0034$. Also worth mentioning is a recent still unpublished extraction of $\alpha_s(M_Z^2) = 0.1170 \pm 0.0030$ [535] using HERA jet data and relying on fast interpolation grid techniques.

Many further α_s determinations from jet measurements either could not yet be advanced to NNLO accuracy or the NNLO predictions are not yet available as is the case for observables requiring three or more jets in the final state. A selection of results from inclusive jet [373, 387, 536–541] and multi-jet measurements [332, 334, 335, 373, 542–546] is presented in Fig. 9.4, where the uncertainty in most cases is dominated by the impact of missing higher orders estimated through scale variations. The multi-jet α_s determinations are based on 3-jet cross sections (m3j), 3- to 2-jet cross-section ratios (R32), dijet angular decorrelations (RdR, RdPhi), and transverse energy-energy-correlations and their asymmetry (TEEC, ATEEC). The H1 result is extracted from a fit to inclusive 1-, 2-, and 3-jet cross sections (nj) simultaneously.

The CMS Collaboration has also derived an α_s value at NLO from dijet production at $\sqrt{s} = 8\,$TeV [393], but only in combination with a PDF fit. The last point of the inclusive jet sub-field from Ref. [541] is derived from a simultaneous fit to six datasets from different experiments and partially includes data used already for the other data points, *e.g.* the CMS result at 7 TeV.

All NLO results are within their large uncertainties in agreement with the world average and the associated analyses provide valuable new values for the scale dependence of α_s at energy scales now extending up to almost 2.0 TeV as shown in Fig. 9.3.

9.4.6 *Electroweak precision fit:*

For this category, we update the global electroweak fit result of Ref. [547] to the one of Ref. [548], which now includes kinematic top quark and W boson mass measurements from the LHC, new determinations of the effective leptonic electroweak mixing angles from the Tevatron, a Higgs mass measurement from ATLAS and CMS, and a new evaluation of the hadronic contribution to the running of the electromagnetic coupling at the Z-boson mass. In addition, we use the newer results of the electroweak fit at the Z mass pole from LEP and SLC data presented in Sec. *Electroweak Model and constraints on New Physics* of the 2018 edition of this *Review*. Both very similar results, $\alpha_s(M_Z^2) = 0.1203 \pm 0.0028$ [480], $\alpha_s(M_Z^2) = 0.1194 \pm 0.0029$ [548], are also in perfect agreement with the original result obtained from LEP and SLD data [549]. Our pre-averaging gives $\alpha_s(M_Z^2) = 0.1199 \pm 0.0029$.

We note, however, that results from electroweak precision data strongly depend on the strict validity of Standard Model predictions and the existence of the minimal Higgs mechanism to implement electroweak symmetry breaking. Any - even small - deviation of nature from this model could strongly influence this extraction of α_s.

9.4.7 *Lattice QCD:*

Several methods exist to extract the strong coupling constant from lattice QCD, as reviewed also in Sec. *Lattice QCD* of this *Review*.

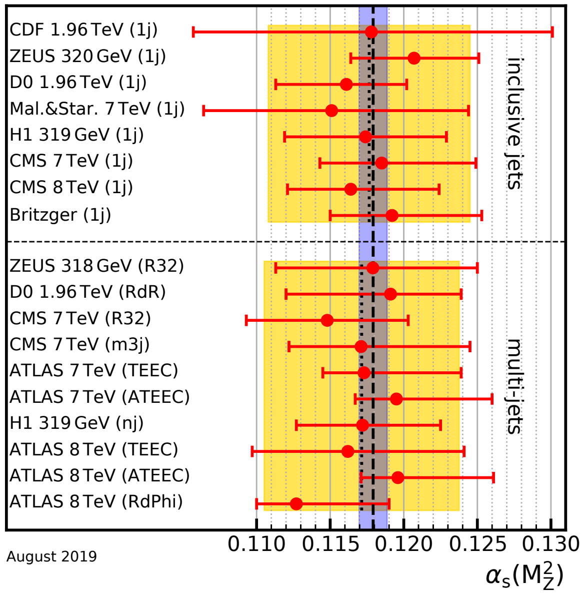

Figure 9.4: Summary of determinations of $\alpha_s(M_Z^2)$ at NLO from inclusive and multi-jet measurements at hadron colliders. The uncertainty is dominated by estimates of the impact of missing higher orders. The yellow (light shaded) bands and dotted lines indicate average values for the two sub-fields. The dashed line and blue (dark shaded) band represent the final world average value of $\alpha_s(M_Z^2)$.

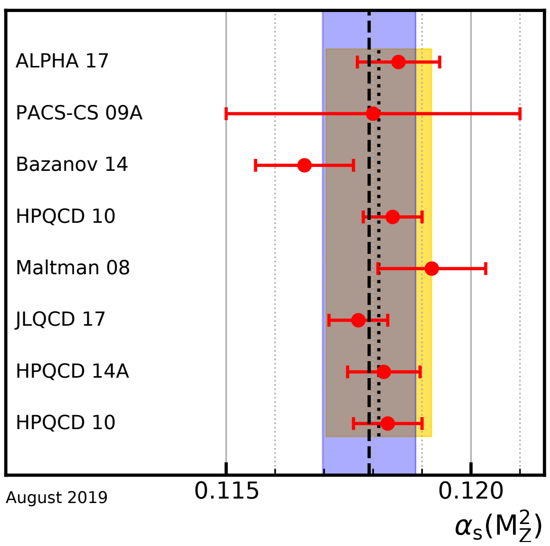

Figure 9.5: Lattice determinations that enter the FLAG2019 average. The yellow (light shaded) band and dotted line indicates the average value for this sub-field. The dashed line and blue (dark shaded) band represent the final world average value of $\alpha_s(M_Z^2)$.

The Flavour Lattice Averaging Group (FLAG) has recently considered the most up-to-date determinations and combined them to produce an update of their average α_s [487]. Their final result is obtained by considering seventeen possible input calculations [550–567] and by retaining in their final average only those eight [551–553, 556, 559–561, 563] that fulfill their predefined quality criteria. These determinations, together with their uncertainties, are displayed in Fig. 9.5. The yellow (light shaded) band and dotted line indicate the FLAG 2018 average, while the dashed line and blue (dark shaded) band represent the world average (see later). The level of agreement of individual results to the world average, or to the non-lattice world average is very similar. The criteria applied are detailed in the Sec. 9.2.1 of Ref. [487]. We note that, as in our case, the calculation must be published in a peer-reviewed journal for it to be eligible to be included in the FLAG average. We also note that the criteria applied now are considered relatively loose by the FLAG collaboration and they have already formulated more stringent criteria. It is likely that in future FLAG averages only results satisfying these stricter criteria will be included in their averaging.

Similarly to what is done here, the FLAG collaboration built pre-averages of results that belong to different classes. The categories that currently contribute to the average are: step-scaling methods ($\alpha_s(M_Z^2) = 0.11848^{+0.00081}_{-0.00081}$), the potential at short distances ($\alpha_s(M_Z^2) = 0.11660^{+0.00160}_{-0.00160}$), Wilson loops ($\alpha_s(M_Z^2) = 0.11858^{+0.00120}_{-0.00120}$), and heavy-quark current two-point functions ($\alpha_s(M_Z^2) = 0.11824^{+0.00150}_{-0.00150}$).

Other categories like the vacuum polarization at short distances, the calculation of QCD vertices, or of the eigenvalue spectrum of the Dirac operator have not yet published results that fulfill all requirements to be included in the average. Ref. [568] has been completed after the publication of Ref. [487], hence these results have not been considered in the last FLAG average.

The final value is obtained by performing an unweighted average of the pre-averages. In order to be conservative, the final uncertainty is not the combined uncertainty of the pre-averages, rather it is taken to be the smallest uncertainty of the pre-averages, which is the uncertainty of the step-scaling category and is dominated by the ALPHA 17 result [563]. The final FLAG average (rounded to four digits) is

$$\alpha_s(M_Z^2) = 0.1182 \pm 0.0008\,, \qquad \text{(lattice)}\,. \tag{9.23}$$

We believe that this result expresses to a large extent the consensus of the lattice community and that the imposed criteria and the rigorous assessment of systematic uncertainties qualify for a direct inclusion of this FLAG average here. In contrast to the previous review, we therefore decided to adopt the FLAG average with its uncertainty as our value of α_s for the lattice category. Moreover, this lattice result will not be directly combined with any other sub-field average, but with our non-lattice average to give our final world average value for α_s.

9.4.8 *Determination of the world average value of $\alpha_s(M_Z^2)$:*

Obtaining a world average value for $\alpha_s(M_Z^2)$ is a non-trivial exercise. A certain arbitrariness and subjective component is inevitable because of the choice of measurements to be included in the average, the treatment of (non-Gaussian) systematic uncertainties of mostly theoretical nature, as well as the treatment of correlations among the various inputs, of theoretical as well as experimental origin.

We have chosen to determine pre-averages for sub-fields of measurements that are considered to exhibit a maximum of independence among each other, considering experimental as well as theoretical issues. The seven pre-averages are summarized in Fig. 9.2. We recall that these are exclusively obtained from extractions that are based on (at least) full NNLO QCD predictions, and are published in peer-reviewed journals at the time of completing this *Review*. To obtain our final world average, we first combine six pre-averages, excluding the lattice result, using a χ^2 *averaging method*. This gives

$$\alpha_s(M_Z^2) = 0.1176 \pm 0.0011\,, \qquad \text{(without lattice)}\,. \tag{9.24}$$

This result is fully compatible with the lattice pre-average Eq. (9.23) and has a comparable error. In order to be conservative, we combine these two numbers using an unweighted average and take as an uncertainty the average between these two uncertainties. This gives our final world average value

$$\alpha_s(M_Z^2) = 0.1179 \pm 0.0010\,. \tag{9.25}$$

This world average value is in very good agreement with the last version of this *Review*, which was $\alpha_s(M_Z^2) = 0.1181 \pm 0.0011$, with only a slightly lower central value and decreased overall uncertainty. Performing a weighted average of all seven categories gives $\alpha_s(M_Z^2) = 0.1180 \pm 0.0007$. Our uncertainty instead is about 50% larger.

Notwithstanding the many open issues still present within each of the sub-fields summarised in this *Review*, the wealth of available results provides a rather precise and reasonably stable world average value of $\alpha_s(M_Z^2)$, as well as a clear signature and proof of the energy dependence of α_s, in full agreement with the QCD prediction of Asymptotic Freedom. This is demonstrated in Fig. 9.3, where results of $\alpha_s(Q^2)$ obtained at discrete energy scales Q, now also including those based just on NLO QCD, are summarised. Thanks to the results from the Tevatron and from the LHC, the energy scales, at which α_s is determined, now extend up to almost 2 TeV.[15]

9.5 Acknowledgments

We are grateful to S. Bethke, G. Dissertori, D. d'Enterria, C. Glasman, A. Hoang, D. Lombardi, G.P. Salam, and B. Webber for discussions and for their comments on the manuscript, and to J. Andersen, A. Bazavov, H.-L. Win, and J. Smillie for useful discussions.

[15] We note, however, that in many such studies, like those based on exclusive states of jet multiplicities, the relevant energy scale of the measurement is not uniquely defined. For instance, in studies of the ratio of 3- to 2-jet cross sections at the LHC, the relevant scale was taken to be the average of the transverse momenta of the two leading jets [543], but could alternatively have been chosen to be the transverse momentum of the 3^{rd} jet.

10.5.3 W and Z decays 190
10.6 Global fit results 192
10.7 Constraints on new physics 194

10.1 Introduction

The standard model of the electroweak interactions (SM) [1–4] is based on the gauge group SU(2) × U(1), with gauge bosons W^i_μ, $i = 1, 2, 3$, and B_μ for the SU(2) and U(1) factors, respectively, and the corresponding gauge coupling constants g and g'. The left-handed fermion fields of the i^{th} fermion family transform as doublets $\Psi_i = \binom{\nu_i}{\ell^-_i}$ and $\binom{u_i}{d'_i}$ under SU(2), where $d'_i \equiv \sum_j V_{ij}\, d_j$, and V is the Cabibbo-Kobayashi-Maskawa mixing [5, 6] matrix[1]. The right-handed fields are SU(2) singlets. From Higgs and electroweak precision data it is known that there are precisely three sequential fermion families.

A complex scalar Higgs doublet, ϕ, is added to the model for mass generation through spontaneous symmetry breaking with potential[2] given by,

$$V(\phi) = \mu^2 \phi^\dagger \phi + \frac{\lambda^2}{2}(\phi^\dagger \phi)^2 \,, \qquad \phi \equiv \begin{pmatrix} \phi^+ \\ \phi^0 \end{pmatrix} \,. \tag{10.1}$$

For μ^2 negative, ϕ develops a vacuum expectation value, $v/\sqrt{2} = |\mu|/\lambda$, where $v = 246.22$ GeV, breaking part of the electroweak (EW) gauge symmetry, after which only one neutral Higgs scalar, H, remains in the physical particle spectrum. In non-minimal models there are additional charged and neutral scalar Higgs particles. Higgs boson physics is reviewed in the Section on the "Status of Higgs Boson Physics" in this *Review*.

After symmetry breaking the Lagrangian for the fermion fields, ψ_i, is

$$\begin{aligned}\mathscr{L}_F = &\sum_i \bar\psi_i \left(i\not\partial - m_i - \frac{m_i H}{v}\right)\psi_i \\ &- \frac{g}{2\sqrt{2}} \sum_i \overline{\Psi}_i\, \gamma^\mu\, (1-\gamma^5)(T^+\, W^+_\mu + T^-\, W^-_\mu\,)\, \Psi_i \\ &- e\sum_i Q_i\, \bar\psi_i\, \gamma^\mu\, \psi_i\, A_\mu \\ &- \frac{g}{2\cos\theta_W} \sum_i \bar\psi_i\, \gamma^\mu (g^i_V - g^i_A \gamma^5)\, \psi_i\, Z_\mu \,.\end{aligned} \tag{10.2}$$

Here $\theta_W \equiv \tan^{-1}(g'/g)$ is the weak mixing angle and $e = g\sin\theta_W$ is the positron electric charge. Furthermore,

$$A_\mu \equiv B_\mu \cos\theta_W + W^3_\mu \sin\theta_W \,, \tag{10.3a}$$

$$W^\pm_\mu \equiv \frac{W^1_\mu \mp i W^2_\mu}{\sqrt{2}} \,, \tag{10.3b}$$

$$Z_\mu \equiv -B_\mu \sin\theta_W + W^3_\mu \cos\theta_W \,, \tag{10.3c}$$

are the photon field (γ) and the charged ($W^\pm$) and neutral (Z) weak boson fields, respectively.

The Yukawa coupling of H to ψ_i in the first term in $\mathscr{L}_F$, which is flavor diagonal in the minimal model, is $g m_i/2M_W$. The boson masses in the EW sector are given (at tree level, *i.e.*, to lowest order in perturbation theory) by,

$$M_H = \lambda\, v \,, \tag{10.4a}$$

$$M_W = \frac{gv}{2} = \frac{ev}{2\sin\theta_W} \,, \tag{10.4b}$$

$$M_Z = \sqrt{g^2 + g'^2}\ \frac{v}{2} = \frac{ev}{2\sin\theta_W \cos\theta_W} \,, \tag{10.4c}$$

$$M_\gamma = 0 \,. \tag{10.4d}$$

The second term in $\mathscr{L}_F$ represents the charged-current weak interaction [8–10], where T^+ and T^- are the weak isospin raising and lowering operators. For example, the coupling of a W to an electron and a neutrino is

$$-\frac{e}{2\sqrt{2}\sin\theta_W}\left[W^-_\mu\, \bar e\, \gamma^\mu (1-\gamma^5)\nu + W^+_\mu\, \bar\nu\, \gamma^\mu\, (1-\gamma^5) e\right] \,. \tag{10.5}$$

For momenta small compared to M_W, this term gives rise to the effective four-fermion interaction with the Fermi constant given by $G_F/\sqrt{2} = 1/2v^2 = g^2/8M^2_W$. CP violation is incorporated into the EW model by a single observable phase in V_{ij}.

The third term in $\mathscr{L}_F$ describes electromagnetic interactions (QED) [11, 12], and the last is the weak neutral-current interaction [9, 10, 13]. The vector and axial-vector couplings are

$$g^i_V \equiv t_{3L}(i) - 2Q_i \sin^2\theta_W \,, \tag{10.6a}$$

$$g^i_A \equiv t_{3L}(i) \,, \tag{10.6b}$$

where $t_{3L}(i)$ is the weak isospin of fermion i ($+1/2$ for u_i and ν_i; $-1/2$ for d_i and e_i) and Q_i is the charge of ψ_i in units of e.

The first term in Eq. (10.2) also gives rise to fermion masses, and in the presence of right-handed neutrinos to Dirac neutrino masses. The possibility of Majorana masses is discussed in the Section on "Neutrino Mass, Mixing, and Oscillations" in this *Review*.

10.2 Renormalization and radiative corrections

In addition to the Higgs boson mass, M_H, the fermion masses and mixings, and the strong coupling constant, α_s, the SM has three parameters. The set with the smallest experimental errors contains the Z mass[3], the Fermi constant, and the fine structure

[1] Constraints on V and tests of universality are discussed in Ref. [7] and in the Section on the "CKM Quark-Mixing Matrix" in this *Review*. The extension of the formalism to allow an analogous leptonic mixing matrix is discussed in the Section on "Neutrino Masses, Mixing, and Oscillations" in this *Review*.

[2] There is no generally accepted convention to write the quartic term. Our numerical coefficient simplifies Eq. (10.4a) below and the squared coupling preserves the relation between the number of external legs and the power counting of couplings at a given loop order. This structure also naturally emerges from physics beyond the SM, such as Supersymmetry.

[3] We emphasize that in the fits described in Sec. 10.6 and Sec. 10.7 the values of the SM parameters are affected by all observables that depend on

constant, to be discussed in turn (the numerical values quoted in Sections 10.2−10.4 correspond to the main fit result in Table 10.7).

The Z boson mass, $M_Z = 91.1876{\pm}0.0021$ GeV, has been determined from the Z lineshape scan at LEP 1 [14]. This value of M_Z corresponds to a definition based on a Breit-Wigner shape with an energy-dependent width[4] (see the Section on the "Z Boson" in this *Review*).

10.2.1 *The Fermi constant*

The Fermi constant, $G_F = 1.1663787(6) \times 10^{-5}$ GeV^{-2}, is derived from the μ lifetime formula[5],

$$\frac{\hbar}{\tau_\mu} = \frac{G_F^2 m_\mu^5}{192\pi^3} F(\rho) \left[1 + H_1(\rho)\frac{\widehat{\alpha}(m_\mu)}{\pi} + H_2(\rho)\frac{\widehat{\alpha}^2(m_\mu)}{\pi^2}\right] , \tag{10.7}$$

where $\rho = m_e^2/m_\mu^2$, and where

$$F(\rho) = 1 - 8\rho + 8\rho^3 - \rho^4 - 12\rho^2 \ln\rho = 0.99981295 , \tag{10.8a}$$

$$\begin{aligned} H_1(\rho) &= \frac{25}{8} - \frac{\pi^2}{2} - \left(9 + 4\pi^2 + 12\ln\rho\right)\rho + 16\pi^2\rho^{3/2} + \mathcal{O}(\rho^2) \\ &= -1.80793 , \end{aligned} \tag{10.8b}$$

$$\begin{aligned} H_2(\rho) &= \frac{156815}{5184} - \frac{518}{81}\pi^2 - \frac{895}{36}\zeta(3) + \frac{67}{720}\pi^4 + \frac{53}{6}\pi^2\ln 2 \\ &\quad - (0.042 \pm 0.002)_{\rm had} - \frac{5}{4}\pi^2\sqrt{\rho} + \mathcal{O}(\rho) = 6.64 , \end{aligned} \tag{10.8c}$$

$$\widehat{\alpha}(m_\mu)^{-1} = \alpha^{-1} + \frac{1}{3\pi}\ln\rho + \mathcal{O}(\alpha) = 135.901 . \tag{10.8d}$$

H_1 and H_2 capture the QED corrections within the Fermi model. The results for $\rho = 0$ have been obtained in Refs. [16] and [17,18] for H_1 and H_2, respectively, where the term in parentheses is from the hadronic vacuum polarization [17]. The mass corrections to H_1 have been known for some time [19], while those to H_2 are more recent [20]. Notice the term linear in m_e whose appearance was unforeseen and can be traced to the use of the muon pole mass in the prefactor [20]. The remaining uncertainty in G_F is mostly experimental and has been reduced by an order of magnitude by the MuLan collaboration [15] at the PSI.

10.2.2 *The electromagnetic coupling*

The fine structure constant, α, can be extracted from the $e^\pm$ anomalous magnetic moment [21], $a_e = (1159652180.91 \pm 0.26) \times 10^{-12}$ [22], which gives the value $\alpha^{-1} = 137.035999150(33)$. Another approach combines measurements of the Rydberg constant and atomic masses with interferometry of atomic recoil kinematics. Applied to ^{87}Rb [23] and ^{133}Cs [24], this method implies the results $\alpha^{-1} = 137.035998997(85)$ and $\alpha^{-1} = 137.035999047(28)$, respectively, which can be combined to give $\alpha^{-1} = 137.035999042(26)$. Finally, combining the anomalous magnetic moment and atomic interferometry methods leads to the world average of $\alpha^{-1} = 137.035999084(21)$, but notice that they also show a 2.6 σ discrepancy. If this is interpreted as due to physics beyond the SM (BSM), the new physics would contribute to a_e with opposite sign compared to the $\mu^\pm$ anomalous magnetic moment, a_μ, to be discussed in Section 10.4.2.

In most EW renormalization schemes, it is convenient to define a running α dependent on the energy scale of the process, with $\alpha^{-1} \approx 137.036$ appropriate at very low energy, *i.e.* close to the Thomson limit. The OPAL [25] and L3 [26] collaborations at LEP could also observe the running directly in small and large angle Bhabha scattering, respectively. For scales above a few hundred MeV the low energy hadronic contribution to vacuum polarization introduces a theoretical uncertainty in α. In the modified minimal subtraction ($\overline{\rm MS}$) scheme[6] [27] (used for this *Review*), and with $\alpha_s(M_Z) = 0.1185 {\pm} 0.0016$ we have $\widehat{\alpha}^{(4)}(m_\tau)^{-1} = 133.472 {\pm} 0.007$ and $\widehat{\alpha}^{(5)}(M_Z)^{-1} = 127.952 \pm 0.009$. The latter corresponds to a quark sector contribution (without the top) to the conventional (on-shell) QED coupling,

$$\alpha(M_Z) = \frac{\alpha}{1 - \Delta\alpha(M_Z)} , \tag{10.9}$$

of $\Delta\alpha^{(5)}_{\rm had}(M_Z) = 0.02766 \pm 0.00007$. These values are updated from Ref. [28] with $\Delta\alpha^{(5)}_{\rm had}(M_Z)$ moved downwards and its uncertainty reduced (partly due to a more precise charm quark mass). Its correlation with a_μ, as well as the non-linear α_s dependence of $\widehat{\alpha}(M_Z)$ and the resulting correlation with the input variable α_s, are fully taken into account in the fits. This is done by using as actual input (fit constraint) instead of $\Delta\alpha^{(5)}_{\rm had}(M_Z)$ the low energy contribution by the three light quarks, $\Delta\alpha^{(3)}_{\rm had}(2.0 \text{ GeV}) = (58.84 \pm 0.51) \times 10^{-4}$ [29], and by calculating the perturbative and heavy quark contributions to $\widehat{\alpha}(M_Z)$ in each call of the fits according to [28]. Part of the error ($\pm 0.37 \times 10^{-4}$) is from e^+e^- annihilation data below 2 GeV, as well as isospin rotated data from τ decays into two- and four-pion final states [30] (including uncertainties from isospin breaking effects [31]), but uncalculated higher order perturbative ($\pm 0.21 \times 10^{-4}$) and non-perturbative ($\pm 0.28 \times 10^{-4}$ [29]) QCD corrections and the $\overline{\rm MS}$ quark mass values (see below) also contribute. Various evaluations of $\Delta\alpha^{(5)}_{\rm had}(M_Z)$ are summarized in Table 10.1, where the relation[7] between the $\overline{\rm MS}$ and on-shell definitions (obtained using Ref [34]) is given by,

$$\begin{aligned} \Delta\widehat{\alpha}(M_Z) = \Delta\alpha(M_Z) + \frac{\alpha}{\pi}\Bigg[&\frac{100}{27} - \frac{1}{6} - \frac{7}{4}\ln\frac{M_Z^2}{M_W^2} \\ &+ \frac{\alpha_s(M_Z)}{\pi}\left(\frac{605}{108} - \frac{44}{9}\zeta(3)\right) \\ &+ \frac{\alpha_s^2}{\pi^2}\left(\frac{976481}{23328} - \frac{253}{36}\zeta(2) - \frac{781}{18}\zeta(3) + \frac{275}{27}\zeta(5)\right)\Bigg] \\ = 0.007127(2) , \end{aligned} \tag{10.10}$$

and where the first entry of the lowest order term is from fermions and the other two are from $W^\pm$ loops, which are usually excluded from the on-shell definition. Fermion mass effects and corrections of $\mathcal{O}(\alpha\alpha_s^3)$ and $\mathcal{O}(\alpha^2)$ contributing to Eq. (10.10) are small, partly cancel each other and are not included here. The most recent results on $\Delta\alpha^{(5)}_{\rm had}(M_Z)$ [29,35–37] typically assume the validity of perturbative QCD (PQCD) at scales of $\sim$ 2 GeV or above and are in good agreement with each other. In regions where PQCD is not trusted, one can use $e^+e^- \to$ hadrons cross-section data and τ decay spectral functions [38], where the latter derive from OPAL [39], CLEO [40], ALEPH [41], and Belle [42]. Recently, new data for various $e^+e^- \to$ hadrons channels was obtained from BaBar, BES III, CLEO, the SND and CMD-3 experiments at VEPP-2000, and the KEDR experiments at VEPP-4M (for a list of references see, *e.g.*, Ref. [29]). While VEPP-2000 and VEPP-4M scanned center-of-mass (CM) energies up to 2 GeV and between about 3 and 4 GeV, respectively, the BaBar collaboration studied multi-hadron events radiatively returned from the $\Upsilon(4S)$,

them. This is of no practical consequence for α and G_F, however, since they are very precisely known.

[4] The theoretically consistent and gauge-invariant definition of the Z-boson mass through the complex pole of the propagator would instead lead to a Breit-Wigner with a constant width. The two definitions differ numerically, and this difference has to be accounted for in theoretical calculations.

[5] In the spirit of the Fermi theory, we incorporated the small propagator correction, $3/5\ m_\mu^2/M_W^2$, into Δr (see below). This is also the convention adopted by the MuLan collaboration [15]. While this breaks with historical consistency, the numerical difference was negligible in the past.

[6] In this Section we denote quantities defined in the $\overline{\rm MS}$ scheme by a caret; the exception is the strong coupling constant, α_s, which will always correspond to the $\overline{\rm MS}$ definition and where the caret will be dropped.

[7] In practice, $\alpha(M_Z)$ is directly evaluated in the $\overline{\rm MS}$ scheme using the FORTRAN package GAPP [32], including the QED contributions of both leptons and quarks. The leptonic three-loop contribution in the on-shell scheme has been obtained in Ref. [33].

reconstructing the radiated photon and normalizing to $\mu^\pm\gamma$ final states. The precision of these results generally exceeds those from τ decays. There are significant discrepancies between the older (CMD-2) and newer (CMD-3) measurements of $e^+e^- \to K^+K^-$, which could be due to difficulties in determining the detection efficiency of low-momentum kaons. The radiative return data from BaBar is expected to be more reliable for this channel owing to an additional boost of the final-state hadrons.

10.2.3 *Quark masses*

Further free parameters entering into Eq. (10.2) are the quark and lepton masses, where m_i is the mass of the $i^{\rm th}$ fermion ψ_i. For the light quarks, as described in the Section on "Quark Masses" in this *Review*, $\widehat{m}_u = 2.16^{+0.49}_{-0.26}$ MeV, $\widehat{m}_d = 4.67^{+0.48}_{-0.17}$ MeV, and $\widehat{m}_s = 93^{+11}_{-5}$ MeV. These are running $\overline{\rm MS}$ masses evaluated at the scale $\mu = 2$ GeV. For the charm mass we use the constraint [51],

$$\widehat{m}_c(\widehat{m}_c) = 1274 \pm 8 + 2616[\alpha_s(M_Z) - 0.1182] \text{ MeV} , \qquad (10.11)$$

which is based on QCD sum rules [52,53], and recalculate $\widehat{m}_c$ in each call of our fits to account for its α_s dependence. Similarly, for the bottom quark mass we use,

$$\widehat{m}_b(\widehat{m}_b) = 4180 \pm 8 + 108[\alpha_s(M_Z) - 0.1182] \text{ MeV} , \qquad (10.12)$$

with a theoretical correlation of about 60% arising mostly from the PQCD truncation uncertainty which is similar for $\widehat{m}_c(\widehat{m}_c)$ and $\widehat{m}_b(\widehat{m}_b)$. To improve the precisions in $\widehat{m}_c(\widehat{m}_c)$ and $\widehat{m}_b(\widehat{m}_b)$ in the future it would help to remeasure the threshold regions of the heavy quarks, as well as the electronic decay widths of the narrow $c\bar{c}$ and $b\bar{b}$ resonances.

The top quark "pole" mass (the quotation marks are a reminder that the experiments do not strictly measure the pole mass and that quarks do not form asymptotic states), has been kinematically reconstructed by the Tevatron collaborations, CDF and DØ, in leptonic, hadronic, and mixed channels with the result $m_t = 174.30 \pm 0.35_{\rm stat.} \pm 0.54_{\rm syst.}$ GeV [54]. Likewise, using data from CM energies $\sqrt{s} = 7$ and 8 TeV (Run 1), ATLAS and CMS (including alternative technique measurements) at the LHC obtained $m_t = 172.69 \pm 0.25_{\rm stat.} \pm 0.41_{\rm syst.}$ GeV [55] and $m_t = 172.43 \pm 0.13_{\rm stat.} \pm 0.46_{\rm syst.}$ GeV [56], respectively. In addition, there are first results with $\sqrt{s} = 13$ TeV data (Run 2). CMS obtained $m_t = 172.26 \pm 0.07_{\rm mostly\,stat.} \pm 0.61_{\rm syst.}$ GeV [57] in the lepton + jets and all-jets channels, and $m_t = 172.33 \pm 0.14_{\rm stat.} \pm 0.69_{\rm syst.}$ GeV [58] in the di-lepton channel. Using a leptonic invariant mass and thus featuring reduced correlation with the more traditional analysis approaches, ATLAS quotes $m_t = 174.48 \pm 0.40_{\rm stat.} \pm 0.67_{\rm syst.}$ GeV [59] from the lepton + jets channel. While there seems to be generally good agreement between all these measurements, we observe a 2.8 σ discrepancy (or more in case of correlated systematics) between the two most precise determinations, 174.98 ± 0.76 GeV [60] (by the DØ collaboration) and 172.25 ± 0.63 GeV [61] (by the CMS collaboration), both from the lepton + jets channels. In addition, the latter is also 2.2 σ lower than the preliminary result of Ref. [59]. Assuming a systematic error component of 0.17 GeV (the QCD, PDF and Monte Carlo type errors at ATLAS at Run 1) is common to all six results, we arrive at the combination,

$$m_t = 172.89 \pm 0.28_{\rm exp.} \text{ GeV} + \Delta m_{\rm MC} , \qquad (10.13)$$

where $\Delta m_{\rm MC}$ is defined to account for any difference between the top pole mass, m_t, and the mass parameter implemented in the Monte Carlo event generators employed by the experimental groups. $\Delta m_{\rm MC}$ is expected to be of order $\alpha_s(Q_0)Q_0$ with a low scale $Q_0 \sim \mathcal{O}(1 \text{ GeV})$ [62], but its value is unknown in hadron collider environments so that we will treat it as an uncertainty instead, and choose for definiteness $Q_0 = \Gamma_t = 1.42$ GeV to arrive at $\Delta m_{\rm MC} = 0 \pm 0.52$ GeV. We further assume that an uncertainty [63] of ± 0.32 GeV in the relation [64] between m_t and the $\overline{\rm MS}$ definition, $\widehat{m}_t(\widehat{m}_t)$, entering electroweak radiative correction libraries, including the renormalon ambiguity [65], is already included in $\Delta m_{\rm MC}$, as m_t merely serves as an intermediate bookkeeping device in Ref. [62]. A promising future direction to arrive at a competitive independent constraint on m_t is to analyze differential top quark pair production cross-sections at next-to-next-to-leading order (NNLO) [66], as m_t extraction based on them are easier to interpret, and experimentally they have become much more precise recently [67,68]. The combination in Eq. (10.13) differs slightly from the average, $m_t = 172.9 \pm 0.4_{\rm exp.}$ GeV, which appears in the Top Quark Listings in this *Review*, as its uncertainty has been scaled up by a factor of 1.3. For more details and references, see the Section on the "Top Quark" and the Quarks Listings in this *Review*.

10.2.4 *The weak mixing angle*

The observables $\sin^2\theta_W$ and M_W can be calculated from M_Z, $\widehat{\alpha}(M_Z)$, and G_F, when values for m_t and M_H are given, or conversely, M_H can be constrained by $\sin^2\theta_W$ and M_W. The value of $\sin^2\theta_W$ is extracted from neutral-current processes (see Sec. 10.3) and Z pole observables (see Sec. 10.5.3) and depends on the renormalization prescription. There are a number of popular schemes [9] leading to values which differ by small factors depending on m_t and M_H. The notation for these schemes is shown in Table 10.2.

(i) The on-shell scheme [70] promotes the tree-level formula $\sin^2\theta_W = 1 - M_W^2/M_Z^2$ to a definition of the renormalized $\sin^2\theta_W$ to all orders in perturbation theory, *i.e.*,

$$\sin^2\theta_W \to s_W^2 \equiv 1 - \frac{M_W^2}{M_Z^2} , \qquad (10.14a)$$

$$M_W = \frac{A_0}{s_W(1-\Delta r)^{1/2}} , \qquad M_Z = \frac{M_W}{c_W} , \qquad (10.14b)$$

where $c_W \equiv \cos\theta_W$, $A_0 = (\pi\alpha/\sqrt{2}G_F)^{1/2} = 37.28038(1)$ GeV, and Δr includes the radiative corrections relating α, $\alpha(M_Z)$, G_F, M_W, and M_Z. One finds $\Delta r \sim \Delta r_0 - \rho_t \tan^{-2}\theta_W$, where $\Delta r_0 = 1 - \alpha/\widehat{\alpha}(M_Z) = 0.06629(7)$ is due to the running of α, and

$$\rho_t = \frac{3G_F m_t^2}{8\sqrt{2}\pi^2} = 0.00937 \times \frac{m_t^2}{(172.89 \text{ GeV})^2} , \qquad (10.15)$$

represents the dominant (quadratic) m_t dependence. There are additional contributions to Δr from bosonic loops, including those which depend logarithmically on M_H and higher-order corrections[8]. One has $\Delta r = 0.03652 \mp 0.00021 \pm 0.00007$, where the first uncertainty is from m_t and the second is from $\alpha(M_Z)$. Thus the value of s_W^2 extracted from M_Z includes an uncertainty (∓ 0.00007) from the currently allowed range of m_t. This scheme is simple conceptually. However, the relatively large ($\sim 3\%$) correction from ρ_t causes large spurious contributions in higher orders. s_W^2 depends not only on the gauge couplings but also on the spontaneous-symmetry breaking, and it is awkward in the presence of any extension of the SM which perturbs the value of M_Z (or M_W). Other definitions are motivated by the tree-level coupling constant definition $\theta_W = \tan^{-1}(g'/g)$:

(ii) In particular, the $\overline{\rm MS}$ scheme introduces the quantity,

$$\sin^2\widehat{\theta}_W(\mu) \equiv \frac{\widehat{g}'^2(\mu)}{\widehat{g}^2(\mu) + \widehat{g}'^2(\mu)} , \qquad (10.16)$$

where the couplings $\widehat{g}$ and $\widehat{g}'$ are defined by modified minimal subtraction and the scale μ is conveniently chosen to be M_Z for many EW processes. The value of $\widehat{s}_Z^2 \equiv \sin^2\widehat{\theta}_W(M_Z)$ extracted from M_Z is less sensitive than s_W^2 to m_t (by a factor of $\tan^2\theta_W$), and is less sensitive to most types of new physics. It is also very useful for comparing with the predictions of grand unification. There are actually several variant definitions of $\sin^2\widehat{\theta}_W(M_Z)$, differing according

[8] All explicit numbers quoted here and below include the two- and three-loop corrections described near the end of Sec. 10.2.

Table 10.1: Evaluations of the on-shell $\Delta\alpha^{(5)}_{\rm had}(M_Z)$ by different groups (for a more complete list of evaluations see the 2012 edition of this *Review*). For better comparison we adjusted central values and errors to correspond to a common and fixed value of $\alpha_s(M_Z) = 0.120$. References quoting results without the top quark decoupled are converted to the five flavor definition. Ref. [43] uses $\Lambda_{\rm QCD} = 380 \pm 60$ MeV; for the conversion we assumed $\alpha_s(M_Z) = 0.118 \pm 0.003$.

Table 10.2: Notations used to indicate the various schemes discussed in the text. Each definition of $\sin^2\theta_W$ leads to values that differ by small factors depending on m_t and M_H. Numerical values and the uncertainties induced by the imperfectly known SM parameters and unknown higher orders [69] are also given for illustration.

Scheme	Notation	Value	Uncertainty
On-shell	s_W^2	0.22337	± 0.00010
$\overline{\rm MS}$	$\widehat{s}_Z^2$	0.23121	± 0.00004
$\overline{\rm MS}$ND	$\widehat{s}_{\rm ND}^2$	0.23141	± 0.00004
$\overline{\rm MS}$	$\widehat{s}_0^2$	0.23857	± 0.00005
Effective angle	$\bar{s}_\ell^2$	0.23153	± 0.00004

to whether or how finite $\alpha\ln(m_t/M_Z)$ terms are decoupled (subtracted from the couplings). One cannot entirely decouple the $\alpha\ln(m_t/M_Z)$ terms from all EW quantities because $m_t \gg m_b$ breaks SU(2) symmetry. The scheme that will be adopted here decouples the $\alpha\ln(m_t/M_Z)$ terms from the γ–Z mixing [27, 71], essentially eliminating any $\ln(m_t/M_Z)$ dependence in the formulae for asymmetries at the Z pole when written in terms of $\widehat{s}_Z^2$. (A similar definition is used for $\widehat{\alpha}$.) The on-shell and $\overline{\rm MS}$ definitions are related by

$$\widehat{s}_Z^2 = c\,(m_t, M_H) s_W^2 = (1.0351 \pm 0.0003) s_W^2 \ . \tag{10.17}$$

The quadratic m_t dependence is given by $c \sim 1 + \rho_t/\tan^2\theta_W$. The expressions for M_W and M_Z in the $\overline{\rm MS}$ scheme are

$$M_W = \frac{A_0}{\widehat{s}_Z(1 - \Delta\widehat{r}_W)^{1/2}} \ , \qquad M_Z = \frac{M_W}{\widehat{\rho}^{1/2}\,\widehat{c}_Z} \ , \tag{10.18}$$

and one predicts $\Delta\widehat{r}_W = 0.06918 \pm 0.00007$. $\Delta\widehat{r}_W$ has no quadratic m_t dependence, because shifts in M_W are absorbed into the observed G_F, so that the error in $\Delta\widehat{r}_W$ is almost entirely due to $\Delta r_0 = 1 - \alpha/\widehat{\alpha}(M_Z)$. The quadratic m_t dependence has been shifted into $\widehat{\rho} \sim 1 + \rho_t$, where including bosonic loops, $\widehat{\rho} = 1.01019 \pm 0.00009$.

(iii) A variant $\overline{\rm MS}$ quantity $\widehat{s}_{\rm ND}^2$ (used in the 1992 edition of this *Review*) does not decouple the $\alpha\ln(m_t/M_Z)$ terms [72]. It is related to $\widehat{s}_Z^2$ by

$$\widehat{s}_Z^2 = \frac{\widehat{s}_{\rm ND}^2}{1 + \frac{\widehat{\alpha}}{\pi} d} \ , \qquad d = \frac{1}{3}\left(\frac{1}{\widehat{s}^2} - \frac{8}{3}\right)\left[\left(1 + \frac{\alpha_s}{\pi}\right)\ln\frac{m_t}{M_Z} - \frac{15\alpha_s}{8\pi}\right] \ . \tag{10.19}$$

Thus, $\widehat{s}_Z^2 - \widehat{s}_{\rm ND}^2 = -0.0002$.

(iv) Some of the low-energy experiments discussed in the next section are sensitive to the weak mixing angle at almost vanishing momentum transfer [35, 73–75]. Thus, Table 10.2 also includes $\widehat{s}_0^2 \equiv \sin^2\widehat{\theta}_W(0)$.

(v) Yet another definition, the effective angle [76, 77], $\bar{s}_f^2 \equiv \sin\theta_{\rm eff}^f$, for the Z vector coupling to fermion f, is based on Z pole observables and described in Sec. 10.5.

10.2.5 *Radiative corrections*

Experiments are at such level of precision [69] that complete one-loop, dominant two-loop, and partial three and four-loop radiative corrections must be applied. For neutral-current and Z pole processes, these corrections are conveniently divided into two classes:

1. QED diagrams involving the emission of real photons or the exchange of virtual photons in loops, but not including vacuum polarization diagrams. These graphs often yield finite and gauge-invariant contributions to observable processes. However, they are dependent on energies, experimental cuts, *etc.*, and must be calculated individually for each experiment.
2. EW corrections, including $\gamma\gamma$, γZ, ZZ, and WW vacuum polarization diagrams, as well as vertex corrections, box graphs, *etc.*, involving virtual W and Z bosons. One-loop corrections [78] are included for all processes, and many two-loop corrections are also important. In particular, two-loop corrections involving the top quark modify ρ_t in $\widehat{\rho}$, Δr, and elsewhere by

$$\rho_t \to \rho_t\left[1 + R(M_H, m_t)\,\frac{\rho_t}{3}\right] \ . \tag{10.20}$$

$R(M_H, m_t)$ can be described as an expansion in M_Z^2/m_t^2, for which the leading m_t^4/M_Z^4 [79, 80] and next-to-leading m_t^2/M_Z^2 [81, 82] terms are known. The complete two-loop calculation of Δr (without further approximation) has been performed in Refs. [83–87]. More recently, Ref. [88] obtained the $\overline{\rm MS}$ quantities $\Delta\widehat{r}_W$ and $\widehat{\rho}$ to two-loop accuracy, confirming the prediction of M_W in the on-shell scheme from Refs. [85, 89] within about 4 MeV. Similarly, the EW two-loop corrections for the relation between $\bar{s}^2_{\ell,b}$ and s^2_W are known [90–95], as well as for the partial decay and total decay widths and the effective couplings of the Z boson [96–99]. For $\bar{s}_{s,c}$ only two-loop corrections from diagrams with closed fermion loops are available [100], but given the experimental precision this is more than adequate.

The mixed QCD-EW contributions to gauge boson self-energies of order $\alpha\alpha_s m_t^2$ [101, 102], $\alpha\alpha_s^2 m_t^2$ [103, 104], and $\alpha\alpha_s^3 m_t^2$ [105–107] increase the predicted value of m_t by 6%. This is, however, almost entirely an artifact of using the pole mass definition for m_t. The equivalent corrections when using the $\overline{\rm MS}$ definition $\widehat{m}_t(\widehat{m}_t)$ increase m_t by less than 0.5%. The sub-leading $\alpha\alpha_s$ corrections [108–111] are also included. Further three-loop corrections of order $\alpha\alpha_s^2$ [112, 113], $\alpha^3 m_t^6$, and $\alpha^2\alpha_s m_t^4$ [114, 115], are rather small. The same is true for $\alpha^3 M_H^4$ [116] corrections unless M_H approaches 1 TeV. The theoretical uncertainty from unknown higher-order corrections [69] is estimated to amount to 4 MeV for the prediction of M_W [89] and 4.5×10^{-5} for $\bar{s}^2_\ell$ [100].

Throughout this *Review* we utilize EW radiative corrections from the program GAPP [32], which works entirely in the $\overline{\rm MS}$ scheme, and which is independent of the package ZFITTER [117].

10.3 Low energy electroweak observables

In the following we discuss EW precision observables obtained at low momentum transfers [118], *i.e.*, $Q^2 \ll M_Z^2$. It is convenient to write the four-fermion interactions relevant to ν-hadron, ν-e, as well as parity violating e-hadron and e-e neutral-current processes, in a form that is valid in an arbitrary gauge theory (assuming massless left-handed neutrinos). One has[9],

$$-\mathscr{L}^{\nu e} = \frac{G_F}{\sqrt{2}}\,\bar\nu\gamma_\mu(1-\gamma^5)\nu\;\bar e\gamma^\mu(g^{\nu e}_{LV} - g^{\nu e}_{LA}\gamma^5)e\;, \tag{10.21a}$$

$$-\mathscr{L}^{\nu h} = \frac{G_F}{\sqrt{2}}\,\bar\nu\gamma_\mu(1-\gamma^5)\nu\sum_q\Big[g^{\nu q}_{LL}\,\bar q\gamma^\mu(1-\gamma^5)q + g^{\nu q}_{LR}\,\bar q\gamma^\mu(1+\gamma^5)q\Big] \tag{10.21b}$$

$$-\mathscr{L}^{ee} = -\frac{G_F}{\sqrt{2}}\,g^{ee}_{AV}\,\bar e\gamma_\mu\gamma^5 e\;\bar e\gamma^\mu e\;, \tag{10.21c}$$

$$-\mathscr{L}^{eh} = -\frac{G_F}{\sqrt{2}}\sum_q\Big[g^{eq}_{AV}\,\bar e\gamma_\mu\gamma^5 e\;\bar q\gamma^\mu q + g^{eq}_{VA}\,\bar e\gamma_\mu e\;\bar q\gamma^\mu\gamma^5 q\Big]\;, \tag{10.21d}$$

where one must include the charged-current contribution for ν_e-e and $\bar\nu_e$-e and the parity conserving QED contribution for electron scattering. The SM tree level expressions for the four-Fermi couplings are given in Table 10.3. Note that they differ from the respective products of the gauge couplings in (10.6) in the radiative corrections and in the presence of possible physics beyond the SM.

10.3.1 *Neutrino scattering*

The cross-section in the laboratory system for $\nu_\mu e \to \nu_\mu e$ or $\bar\nu_\mu e \to \bar\nu_\mu e$ elastic scattering [9, 119] is (in this subsection we drop the redundant index L in the effective neutrino couplings),

$$\frac{d\sigma_{\nu,\bar\nu}}{dy} = \frac{G_F^2 m_e E_\nu}{2\pi}\Big[\,(g^{\nu e}_V \pm g^{\nu e}_A)^2 + (g^{\nu e}_V \mp g^{\nu e}_A)^2(1-y)^2 - (g^{\nu e2}_V - g^{\nu e2}_A)\frac{y\,m_e}{E_\nu}\Big]\;, \tag{10.22}$$

where the upper (lower) sign refers to $\nu_\mu(\bar\nu_\mu)$, and $y \equiv T_e/E_\nu$ (which runs from 0 to $(1+m_e/2E_\nu)^{-1}$) is the ratio of the kinetic energy of the recoil electron to the incident ν or $\bar\nu$ energy. For $E_\nu \gg m_e$ this yields a total cross-section

$$\sigma = \frac{G_F^2 m_e E_\nu}{2\pi}\left[(g^{\nu e}_V \pm g^{\nu e}_A)^2 + \frac{1}{3}(g^{\nu e}_V \mp g^{\nu e}_A)^2\right]\;. \tag{10.23}$$

The most accurate measurements of $\sin^2\theta_W$ from ν-lepton scattering (see Sec. 10.6) are from the ratio $R \equiv \sigma_{\nu_\mu e}/\sigma_{\bar\nu_\mu e}$, in which many of the systematic uncertainties cancel. The results are $\sin^2\theta_W = 0.211\pm0.037$ [120], $\sin^2\theta_W = 0.195\pm0.022$ [121], and $\sin^2\theta_W = 0.2324\pm0.0083$ [122], where radiative corrections (other than m_t effects) are small compared to the precision of present experiments and have negligible effect. As shown in Fig. 10.1, one can determine $g^{\nu e}_{V,A}$ from the experimental data as well. The cross-sections for ν_e-e and $\bar\nu_e$-e may be obtained from Eq. (10.22) by replacing $g^{\nu e}_{V,A}$ by $g^{\nu e}_{V,A}+1$, where the 1 is due to the charged-current contribution.

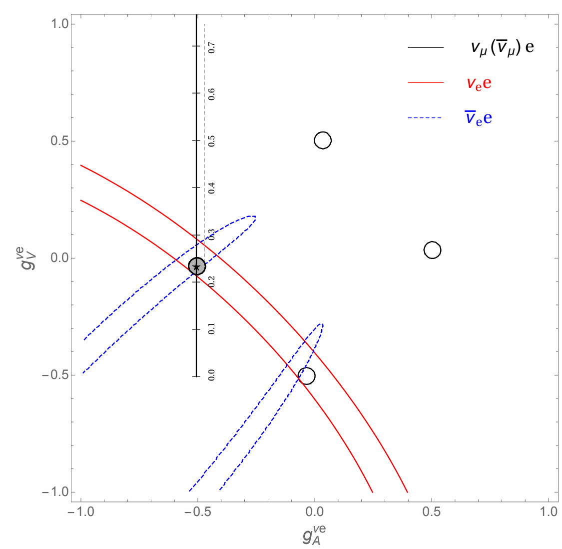

Figure 10.1: Allowed contours in $g^{\nu e}_A$ *vs.* $g^{\nu e}_V$ from neutrino-electron scattering and the SM prediction as a function of $\widehat{s}^2_Z$. (The SM best fit value, $\widehat{s}^2_Z = 0.23121$, is also indicated.) The ν_e-e [123, 124] and $\bar\nu_e$-e [125] constraints are at 1 σ, while each of the four equivalent $\nu_\mu(\bar\nu_\mu)$-e [120–122] solutions ($g_{V,A} \to -g_{V,A}$ and $g_{V,A} \to g_{A,V}$) are at the 90% CL. The global best fit region (shaded) almost exactly coincides with the corresponding $\nu_\mu(\bar\nu_\mu)$-e region. The solution near $g_A = 0$ and $g_V = -0.5$ is eliminated by $e^+e^- \to \ell^+\ell^-$ data under the weak additional assumption that the neutral current is dominated by the exchange of a single Z boson.

A precise determination of the on-shell s^2_W, which depends only very weakly on m_t and M_H, is obtained from deep inelastic scattering (DIS) of neutrinos [119, 126] from (approximately) isoscalar targets. The ratio $R_\nu \equiv \sigma^{NC}_{\nu N}/\sigma^{CC}_{\nu N}$ of neutral-to-charged-current cross-sections has been measured to 1% accuracy by CDHS [127] and CHARM [128] at CERN. CCFR [129] at Fermilab has obtained an even more precise result, so it is important to obtain theoretical expressions for R_ν and $R_{\bar\nu} \equiv \sigma^{NC}_{\bar\nu N}/\sigma^{CC}_{\bar\nu N}$ to comparable accuracy. Fortunately, many of the uncertainties from the strong interactions and neutrino spectra cancel in the ratio. A large theoretical uncertainty is associated with the c-threshold,

[9] We use here slightly different definitions (and to avoid confusion also a different notation) for the coefficients of these four-Fermi operators than we did in previous editions of this *Review*. The new couplings [13] are defined in the static limit, $Q^2 \to 0$, with specific radiative corrections included, while others (more experiment specific ones) are assumed to be removed by the experimentalist. They are convenient in that their determinations from very different types of processes can be straightforwardly combined.

Table 10.3: SM tree level expressions for the neutral-current parameters for ν-hadron, ν-e, and e^- scattering processes. To obtain the SM values in the last column, the tree level expressions have to be multiplied by the low-energy neutral-current ρ parameter, $\rho_{\rm NC} = 1.00063$, and further vertex and box corrections need to be added as detailed in Ref. [13]. The dominant m_t dependence is again given by $\rho_{\rm NC} \sim 1 + \rho_t$.

Quantity	SM tree level	SM value
$g_{LV}^{\nu_\mu e}$	$-\frac{1}{2} + 2\,\widehat{s}_0^2$	-0.0398
$g_{LA}^{\nu_\mu e}$	$-\frac{1}{2}$	-0.5064
$g_{LL}^{\nu_\mu u}$	$\frac{1}{2} - \frac{2}{3}\,\widehat{s}_0^2$	0.3458
$g_{LL}^{\nu_\mu d}$	$-\frac{1}{2} + \frac{1}{3}\,\widehat{s}_0^2$	-0.4288
$g_{LR}^{\nu_\mu u}$	$-\frac{2}{3}\,\widehat{s}_0^2$	-0.1552
$g_{LR}^{\nu_\mu d}$	$\frac{1}{3}\,\widehat{s}_0^2$	0.0777
g_{AV}^{ee}	$\frac{1}{2} - 2\,\widehat{s}_0^2$	0.0227
g_{AV}^{eu}	$-\frac{1}{2} + \frac{4}{3}\,\widehat{s}_0^2$	-0.1888
g_{AV}^{ed}	$\frac{1}{2} - \frac{2}{3}\,\widehat{s}_0^2$	0.3419
g_{VA}^{eu}	$-\frac{1}{2} + 2\,\widehat{s}_0^2$	-0.0352
g_{VA}^{ed}	$\frac{1}{2} - 2\,\widehat{s}_0^2$	0.0249

which mainly affects σ^{CC}. Using the slow rescaling prescription [130, 131] the central value of $\sin^2\theta_W$ from CCFR varies as $0.0111(m_c/\text{GeV}-1.31)$, where m_c is the effective mass which is numerically close to the $\overline{\rm MS}$ mass $\widehat{m}_c(\widehat{m}_c)$, but their exact relation is unknown at higher orders. For $m_c = 1.31 \pm 0.24$ GeV, which was determined from ν-induced di-muon production [132], this contributes ± 0.003 to the total uncertainty of $\Delta\sin^2\theta_W = \pm 0.004$, where the experimental uncertainty was also ± 0.003. This uncertainty largely cancels, however, in the Paschos-Wolfenstein ratio [133],

$$R^- = \frac{\sigma_{\nu N}^{NC} - \sigma_{\bar\nu N}^{NC}}{\sigma_{\nu N}^{CC} - \sigma_{\bar\nu N}^{CC}} \,. \tag{10.24}$$

It was measured by Fermilab's NuTeV collaboration [134] for the first time, and required a high-intensity and high-energy anti-neutrino beam.

A simple zero$^{\rm th}$-order approximation is,

$$R_\nu = g_L^2 + g_R^2 r\,, \qquad R_{\bar\nu} = g_L^2 + \frac{g_R^2}{r}\,, \tag{10.25a}$$

$$R^- = g_L^2 - g_R^2\,, \qquad r \equiv \frac{\sigma_{\bar\nu N}^{CC}}{\sigma_{\nu N}^{CC}}\,, \tag{10.25b}$$

where r is the ratio of $\bar\nu$ to ν charged-current cross-sections which can be measured directly[10], and

$$g_L^2 \equiv (g_{LL}^{\nu_\mu u})^2 + (g_{LL}^{\nu_\mu d})^2 \approx \frac{1}{2} - \sin^2\theta_W + \frac{5}{9}\sin^4\theta_W\,, \tag{10.26a}$$

$$g_R^2 \equiv (g_{LR}^{\nu_\mu u})^2 + (g_{LR}^{\nu_\mu d})^2 \approx \frac{5}{9}\sin^4\theta_W\,. \tag{10.26b}$$

In practice, Eq. (10.25b) must be corrected for quark mixing, quark sea effects, c quark threshold effects, non-isoscalarity, W–Z propagator differences, the finite muon mass, QED and EW radiative corrections. Details of the neutrino spectra, experimental cuts, x and Q^2 dependence of structure functions, and longitudinal structure functions, enter only at the level of these corrections and therefore lead to very small uncertainties. CCFR quotes $s_W^2 = 0.2236 \pm 0.0041$ for the reference values $(m_t, M_H) = (175, 150)$ GeV with very little sensitivity to (m_t, M_H).

The NuTeV collaboration found $s_W^2 = 0.2277 \pm 0.0016$ (for the same reference values), which was 3.0 σ higher than the SM prediction [134]. However, since then several groups have raised concerns about the interpretation of the NuTeV result, which could affect the extracted $g_{L,R}^2$ (and thus s_W^2) including their uncertainties and correlation. These include the assumption of symmetric strange and anti-strange sea quark distributions, the electron neutrino contamination from K_{e3} decays, isospin symmetry violation in the parton distribution functions and from QED splitting effects, nuclear shadowing effects, and a more complete treatment of EW and QCD radiative corrections. A more detailed discussion and a list of references can be found in the 2016 edition of this *Review*. The precise impact of these effects would need to be evaluated carefully by the collaboration, but in the absence of such an effort we do not include the νDIS constraints in our default set of fits.

Very recently, the COHERENT collaboration was the first to observe the coherent elastic neutrino nucleus scattering (CEνNS) process [135] on a target consisting mostly of ^{133}Cs and ^{127}I, and at the opposite end of the kinematic scale where the momentum transfer is significantly smaller than the inverse of the nuclear radius. The coherence enhances the process roughly proportional to the square of the number of neutrons in the nuclei, but the process is difficult to observe as the experimental signature is a mere keV scale nuclear recoil.

10.3.2 *Parity violating lepton scattering*

Reviews on weak polarized electron scattering may be found in Refs. [9, 136]. The SLAC polarized electron-deuteron DIS (eDIS) experiment [137] measured the parity violating right-left asymmetry,

$$A_{RL} \equiv \frac{\sigma_R - \sigma_L}{\sigma_R + \sigma_L}\,, \tag{10.27}$$

where $\sigma_{R,L}$ is the cross-section for the deep-inelastic scattering of a right- or left-handed electron, $e_{R,L}N \to e$X. In the quark parton model,

$$\frac{A_{RL}}{Q^2} = a_1 + a_2\,\frac{1-(1-y)^2}{1+(1-y)^2}\,, \tag{10.28}$$

where $Q^2 > 0$ is the momentum transfer and y is the fractional energy transfer from the electron to the hadrons. For the deuteron or other isoscalar targets, one has, neglecting the s quark and anti-quarks,

$$a_1 = \frac{3G_F}{5\sqrt{2}\pi\alpha}\left(g_{AV}^{eu} - \frac{1}{2}g_{AV}^{ed}\right) \approx \frac{3G_F}{5\sqrt{2}\pi\alpha}\left(-\frac{3}{4} + \frac{5}{3}\widehat{s}_0^2\right)\,, \tag{10.29a}$$

$$a_2 = \frac{3G_F}{5\sqrt{2}\pi\alpha}\left(g_{VA}^{eu} - \frac{1}{2}g_{VA}^{ed}\right) \approx \frac{9G_F}{5\sqrt{2}\pi\alpha}\left(\widehat{s}_0^2 - \frac{1}{4}\right)\,. \tag{10.29b}$$

The Jefferson Lab Hall A collaboration [138, 139] improved on the SLAC result by measuring A_{RL} at $Q^2 = 1.085$ GeV^2 and

[10] In the simple parton model, ignoring hadron energy cuts, $r \approx (1+3\epsilon)/(3+\epsilon)$, where $\epsilon \sim 0.125$ is the ratio of the fraction of the nucleon's momentum carried by anti-quarks to that carried by quarks.

1.901 GeV^2, and determined the weak mixing angle to 2% precision, $\widehat{s}^2(161 \text{ MeV}) = 0.2403 \pm 0.0043$. In another polarized electron scattering experiment on deuterons, but in the quasi-elastic kinematic regime, the SAMPLE experiment [140, 141] at MIT-Bates extracted the combination $g_{VA}^{eu} - g_{VA}^{ed}$ at Q^2 values of 0.038 GeV^2 and 0.091 GeV^2. What was actually determined were nucleon form factors from which the quoted results were obtained by the removal of a multi-quark radiative correction [142]. Other linear combinations of the effective couplings have been determined in polarized lepton scattering at CERN in μ-^{12}C DIS [143] (the observable was the double charge-helicity cross-section asymmetry), at Mainz in e-^{9}Be (quasi-elastic) [144], and at Bates in e-^{12}C (elastic) [145]. More recent polarized electron scattering experiments, *i.e.*, SAMPLE, the PVA4 experiment at Mainz, and the HAPPEX and GØ experiments at Jefferson Lab, have focussed on the strange quark content of the nucleon [146].

A_{RL} can also be measured in fixed target polarized Møller scattering, $e^-e^- \to e^-e^-$, and reads [147],

$$\frac{A_{RL}}{Q^2} = -2\, g_{AV}^{ee}\, \frac{G_F}{\sqrt{2}\pi\alpha}\, \frac{1-y}{1+y^4+(1-y)^4} \; . \tag{10.30}$$

It has been determined at low $Q^2 = 0.026$ GeV^2 in the SLAC E158 experiment [148], with the result, $A_{RL} = (-1.31 \pm 0.14_{\text{stat.}} \pm$

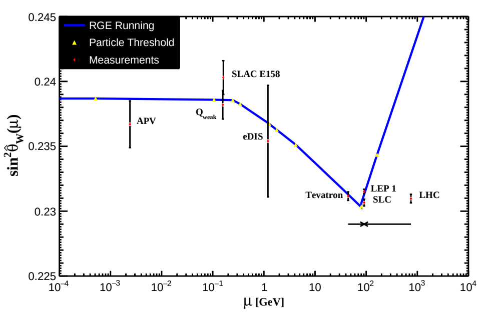

Figure 10.2: Scale dependence of the weak mixing angle defined in the $\overline{\text{MS}}$ scheme [35, 74] (for the scale dependence in a mass-dependent renormalization scheme, see Ref. [73]). The minimum of the curve corresponds to $\mu = M_W$, below which we switch to an effective theory with the $W^\pm$ bosons integrated out, and where the β-function for $\widehat{s}^2(\mu)$ changes sign. At M_W and each fermion mass there are also discontinuities arising from scheme dependent matching terms, which are necessary to ensure that the various effective field theories within a given loop order describe the same physics. However, in the $\overline{\text{MS}}$ scheme these are very small numerically and barely visible in the figure provided one decouples quarks at $\mu = \widehat{m}_q(\widehat{m}_q)$. The width of the curve exceeds the theory uncertainty from strong interaction effects which at low energies is at the level of $\pm 2 \times 10^{-5}$ [35]. The Tevatron and LHC measurements are strongly dominated by invariant masses of the final-state di-lepton pair of $\mathcal{O}(M_Z)$ and can thus be considered as additional Z pole data points. For clarity we displayed the Tevatron and LHC points horizontally to the left and right, respectively.

$0.10_{\text{syst.}}) \times 10^{-7}$. Expressed in terms of the weak mixing angle in the $\overline{\text{MS}}$ scheme this yields $\widehat{s}^2(161 \text{ MeV}) = 0.2403 \pm 0.0013$, and as shown in Fig. 10.2 established the scale dependence of the weak mixing angle at the level of 6.4 σ. One also extracts the model-independent effective coupling, $g_{AV}^{ee} = 0.0190 \pm 0.0027$ [13]. One-loop radiative corrections and implications are discussed in Ref. [73].

In a similar experiment and at about the same $Q^2 = 0.0248$ GeV^2, the Q$_{\text{weak}}$ collaboration at Jefferson Lab obtained $A_{RL} = (-2.265 \pm 0.073_{\text{stat.}} \pm 0.058_{\text{syst.}}) \times 10^{-7}$ [149, 150] in elastic $e^-p \to e^-p$ scattering. To extract the physical quantity of interest, the weak charge of the proton [151], a large ($\approx 30\%$) correction had to be applied to A_{RL} arising from electromagnetic, strange, and axial form factors. This was achieved by performing a global fit [152] including a large number of A_{RL} data points at larger Q^2, dominated by the HAPPEX result at $Q^2 = 0.109$ GeV^2 [153]. Finally, the constraint, $2g_{AV}^{eu} + g_{AV}^{ed} = 0.0356 \pm 0.0023$, which translates into a weak mixing angle measurement of $\widehat{s}^2(157 \text{ MeV}) = 0.2382 \pm 0.0011$, could be deduced, after correcting for a relatively large and uncertain contribution from the γZ box diagram [154–157].

10.3.3 *Atomic parity violation*

There are precise measurements of atomic parity violation (APV) [9, 158, 159] in ^{133}Cs [160, 161] (at the 0.4% level [160]), ^{205}Tl [162, 163], ^{208}Pb [164], and ^{209}Bi [165]. The EW physics is contained in the nuclear weak charges $Q_W(Z,N)$, where Z and N are the numbers of protons and neutrons in the nucleus. In terms of the nucleon vector couplings,

$$g_{AV}^{ep} \equiv 2g_{AV}^{eu} + g_{AV}^{ed} \approx -\frac{1}{2} + 2\widehat{s}_0^2 \; , \tag{10.31a}$$

$$g_{AV}^{en} \equiv g_{AV}^{eu} + 2g_{AV}^{ed} \approx +\frac{1}{2} \; , \tag{10.31b}$$

one has,

$$Q_W(Z,N) \equiv -2\left[Z(g_{AV}^{ep} + 0.00005) + N(g_{AV}^{en} + 0.00006)\right] \times \left(1 - \frac{\alpha}{2\pi}\right) \; , \tag{10.32}$$

where the numerically small adjustments are discussed in Ref. [13] and include the result of the γZ-box correction from Ref. [166].

E.g., $Q_W(^{133}_{78}\text{Cs})$ is extracted by measuring experimentally the ratio of the parity violating amplitude, E_{PNC}, to the Stark vector transition polarizability, β, and by calculating theoretically E_{PNC} in terms of Q_W. One can then write,

$$Q_W(^{133}_{78}\text{Cs}) = N\left(\frac{\text{Im}\, E_{\text{PNC}}}{\beta}\right)_{\text{exp.}} \left(\frac{|e|\, a_B}{\text{Im}\, E_{\text{PNC}}}\frac{Q_W}{N}\right)_{\text{th.}} \times \left(\frac{\beta}{a_B^3}\right)_{\text{exp.+th.}} \left(\frac{a_B^2}{|e|}\right) \; , \tag{10.33}$$

where a_B is the Bohr radius. There are currently two semi-empirical approaches to β of similar precision. The ratio of the off-diagonal hyperfine amplitude to the vector polarizability was measured directly by the Boulder group [167]. Combined with the hyperfine amplitude, computed precisely in Ref. [168], one finds $\beta = (26.957 \pm 0.044_{\text{exp.}} \pm 0.027_{\text{th.}})\, a_B^3$. Alternatively, one can combine [169] the measurement of the ratio of scalar to vector transition polarizabilities [170] with the recent calculation of the scalar polarizability [171] to obtain $\beta = (27.139 \pm 0.030_{\text{exp.}} \pm 0.030_{\text{th.}})\, a_B^3$, in agreement with earlier results [172, 173] based on this approach. The two determinations average to $\beta = (27.064 \pm 0.025_{\text{exp.}} \pm 0.021_{\text{th.}})\, a_B^3$, while they differ by 2.7 σ.

The uncertainties associated with the atomic wave function calculations are relatively small for cesium [9, 174–176]. State-of-the-art many-body atomic structure computations of the parity non-conserving amplitude, $\text{Im}\, E_{\text{PNC}} = (0.8977 \pm 0.0040) \times 10^{-11} |e|\, a_B\, Q_W/N$ [177–182], together with the measurements [160, 161] which can be combined to give $\text{Im}\, E_{\text{PNC}}/\beta = -1.5924 \pm 0.0055$ mV/cm, imply,

$$Q_W(^{133}_{78}\text{Cs}) = -72.82 \pm 0.26_{\text{exp.}} \pm 0.33_{\text{th.}} \; , \tag{10.34}$$

or equivalently the constraint, $55g_{AV}^{ep} + 78g_{AV}^{en} = 36.46 \pm 0.21$. Within the SM this can also be translated into a determination of the weak mixing angle, $\widehat{s}^2(2.4 \text{ MeV}) = 0.2367 \pm 0.0018$, where the scale setting follows the estimate in Ref. [183] for the typical momentum transfer for parity violation experiments in Cs (the corresponding estimate for Tl amounts to 8 MeV). By comparing different hyperfine transitions, the Boulder experiment in cesium also observed the parity violating weak corrections to the nuclear electromagnetic vertex, called the nuclear anapole moment [184–186].

The theoretical atomic structure uncertainties are 3% for thallium [187] and even larger for the other atoms. However, they mostly cancel if one takes ratios of parity violation in different isotopes [188]. The first result of this type of experiment was announced very recently by the Mainz group [189], who studied APV in ^{100}Yb, ^{102}Yb, ^{104}Yb, and ^{106}Yb, at the 0.5% level. The resulting three ratios can be interpreted as a measurement of $\widehat{s}_0^2 = 0.258 \pm 0.052$, and represent a very complementary approach to search for BSM physics [190]. If the precision increases in the future, one would ultimately face uncertainties from differences in the neutron charge radii [191, 192]. These can be constrained experimentally [193], *e.g.*, by measuring A_{RL} in heavier nuclei as done by the PREX collaboration at Jefferson Lab on ^{208}Pb [194].

10.4 Precision flavor physics

In addition to cross-sections, asymmetries, parity violation, W, Z, Higgs and other collider physics, there is a large number of experiments and observables testing the flavor structure of the SM. These are addressed elsewhere in this *Review*, and are generally not included in this Section. However, we identify three precision observables with sensitivity to similar types of new physics as the other processes discussed here. The branching fraction of the flavor changing transition $b \to s\gamma$ is of comparatively low precision, but since it is a loop-level process (in the SM) its sensitivity to new physics (and SM parameters, such as heavy quark masses) is enhanced. A discussion can be found in the 2010 edition of this *Review*.

The τ lepton lifetime and leptonic branching ratios are primarily sensitive to α_s and not affected significantly by many types of new physics. However, having an independent and reliable low energy measurement of α_s in a global analysis allows the comparison with the Z lineshape determination of α_s which shifts easily in the presence of new physics contributions. By far the most precise observable discussed here is the anomalous magnetic moment of the muon. Its combined experimental and theoretical uncertainty is smaller than typical electroweak scale contributions. The electron magnetic moment is measured to even greater precision, and as discussed in Sec. 10.2.2 can be used to determine α. Its new physics sensitivity, however, is suppressed by an additional factor of m_e^2/m_μ^2, unless there is a new light degree of freedom such as a dark Z [195] boson.

10.4.1 *The τ lifetime*

The extraction of α_s from the τ lifetime τ_τ [196, 197] is standing out from other determinations because of a variety of independent reasons:

(i) The τ-scale is low, so that upon extrapolation to the Z scale (where it can be compared to the theoretically clean Z lineshape determinations) the α_s error shrinks by about an order of magnitude.

(ii) Yet, this scale is high enough that perturbation theory and the operator product expansion (OPE) can be applied.

(iii) These observables are fully inclusive and thus free of fragmentation and hadronization effects that would have to be modeled or measured.

(iv) Duality violation (DV) effects are most problematic near the branch cut but there they are suppressed by a double zero at $s = m_\tau^2$.

(v) There are data [39, 41, 198] to constrain non-perturbative effects both within and breaking the OPE.

(vi) A complete four-loop order QCD calculation is available [199–203] in the massless limit.

(vii) Large effects associated with the QCD β-function can be re-summed [204] in what has become known as contour improved perturbation theory (CIPT).

However, while CIPT certainly shows faster convergence in the lower (calculable) orders, doubts have been cast on the method by the observation that at least in a specific model [205], which includes the exactly known coefficients and theoretical constraints on the large-order behavior, ordinary fixed order perturbation theory (FOPT) may nevertheless give a better approximation to the full result. We therefore use the expressions [53, 203, 206],

$$\tau_\tau = \hbar \frac{1 - \mathcal{B}_\tau^s}{\Gamma_\tau^e + \Gamma_\tau^\mu + \Gamma_\tau^{ud}} = 290.75 \pm 0.36 \text{ fs} , \qquad (10.35)$$

and

$$\Gamma_\tau^{ud} = \frac{G_F^2 m_\tau^5 |V_{ud}|^2}{64\pi^3} S(m_\tau, M_Z) \left(1 + \frac{3}{5} \frac{m_\tau^2 - m_\mu^2}{M_W^2}\right) \times \left[1 + \frac{\alpha_s(m_\tau)}{\pi} + 5.202 \frac{\alpha_s^2}{\pi^2} + 26.37 \frac{\alpha_s^3}{\pi^3} + 127.1 \frac{\alpha_s^4}{\pi^4} + \frac{\widehat{\alpha}}{\pi}\left(\frac{85}{24} - \frac{\pi^2}{2}\right) + \delta_{\rm NP}\right] , \qquad (10.36)$$

where Γ_τ^e and Γ_τ^μ can be taken from Eq. (10.7) with obvious replacements. The relative fraction of strangeness changing ($\Delta S = -1$) decays, $\mathcal{B}_\tau^s = 0.0292 \pm 0.0004$, is based on experimental data since the value for the strange quark mass, $\widehat{m}_s(m_\tau)$, is not well known and the QCD expansion proportional to $\widehat{m}_s^2$ converges poorly and cannot be trusted. $S(m_\tau, M_Z) = 1.01907 \pm 0.0003$ is a logarithmically enhanced EW correction factor [207] with higher orders re-summed [208].

$\delta_{\rm NP}$ collects non-perturbative and quark-mass suppressed contributions, including the dimension four, six and eight terms in the OPE, as well as DV effects. We use the average $\delta_{\rm NP} = 0.0141 \pm 0.0072$ derived from the τ decay spectral functions provided by OPAL [39] and ALEPH [41, 198], which give $\delta_{\rm NP} = 0.000 \pm 0.012$ and $\delta_{\rm NP} = 0.022 \pm 0.009$, respectively. These numbers are based on the original analyses in Refs. [209, 210], but are modified to correspond to a strict FOPT analysis as is appropriate for our purpose[11] (for alternative analyses, see Refs. [197, 198, 211]).

The dominant uncertainty arises from the truncation of the FOPT series and is conservatively taken as the α_s^4 term (this is re-calculated in each call of the fits, leading to an α_s-dependent and thus asymmetric error) until a better understanding of the numerical differences between FOPT and CIPT has been gained. Our perturbative error covers almost the entire range from using CIPT to assuming that the nearly geometric series in Eq. (10.36) continues to higher orders. The experimental uncertainty in Eq. (10.35) is from the combination of the two leptonic branching ratios with the direct τ_τ. Included are also various smaller uncertainties (± 0.15 fs) from other sources. Based on the method of Refs. [53, 212], we obtain in total

$$\alpha_s^{(4)}(m_\tau) = 0.312^{+0.016}_{-0.013} , \qquad \alpha_s^{(5)}(M_Z) = 0.1170^{+0.0019}_{-0.0017} , \qquad (10.37)$$

which represents a 1.5% determination of $\alpha_s(M_Z)$. For more details, see Refs. [209, 210] where the τ spectral functions themselves and an estimate of the unknown α_s^5 term were used as additional inputs.

10.4.2 *The muon anomalous magnetic moment*

The world average of the muon anomalous magnetic moment[12],

$$a_\mu^{\rm exp} = \frac{g_\mu - 2}{2} = (1165920.91 \pm 0.63) \times 10^{-9} , \qquad (10.38)$$

is dominated by the final result of the BNL E821 collaboration [213]. The QED contribution has been calculated to five loops [214–216] (fully analytic to three loops [217–221] and semi-analytic to four loops [222]). The estimated SM EW contribution [223–228], $a_\mu^{\rm EW} = (1.54 \pm 0.01) \times 10^{-9}$, includes two-

[11] We are indebted to Diogo Boito, Maarten Golterman, Kim Maltman and Santiago Peris for privately communicating these results to us.

[12] In what follows, we summarize the most important aspects of a_μ and give some details on the evaluation in our fits. For more details and references, see the Section on the "Muon Anomalous Magnetic Moment" in this *Review*. There are some numerical differences, which are well understood and arise because internal consistency of the fits requires the calculation of all observables from analytical expressions and common inputs and fit parameters, so that an independent evaluation is necessary for this Section. Note, that in the spirit of a global analysis based on all available information we have chosen here to also include τ decay data [30], corrected for isospin breaking effects [31].

loop [229–233] and leading three-loop [234, 235] corrections and is at the level of twice the current uncertainty.

The limiting factor in the interpretation of the result are the uncertainties from hadronic effects. The most recent evaluations of the leading-order (two-loop) hadronic vacuum polarization contribution obtained $a_\mu^{\rm had,VP}(\alpha^2) = (68.81 \pm 0.41) \times 10^{-9}$ [236], $a_\mu^{\rm had,VP}(\alpha^2) = (69.39 \pm 0.40) \times 10^{-9}$ [29], and $a_\mu^{\rm had,VP}(\alpha^2) = (69.28 \pm 0.24) \times 10^{-9}$ [37]. These are mainly based on data from $e^+e^- \to$ hadrons (see, *e.g.*, Ref. [29] for references). Our analysis combines the e^+e^- [29] and τ-decay data [30,31] for contributions up to $\sqrt{s} = 2$ GeV, $a_\mu^{\rm had,VP}(\alpha^2, 2\ {\rm GeV}) = (64.49 \pm 0.33) \times 10^{-9}$, with analytical PQCD expressions for energies beyond 2 GeV and for the c and b quark contributions [221]. By now there are also precise results for the determination of $a_\mu^{\rm had,VP}(\alpha^2)$ from lattice QCD calculations [237] at the 2–3% level [238–242], while the most recent one has a 0.6% quoted uncertainty [243] (for a comparative appraisal and further references, see Ref. [244]). The result of Ref. [243], $(71.24 \pm 0.45) \times 10^{-9}$, has a more than 3 σ conflict with the data-driven evaluations, while there is very good statistical agreement among the different lattice results, assuming them to be uncorrelated ($\chi^2/{\rm d.o.f.} = 5.1/5$). If confirmed, the recent lattice determinations for $a_\mu^{\rm had,VP}(\alpha^2)$ may point to a problem with the data-driven approach to this quantity.

The other hadronic uncertainty is induced by the three-loop light-by-light scattering amplitude, where a number of independent model calculations yield results which are in reasonable agreement with each other, $a_\mu^{{\rm had},\gamma\times\gamma}(\alpha^3) = (1.36 \pm 0.25) \times 10^{-9}$ [245], $a_\mu^{{\rm had},\gamma\times\gamma}(\alpha^3) = 1.37^{+0.15}_{-0.27} \times 10^{-9}$ [246], $a_\mu^{{\rm had},\gamma\times\gamma}(\alpha^3) = (1.05 \pm 0.26) \times 10^{-9}$ [247], and $a_\mu^{{\rm had},\gamma\times\gamma}(\alpha^3) = (1.03 \pm 0.29) \times 10^{-9}$ [236], but the sign of this effect is opposite [248] to the one quoted in the 2002 edition of this *Review*. There is also an upper bound given by $a_\mu^{{\rm had},\gamma\times\gamma}(\alpha^3) < 1.59 \times 10^{-9}$ [246] but this requires an *ad hoc* assumption, too. An effort to improve the evaluation of the light-by-light contribution by using experimental input where available yields a slightly lower value, $a_\mu^{{\rm had},\gamma\times\gamma}(\alpha^3) = (0.87 \pm 0.13) \times 10^{-9}$ [249]. A first complete result from lattice simulations, $a_\mu^{{\rm had},\gamma\times\gamma}(\alpha^3) = (0.79 \pm 0.35) \times 10^{-9}$ [250], accounting for all systematic errors, is consistent with the model and data-driven calculations. For the fits, we take the result from Ref. [236], shifted by 2×10^{-11} to account for the more accurate charm quark treatment of Ref. [246], and with increased error to cover all recent evaluations, resulting in $a_\mu^{{\rm had},\gamma\times\gamma}(\alpha^3) = (1.05 \pm 0.33) \times 10^{-9}$.

Sub-leading hadronic vacuum polarization effects at three-loop [251] and four-loop order [252] contribute $a_\mu^{\rm had,VP}(\alpha^3) = (-0.983 \pm 0.004) \times 10^{-9}$ [37] and $a_\mu^{\rm had,VP}(\alpha^4) = (0.124 \pm 0.001) \times 10^{-9}$ [252], respectively. The correlations with the two-loop hadronic contribution and with $\Delta\alpha(M_Z)$ (see Sec. 10.2) were considered in Ref. [221]. The contributions with a hadronic light-by-light scattering subgraph have been estimated in Ref. [253], with the result, $a_\mu^{{\rm had},\gamma\times\gamma}(\alpha^4) = (0.03 \pm 0.02) \times 10^{-9}$.

Altogether, the SM prediction is

$$a_\mu^{\rm theory} = (1165918.46 \pm 0.47) \times 10^{-9} , \tag{10.39}$$

where the error is from the hadronic uncertainties excluding parametric ones such as from α_s and the heavy quark masses. We evaluate the correlation of the total (experimental plus theoretical) uncertainty in a_μ with $\Delta\alpha(M_Z)$ to amount to roughly 30%. The overall 3.1 σ discrepancy between $a_\mu^{\rm theory}$ and $a_\mu^{\rm exp}$ could be due to fluctuations (the E821 result is statistics dominated) or underestimates of the theoretical uncertainties. On the other hand, the deviation could also arise from physics beyond the SM, such as supersymmetric models with large $\tan\beta$ and moderately light superparticle masses [254], or a dark Z boson [195].

10.5 Physics of the massive electroweak bosons

If the CM energy $\sqrt{s}$ is large compared to the fermion mass m_f, the unpolarized Born cross-section for $e^+e^- \to f\bar{f}$ [255] can be written as,

$$\frac{d\sigma}{d\cos\theta} = \frac{\pi\alpha^2(s)}{2s}\left[F_1(1+\cos^2\theta) + 2F_2\cos\theta\right] + B , \tag{10.40a}$$

$$F_1 = Q_e^2 Q_f^2 - 2\chi Q_e Q_f \bar{g}_V^e \bar{g}_V^f \cos\delta_R + \chi^2(\bar{g}_V^{e2} + \bar{g}_A^{e2})(\bar{g}_V^{f2} + \bar{g}_A^{f2}) , \tag{10.40b}$$

$$F_2 = -2\chi Q_e Q_f \bar{g}_A^e \bar{g}_A^f \cos\delta_R + 4\chi^2 \bar{g}_V^e \bar{g}_A^e \bar{g}_V^f \bar{g}_A^f , \tag{10.40c}$$

where,

$$\tan\delta_R = \frac{\overline{M}_Z \overline{\Gamma}_Z}{\overline{M}_Z^2 - s} , \quad \chi = \frac{G_F}{2\sqrt{2}\pi\alpha(s)} \frac{s\overline{M}_Z^2}{\left[(\overline{M}_Z^2 - s)^2 + \overline{M}_Z^2\overline{\Gamma}_Z^2\right]^{1/2}} . \tag{10.41}$$

B accounts for box graphs involving virtual Z and W bosons, and the $\bar{g}_{V,A}^f$ are defined in Eq. (10.42) below. $\overline{M}_Z$ and $\overline{\Gamma}_Z$ correspond to mass and width definitions based on a Breit-Wigner shape with an energy-independent width (see the Section on the "Z Boson" in this *Review*). The differential cross-section receives important corrections from QED effects in the initial and final state, and interference between the two [256]. For $q\bar{q}$ production, there are additional final-state QCD corrections, which are relatively large. Note also that the equations above are written in the CM frame of the incident e^+e^- system, which may be boosted due to the initial-state QED radiation.

Some of the leading virtual EW corrections are captured by the running QED coupling $\alpha(s)$ and the Fermi constant G_F. The remaining corrections to the $Zf\bar{f}$ interactions are absorbed by replacing the tree-level couplings in Eq. (10.6) with the s-dependent *effective couplings* [14],

$$\bar{g}_V^f = \sqrt{\rho_f}\left(t_{3L}^f - 2Q_f\kappa_f\sin^2\theta_W\right) , \tag{10.42a}$$

$$\bar{g}_A^f = \sqrt{\rho_f}\, t_{3L}^f . \tag{10.42b}$$

In these equations, the effective couplings are to be taken at the scale $\sqrt{s}$, but for notational simplicity we do not show this explicitly. At tree-level, $\rho_f = \kappa_f = 1$, but inclusion of EW radiative corrections leads to $\rho_f \neq 1$ and $\kappa_f \neq 1$, which depend on the fermion f and on the renormalization scheme. In the on-shell scheme, the quadratic m_t dependence is given by,

$$\rho_f \sim 1 + \rho_t , \qquad \kappa_f \sim 1 + \frac{\rho_t}{\tan^2\theta_W} , \tag{10.43}$$

while in $\overline{\rm MS}$, $\widehat{\rho}_f \sim \widehat{\kappa}_f \sim 1$, for $f \neq b$, and

$$\widehat{\rho}_b \sim 1 - \frac{4}{3}\rho_t , \qquad \widehat{\kappa}_b \sim 1 + \frac{2}{3}\rho_t . \tag{10.44}$$

In the $\overline{\rm MS}$ scheme the normalization is changed according to $G_F M_Z^2/2\sqrt{2}\pi \to \widehat{\alpha}/4\widehat{s}_Z^2\widehat{c}_Z^2$ in the second Eq. (10.41).

As reviewed in Sec. 10.2.5, for the high precision Z pole observables discussed below, many additional bosonic and fermionic loop effects, vertex corrections, and higher order contributions, *etc.*, must be included. For example, in the $\overline{\rm MS}$ scheme one then has $\widehat{\rho}_\ell = 0.9977$, $\widehat{\kappa}_\ell = 1.0014$, $\widehat{\rho}_b = 0.9866$, and $\widehat{\kappa}_b = 1.0068$.

To connect to measured quantities, it is convenient to define an effective angle

$$\bar{s}_f^2 \equiv \sin^2\bar{\theta}_{Wf} \equiv \widehat{\kappa}_f \widehat{s}_Z^2 = \kappa_f s_W^2 , \tag{10.45}$$

in terms of which $\bar{g}_V^f$ and $\bar{g}_A^f$ are given by $\sqrt{\rho_f}$ times their tree-level formulae. One finds that the $\widehat{\kappa}_f$ ($f \neq b$) are almost independent of m_t and M_H, and thus one can write,

$$\bar{s}_\ell^2 = \widehat{s}_Z^2 + 0.00032 , \tag{10.46}$$

while the κ_f for the on-shell scheme are m_t dependent.

10.5.1 *Electroweak physics off the Z pole*

Experiments at PEP, PETRA and TRISTAN have measured the unpolarized forward-backward asymmetry, A_{FB}, and the total cross-section relative to pure QED, R, for $e^+e^- \to \ell^+\ell^-$, $\ell = \mu$ or τ at CM energies $\sqrt{s} < M_Z$. They are defined as

$$A_{FB} \equiv \frac{\sigma_F - \sigma_B}{\sigma_F + \sigma_B} , \qquad R = \frac{\sigma}{\mathcal{R}_{\rm ini} \otimes 4\pi\alpha^2/3s} , \tag{10.47}$$

where σ_F (σ_B) is the cross-section for ℓ^- to travel forward (backward) with respect to the e^- direction, and $\mathcal{R}_{\rm ini}\otimes$ denotes convolution with initial-state QED corrections. Neglecting box graph contributions, they are given by,

$$A_{FB} = \frac{3}{4}\frac{F_2}{F_1} , \qquad R = F_1 . \tag{10.48}$$

For the available data, it is sufficient to approximate the EW corrections through the leading running $\alpha(s)$ and quadratic m_t contributions [257], as described above. Reviews and formulae for $e^+e^- \to$ hadrons may be found in [9, 258, 259].

LEP 2 [260] ran at several energies above the Z pole up to ~ 209 GeV. Measurements were made of a number of observables, including the total production cross-sections of $f\bar{f}$ pairs for $f = \mu, \tau$, and q (hadrons), of four-fermion final states, of $\gamma\gamma$, ZZ, WW, $WW\gamma$, and WWZ, as well as of single resonant W and Z bosons. The differential cross-sections for all three lepton flavors, and the leptonic and hadronic W branching ratios were also extracted.

Among the most important LEP 2 results were the measurements [260] of the W boson mass,

$$M_W = 80.376 \pm 0.025_{\rm stat.} \pm 0.022_{\rm syst.} \text{ GeV (LEP 2)} , \tag{10.49}$$

which were dominated by kinematic reconstruction, but included the complementary albeit statistics limited and thus much less precise determination from a WW threshold cross section scan. The kinematic method was also employed at the Tevatron [261] and by ATLAS [263]. They quote,

$$M_W = 80.387 \pm 0.016 \text{ GeV (Tevatron)} , \tag{10.50a}$$

$$M_W = 80.3695 \pm 0.0068_{\rm stat.} \pm 0.0106_{\rm syst.} \pm 0.0136_{\rm th.} \text{ GeV (ATLAS)} . \tag{10.50b}$$

We assume an error component of 7 MeV to be common between the two hadron collider determinations. This is smaller than the 10 MeV PDF uncertainty quoted by CDF, because the larger CM energy at the LHC enhances the sensitivity to second generation quark PDFs, in addition to the greater sea quark PDF dependence of the Drell-Yan process in the *pp* environment. There may also be some correlation due to other production modeling uncertainties. This implies for the average,

$$M_W = 80.379 \pm 0.012 \text{ GeV (world average)} . \tag{10.51}$$

For details and references, see the Section on the "Mass and Width of the W Boson" in this *Review*.

Strong constraints on anomalous triple and quartic gauge couplings have been obtained at LEP 2, the Tevatron, and the LHC. These are described in detail in the three Sections on the "Extraction of Triple Gauge Couplings (TGCs)", "Anomalous W/Z Quartic Couplings (QGCs)", and "Anomalous $ZZ\gamma$, $Z\gamma\gamma$, and ZZV Couplings" in this *Review*.

After their discovery of the Higgs boson [264, 265], the LHC experiments are now performing high precision measurements of its mass. We average the results, $M_H = 124.97 \pm 0.16_{\rm stat.} \pm 0.18_{\rm syst.}$ GeV from ATLAS [266], and $M_H = 125.38 \pm 0.11_{\rm stat.} \pm 0.09_{\rm syst.}$ GeV from CMS [267], by conservatively treating the smaller systematic error as common among the two determinations, and arrive at,

$$M_H = 125.30 \pm 0.09_{\rm stat.} \pm 0.09_{\rm syst.} \text{ GeV (LHC)} . \tag{10.52}$$

For further references and many more details on Higgs boson properties, see the Section on the "Status of Higgs Boson Physics" in this *Review*. The principal non-Z pole observables discussed here and in Sections 10.2−10.4 are summarized in Table 10.4.

10.5.2 *Z pole physics*

High precision measurements of various Z pole ($\sqrt{s} \approx M_Z$) observables [9, 276, 277] have been performed at LEP 1 and SLC [14, 273, 274, 278, 279], as summarized in Table 10.5. These include the Z mass and total width, Γ_Z, and partial widths $\Gamma_{f\bar{f}}$ for $Z \to f\bar{f}$, where $f = e$, μ, τ, light hadrons, b, and c. It is convenient to use the variables M_Z, Γ_Z,

$$\sigma_{\rm had} \equiv \frac{12\pi \Gamma_{e^+e^-}\Gamma_{\rm had}}{M_Z^2\,\Gamma_Z^2} , \qquad R_\ell \equiv \frac{\Gamma_{\rm had}}{\Gamma_{\ell^+\ell^-}} , \qquad R_q \equiv \frac{\Gamma_{q\bar{q}}}{\Gamma_{\rm had}} , \tag{10.53}$$

for $\ell = e, \mu$ or τ, and $q = b$ or c, where $\Gamma_{\rm had}$ is the partial width into hadrons. Most of these are weakly correlated experimentally. The three values for R_ℓ are consistent with lepton universality (although R_τ is somewhat low compared to R_e and R_μ), but we use the general analysis in which the three observables are treated as independent. Similar remarks apply to $A_{FB}^{0,\ell}$ defined through Eq. (10.54) with $P_e = 0$, where $A_{FB}^{0,\tau}$ is somewhat high. Initial-state radiation reduces the peak cross section by more than 25%, where $\mathcal{O}(\alpha^3)$ QED effects induce a large anti-correlation (−30%) between Γ_Z and $\sigma_{\rm had}$. The anti-correlation between R_b and R_c amounts to −18% [14]. The R_ℓ are insensitive to m_t except for the $Z \to b\bar{b}$ vertex, final-state corrections, and the implicit dependence through $\sin^2\theta_W$. Thus, they are especially useful for constraining α_s.

Very important constraints follow from measurements of various Z pole asymmetries. These include the forward-backward asymmetry, A_{FB}, and the polarization or left-right asymmetry, A_{LR}, defined analogously to Eq. (10.27). The latter was measured precisely by the SLD collaboration at the SLC [273], and has the advantages of being very sensitive to $\bar{s}_\ell^2$ and that systematic uncertainties largely cancel. After removing initial-state QED corrections and contributions from photon exchange, γ–Z interference, as well as the EW boxes in Eq. (10.40a), one can use the effective tree-level expressions,

$$A_{LR} = A_e P_e , \qquad A_{FB} = \frac{3}{4} A_f \frac{A_e + P_e}{1 + P_e A_e} , \tag{10.54}$$

where,

$$A_f \equiv \frac{2\bar{g}_V^f \bar{g}_A^f}{\bar{g}_V^{f2} + \bar{g}_A^{f2}} = \frac{1 - 4|Q_f|\bar{s}_f^2}{1 - 4|Q_f|\bar{s}_f^2 + 8(|Q_f|\bar{s}_f^2)^2} . \tag{10.55}$$

P_e is the initial e^- polarization, so that the second equality in Eq. (10.56) is reproduced for $P_e = 1$, and the Z pole forward-backward asymmetries at LEP 1 ($P_e = 0$) are given by $A_{FB}^{(0,f)} = \frac{3}{4} A_e A_f$ for $f = e$, μ, τ, b, c, s [14], and q, and where $A_{FB}^{(0,q)}$ refers to the hadronic charge asymmetry. Corrections for t-channel exchange and s/t-channel interference cause $A_{FB}^{(0,e)}$ to be strongly anti-correlated with R_e (−37%). Very recently, the m_b-dependence [280] of the $\mathcal{O}(\alpha_s^2)$ QCD correction [281], affecting the reference axis of the b quark asymmetry [282], increased the extracted[13] $A_{FB}^{(0,b)}$ by about 0.2 σ. The correlation between $A_{FB}^{(0,b)}$ and $A_{FB}^{(0,c)}$ amounts to 15%.

In addition, SLD extracted the final-state couplings A_b, A_c [14], A_s [278], A_τ, and A_μ [274], from left-right forward-backward asymmetries, using

$$A_{LR}^{FB}(f) = \frac{\sigma_{LF}^f - \sigma_{LB}^f - \sigma_{RF}^f + \sigma_{RB}^f}{\sigma_{LF}^f + \sigma_{LB}^f + \sigma_{RF}^f + \sigma_{RB}^f} = \frac{3}{4} A_f , \tag{10.56}$$

where, for example, σ_{LF}^f is the cross-section for a left-handed incident electron to produce a fermion f traveling in the forward hemisphere. Similarly, A_τ and A_e were measured at LEP 1 [14] through the τ polarization, $\mathcal{P}_\tau$, as a function of the scattering

[13] We are grateful to Werner Bernreuther and Long Chen for the recalculation of their result employing the more appropriate $\overline{\rm MS}$ mixing angle, $\widehat{s}_Z^2$, instead of the on-shell quantity, s_W^2.

Table 10.4: Non-Z pole observables, compared with the SM best fit predictions. The first M_W and Γ_W values are from the Tevatron [261,262], the second ones from LEP 2 [260], while the third M_W is from ATLAS [263]. The entry of m_t differs from the one in the Particle Listings as it includes an additional theory error. The world averages for $g_{V,A}^{\nu e}$ are dominated by the CHARM II [122] results, $g_V^{\nu e} = -0.035 \pm 0.017$ and $g_A^{\nu e} = -0.503 \pm 0.017$. The τ_τ value is the τ lifetime world average computed by combining the direct measurements with values derived from the leptonic branching ratios [53]; in this case, the theory error is included in the SM prediction. In all other SM predictions, the uncertainty is parametric from M_Z, M_H, m_t, m_b, m_c, $\widehat{\alpha}(M_Z)$, and α_s, and theoretical from unknown higher orders [69], where correlations due to both types have been accounted for. The column denoted by Pull gives the standard deviations.

Quantity	Value	Standard Model	Pull
m_t [GeV]	172.89 ± 0.59	173.19 ± 0.55	-0.5
M_H [GeV]	125.30 ± 0.13	125.30 ± 0.13	0.0
M_W [GeV]	80.387 ± 0.016	80.361 ± 0.006	1.6
	80.376 ± 0.033		0.5
	80.370 ± 0.019		0.5

$\frac{1}{2}(g_\mu - 2 - \frac{\alpha}{\pi})$	$(4511.18 \pm 0.78) \times 10^{-9}$	$(4508.74 \pm 0.03) \times 10^{-9}$	3.1

angle θ, which can be written as,

$$\mathcal{P}_\tau = -\frac{A_\tau(1+\cos^2\theta) + 2A_e\cos\theta}{(1+\cos^2\theta) + 2A_\tau A_e\cos\theta} \; . \tag{10.57}$$

The average polarization, $\langle \mathcal{P}_\tau \rangle$, obtained by integrating over $\cos\theta$ in the numerator and denominator of Eq. (10.57), yields $\langle \mathcal{P}_\tau \rangle = -A_\tau$, and A_e can be extracted from the $\mathcal{P}_\tau$ angular distribution. The initial-state coupling, A_e, was also determined through the left-right charge asymmetry [279] and in polarized Bhabba scattering [274] at the SLC. Because $\bar{g}_V^\ell$ is very small, not only $A_{LR}^0 = A_e$, $A_{FB}^{(0,\ell)}$, and $\mathcal{P}_\tau$, but also $A_{FB}^{(0,q)}$ for $q = b$, c, and s, as well as the hadronic asymmetries are mainly sensitive to $\bar{s}_\ell^2$.

As an example of the precision of the Z pole observables, the values of $\bar{g}_A^f$ and $\bar{g}_V^f$ for $f = e, \mu, \tau$, and ℓ, extracted from the LEP and SLC lineshape and asymmetry data, are shown in Fig. 10.3. It may be compared with Fig. 10.1 as the two sets of parameters coincide at the SM at tree-level.

As for hadron colliders, the forward-backward asymmetry, A_{FB}, for e^+e^- and $\mu^+\mu^-$ final states (with invariant masses restricted to or dominated by values around M_Z) in $p\bar{p}$ collisions has been measured by the CDF [283] and DØ [284] collaborations, and the values $\bar{s}_\ell^2 = 0.23221 \pm 0.00046$ and $\bar{s}_\ell^2 = 0.23095 \pm 0.00040$ were extracted, respectively. The combination of these measurements (which differ by more than 2 σ) yields [268],

$$\bar{s}_\ell^2 = 0.23148 \pm 0.00033 \text{ (Tevatron)} \; . \tag{10.58}$$

By varying the invariant mass and the scattering angle (and assuming the electron couplings), information on the effective Z couplings to light quarks, $\bar{g}_{V,A}^{u,d}$, could also be obtained [285,286], but with large uncertainties, mutual correlations, and not independently of $\bar{s}_\ell^2$ above. Similar analyses have also been reported by the H1 [287] and ZEUS [288] collaborations at HERA and by the LEP collaborations [14]. This kind of measurement is harder in the *pp* environment due to the difficulty to assign the initial quark and antiquark in the underlying Drell-Yan process to the protons, thus requiring excellent control of uncertainties from parton distribution functions. ATLAS obtained $\bar{s}_\ell^2 = 0.2308 \pm 0.0012$ using 7 TeV data [269] and $\bar{s}_\ell^2 = 0.23140 \pm 0.00036$ at 8 TeV [270],

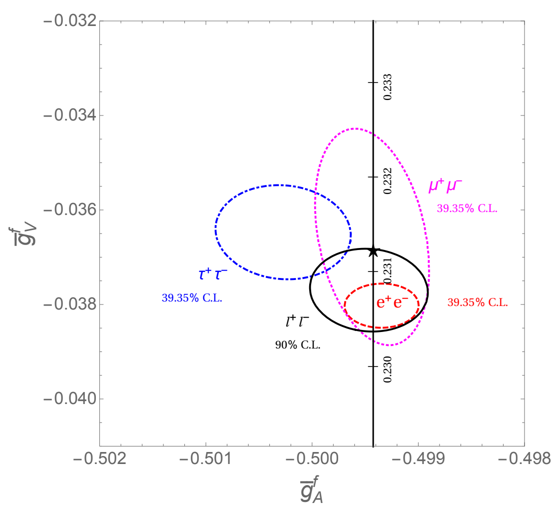

Figure 10.3: 1 σ (39.35% CL) contours of the effective couplings $\bar{g}_A^f$ and $\bar{g}_V^f$ for $f = e, \mu$ and τ from LEP and SLC, compared to the SM expectation as a function of $\widehat{s}_Z^2$. (The SM best fit value $\widehat{s}_Z^2 = 0.23121$ is also indicated.) Also shown is the 90% CL allowed region in $\bar{g}_{A,V}^\ell$ obtained assuming lepton universality.

while CMS measured $\bar{s}_\ell^2 = 0.23101 \pm 0.00053$ (8 TeV) [271] and LHCb reported $\bar{s}_\ell^2 = 0.23142 \pm 0.00106$ (from both 7 and 8 TeV data, but only analyzing $\mu^+\mu^-$ final state) [272]. Assuming that the smallest theoretical and PDF uncertainty (± 0.00024 from ATLAS [270]) is fully correlated among the four determinations, they combine to

$$\bar{s}_\ell^2 = 0.23129 \pm 0.00033 \text{ (LHC)} \; . \tag{10.59}$$

10.5.3 *W and Z decays*

The partial decay widths for gauge bosons to decay into massless fermions $f_1\bar{f}_2$ (the numerical values include the small EW

Table 10.5: Principal Z pole observables and their SM predictions (*cf.* Table 10.4). The first $\bar{s}_\ell^2$ is the effective weak mixing angle extracted from the hadronic charge asymmetry at LEP 1 [14], the second is the combined value from the Tevatron [268], and the third is from the LHC [269–272]. The values of A_e are (i) from A_{LR} for hadronic final states [273]; (ii) from A_{LR} for leptonic final states and from polarized Bhabba scattering [274]; and (iii) from the angular distribution of the τ polarization at LEP 1 [14]. The A_τ values are from SLD [274] and the total τ polarization, respectively. Note that the SM errors in Γ_Z, the R_ℓ, and $\sigma_{\rm had}$ are largely dominated by the uncertainty in α_s.

radiative corrections and final-state mass effects) are given by,

$$\Gamma(W^+ \to e^+\nu_e) = \frac{M_W^3}{12\pi v^2} = 226.35 \pm 0.05\,\text{MeV} , \tag{10.60a}$$

$$\Gamma(W^+ \to u_i\bar{d}_j) = \frac{M_W^3}{12\pi v^2}\, |V_{ij}|^2 \mathcal{R}_V^q = (705.4 \pm 0.4\,\text{MeV})|V_{ij}|^2 , \tag{10.60b}$$

$$\Gamma(Z \to f\bar{f}) = \frac{M_Z^3}{12\pi v^2}\left[\mathcal{R}_V^f \bar{g}_V^{f2} + \mathcal{R}_A^f \bar{g}_A^{f2}\right] , \tag{10.60c}$$

where the result for the latter are shown in Table 10.6. Final-state QED and QCD corrections [289] to the vector and axial-vector form factors are given by,

$$\mathcal{R}_{V,A}^f = N_C\left[1 + \frac{3}{4}\left(Q_f^2\frac{\alpha(s)}{\pi} + \frac{N_C^2-1}{2N_C}\frac{\alpha_s(s)}{\pi}\right) + \cdots\right] , \tag{10.61}$$

where $N_C = 3$ (1) is the color factor for quarks (leptons) and the dots indicate finite fermion mass effects proportional to m_f^2/s which are different for $\mathcal{R}_V^f$ and $\mathcal{R}_A^f$, as well as higher-order QCD corrections [290], which are known to $\mathcal{O}(\alpha_s^4)$ [203]. These include singlet contributions starting from two-loop order which are large, strongly top quark mass dependent, family universal, and flavor non-universal [291–295]. The $\mathcal{O}(\alpha^2)$ self-energy corrections from Ref. [296] are also taken into account.

For the W decay into quarks, Eq. (10.60b), only the universal massless part (non-singlet and $m_q = 0$) of the final-state QCD radiator function in $\mathcal{R}_V$ from Eq. (10.61) is used, and the QED corrections are modified. Expressing the widths in terms of $G_F M^3_{W,Z}$ incorporates the largest radiative corrections from the running QED coupling. EW corrections to the Z widths are then taken into account through the effective couplings $\bar{g}^{\,i\,2}_{V,A}$. Hence, in the on-shell scheme the Z widths are proportional to $\rho_i \sim 1 + \rho_t$. There is additional (negative) quadratic m_t dependence in the $Z \to b\bar{b}$ vertex corrections [297, 298] which causes $\Gamma_{b\bar{b}}$ to decrease with m_t. The dominant effect is to multiply $\Gamma_{b\bar{b}}$ by the vertex correction $1 + \delta\rho_{b\bar{b}}$, where $\delta\rho_{b\bar{b}} \sim 10^{-2}(-\frac{1}{2}m_t^2/M_Z^2 + \frac{1}{5})$. In practice, the corrections are included in $\widehat{\rho}_b$ and $\widehat{\kappa}_b$, as discussed in Sec. 10.5.

Starting at $\mathcal{O}(\alpha\alpha_s)$, the factorized form indicated in Eq. (10.60) is violated and corrections need to be included [299–301]. They add coherently, resulting in a sizable effect, and shift $\alpha_s(M_Z)$ when extracted from Z lineshape observables by about $+0.0007$. Similar non-factorizable corrections are also known for mixed QED-EW corrections [97, 98, 100, 302].

For three fermion families the total widths of the Z [303–307] and W [308, 309] bosons are predicted to be,

$$\Gamma_Z = 2.4942 \pm 0.0009\,\text{GeV}\,, \qquad \Gamma_W = 2.0896 \pm 0.0008\,\text{GeV}\,. \tag{10.62}$$

The uncertainties in these predictions are almost entirely induced by the parametric error in $\alpha_s(M_Z) = 0.1185 \pm 0.0016$ from the global fit. These predictions can be compared with the experimental results, $\Gamma_Z = 2.4955 \pm 0.0023$ GeV [14, 275] and $\Gamma_W = 2.085 \pm 0.042$ GeV [260, 262] (see the Gauge & Higgs Bosons Particle Listings). The measurements of the total and partical widths are generally in good agreement with the SM. The exception is the branching ratio $W \to \tau + \nu_\tau$ from LEP 2, which is 2.6 σ larger than the electron-muon average [260].

The invisible decay width, $\Gamma_{\rm inv} = \Gamma_Z - \Gamma_{e^+e^-} - \Gamma_{\mu^+\mu^-} - \Gamma_{\tau^+\tau^-} - \Gamma_{\rm had}$, can be used to determine the number of neutrino flavors, N_ν, much lighter than $M_Z/2$. The hadronic peak cross section, and therefore the extracted $\Gamma_{\rm had}$, depends strongly on the knowledge of the LEP 1 luminosity derived from small-angle Bhabha scattering. However, the prediction for the Bhabha cross-section was very recently found to be overestimated, and consequently the luminosity underestimated [275]. The updated analysis involved an improved Z lineshape fit, significantly reducing $\sigma_{\rm had}$, while slightly increasing Γ_Z, with the result, $N_\nu = 2.9963 \pm 0.0074$ [275]. In practice, we determine N_ν by allowing it as an additional fit parameter and obtain,

$$N_\nu = 3.0026 \pm 0.0061\,, \tag{10.63}$$

which is now in perfect agreement with the observed number of fermion generations and $N_\nu = 3$ (a 1.3 σ deviation was observed in the 2018 edition of this *Review* before including the correction in the luminosity determination).

10.6 Global fit results

In this section, we present the results of global fits, subject to the experimental data and theoretical constraints discussed in Section 10.2−10.4. For earlier analyses, see Refs. [14, 69, 310–313] and previous editions of this *Review*. The values for m_t, M_W [260, 261, 263], Γ_W [260, 262], the weak charges of the electron [148], the proton [149], cesium [160, 161] and thallium [162, 163], the weak mixing angle extracted from eDIS [138], $\nu_\mu(\bar{\nu}_\mu)$-e scattering [120–122], the τ lifetime, and the μ anomalous magnetic moment [213] are listed in Table 10.4. Likewise, Table 10.5 summarizes the principal Z pole observables, where the LEP 1 averages of the ALEPH, DELPHI, L3, and OPAL results include common systematic uncertainties and correlations [14, 275]. The heavy flavor results [14, 280] of LEP 1 and SLD are based on common inputs, and are thus correlated, as well.

Also shown in both tables are the SM predictions for the values of M_Z, M_H, $\alpha_s(M_Z)$, $\Delta\alpha^{(3)}_{\rm had}$ and the heavy quark masses shown in Table 10.7. The predictions result from a global least-square (χ^2) fit to all data using the minimization package MINUIT [314] and the EW library GAPP [32]. In most cases, we treat all input errors (the uncertainties of the values) as Gaussian. The reason is not that we assume that theoretical and systematic errors are intrinsically bell-shaped (which they are not) but because in most cases the input errors are either dominated by the statistical components or they are combinations of many different (including statistical) error sources, which should yield approximately Gaussian *combined* errors by the large number theorem. An exception is the theory dominated error on the τ lifetime, which we recalculate in each χ^2-function call since it depends itself on α_s. Sizes and shapes of the output errors (the uncertainties of the predictions and the SM fit parameters) are fully determined by the fit, and 1 σ errors are defined to correspond to $\Delta\chi^2 = \chi^2 - \chi^2_{\rm min} = 1$, and do not necessarily correspond to the 68.3% probability range or the 39.3% probability contour (for 2 parameters).

The agreement is generally very good. Despite the few discrepancies addressed in the following, the global electroweak fit describes the data very well, with an excellent χ^2/d.o.f. = 40.8/41. The probability of a larger χ^2 is 48%, and only $g_\mu - 2$ is currently showing a larger (3.1 σ) conflict. In addition, A^0_{LR} (SLD) from hadronic final states and $A^{(0,b)}_{FB}$ (LEP 1) deviate at the 2 σ level. g_L^2 from NuTeV is nominally in conflict with the SM, as well, but the precise status is unresolved (see Sec. 10.3.1). We also emphasize that there are a number of discrepancies among individual measurements of certain quantities, as discussed in previous sections, but that they are not reflected in the overall χ^2 of the fit as only the corresponding combinations are used as constraints.

A_b can be extracted from $A^{(0,b)}_{FB}$ when $A_e = 0.1501 \pm 0.0016$ is taken from a fit to leptonic asymmetries (using lepton universality). The result, $A_b = 0.885 \pm 0.017$, is 2.9 σ below the SM prediction[14] and also 1.4 σ below $A_b = 0.923 \pm 0.020$ obtained from $A^{FB}_{LR}(b)$ at SLD. Thus, it appears that at least some of the problem in A_b is due to a statistical fluctuation or other experimental effect in one of the asymmetries. Note, however, that the uncertainty in $A^{(0,b)}_{FB}$ is strongly statistics dominated. The combined value, $A_b = 0.901 \pm 0.013$ deviates by 2.6 σ.

The left-right asymmetry, $A^0_{LR} = 0.15138 \pm 0.00216$ [273], from hadronic decays at SLD, differs by 2.1 σ from the SM expectation of 0.1469 ± 0.0003. The combined value of $A_\ell = 0.1513 \pm 0.0021$ from SLD (using lepton-family universality and including correlations) is also 2.1 σ above the SM prediction; but there is experimental agreement between this SLD value and the LEP 1 value, $A_\ell = 0.1481 \pm 0.0027$, obtained from a fit to $A^{(0,\ell)}_{FB}$, $A_e(\mathcal{P}_\tau)$, and $A_\tau(\mathcal{P}_\tau)$, again assuming universality.

The observables in Table 10.4 and Table 10.5, as well as some other less precise observables, are used in the global fits described below. In all fits, the errors include full statistical, systematic, and theoretical uncertainties. The correlations from the LEP 1 lineshape and τ polarization measurements, the LEP/SLD heavy flavor observables, the SLD lepton asymmetries, and the ν-e scattering observables, are included. The theoretical correlations between $\Delta\alpha^{(5)}_{\rm had}$, $\widehat{s}^2_0$, and $g_\mu - 2$, and between the M_W extractions from ATLAS and the Tevatron, are also accounted for.

The electroweak data allow a simultaneous determination of M_Z, m_t, and $\alpha_s(M_Z)$. The direct measurements of M_H at the LHC [266, 267] have reached a precision that the global fit result for M_H coincides with the constraint in Eq. (10.52) with negligible correlations with the other fit parameters. $\widehat{m}_c$, $\widehat{m}_b$, and $\Delta\alpha^{(3)}_{\rm had}$ are also allowed to float in the fits, subject to the theoretical constraints [28, 51] described in Sec. 10.2, and are correlated with α_s, which in turn is determined mainly through R_ℓ, Γ_Z, $\sigma_{\rm had}$, and τ_τ. The global fit to all data, including the hadron collider m_t average in Eq. (10.13), yields the results in Table 10.7, while those

[14] Alternatively, one can use $A_\ell = 0.1481 \pm 0.0027$, which is from LEP 1 alone and in excellent agreement with the SM, and obtain $A_b = 0.897 \pm 0.022$ which is 1.7 σ low. This illustrates that some of the discrepancy is related to the one in A_{LR}.

Table 10.7: Principal SM fit result including mutual correlations.

M_Z [GeV]	91.1882 ± 0.0020	1.00	−0.07	0.00	0.00	0.02	0.02
$\widehat{m}_t(\widehat{m}_t)$ [GeV]	163.51 ± 0.55	−0.07	1.00	0.00	−0.11	−0.22	0.04
$\widehat{m}_b(\widehat{m}_b)$ [GeV]	4.180 ± 0.008	0.00	0.00	1.00	0.20	−0.02	0.00

$\alpha_s(M_Z)$	0.1185 ± 0.0016	0.02	−0.22	−0.02	0.47	1.00	−0.03
$\Delta\alpha^{(3)}_{\rm had}(2\text{ GeV})$	0.00592 ± 0.00005	0.02	0.04	0.00	0.00	−0.03	1.00

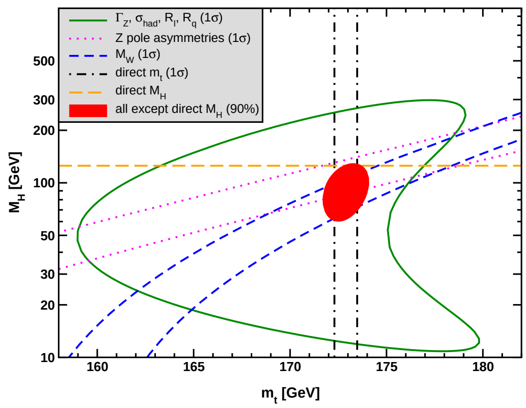

Figure 10.4: Fit result and one-standard-deviation (39.35% for the closed contours and 68% for the others) uncertainties in M_H as a function of m_t for various inputs, and the 90% CL region ($\Delta\chi^2 = 4.605$) allowed by all data. $\alpha_s(M_Z) = 0.1185$ is assumed except for the fits including the Z lineshape. The width of the horizontal dashed band is not visible on the scale of the plot.

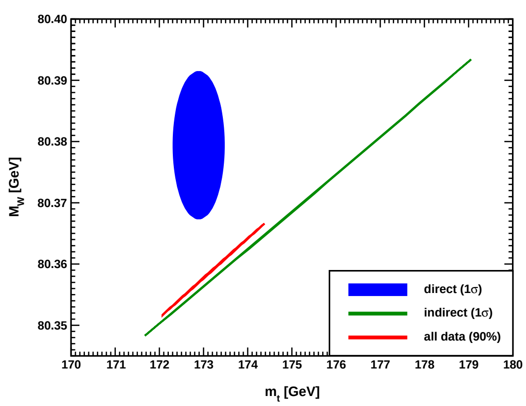

Figure 10.5: One-standard-deviation (39.35%) regions in M_W as a function of m_t for the direct and indirect data, and the 90% CL region ($\Delta\chi^2 = 4.605$) allowed by all data.

for the weak mixing angle in various schemes are summarized in Table 10.2.

Removing the kinematic constraint on M_H from LHC gives the loop-level determination from the precision data,

$$M_H = 90^{+18}_{-16}\text{ GeV}\ , \tag{10.64}$$

which is 1.8 σ below the value in Eq. (10.52). The latter is also slightly outside the 90% central confidence range,

$$64\text{ GeV} < M_H < 122\text{ GeV}\ . \tag{10.65}$$

This is mostly a reflection of the Tevatron determination of M_W, which is 1.6 σ higher than the SM best fit value in Table 10.4. This is shown in Fig. 10.4 where one sees that the precision data together with M_H from the LHC prefer m_t to be closer to the upper end of its 1 σ allowed range.

Conversely, one can remove the explicit M_W and Γ_W constraints from the global fit and use $M_H = 125.30 \pm 0.13$ GeV to obtain $M_W = 80.357 \pm 0.006$ GeV, which is 1.7 σ below the world average in Eq. (10.51). Finally, one can carry out a fit without including the direct constraint, $m_t = 172.89 \pm 0.59$ GeV, from the hadron colliders. One obtains $m_t = 176.3 \pm 1.9$ GeV, which is 1.7 σ higher than the collider average. (The indirect prediction is for the $\overline{\rm MS}$ mass definition, $\widehat{m}_t(\widehat{m}_t) = 166.4 \pm 1.8$ GeV, which is in the end converted to the pole mass.) The situation is summarized in Fig. 10.5 showing the 1 σ contours in the $M_W - m_t$ plane from the direct and indirect determinations, as well as the combined 90% CL region.

In view of these tensions it is instructive to study the effect of doubling the uncertainty in $\Delta\alpha^{(3)}_{\rm had}(2\text{ GeV}) = (58.84 \pm 0.51) \times 10^{-4}$ (see Sec. 10.2) on the loop-level determination of the Higgs boson mass. The result, $M_H = 88^{+18}_{-17}$ GeV, deviates even slightly *more* (1.9 σ) than Eq. (10.64), and demonstrates that the uncertainty in $\Delta\alpha_{\rm had}$ is currently of only secondary importance. Note also that a shift of $\pm 10^{-4}$ in $\Delta\alpha^{(3)}_{\rm had}(2\text{ GeV})$ corresponds to a shift of ∓ 4.4 GeV in M_H. The hadronic contribution to $\alpha(M_Z)$ is correlated with $g_\mu - 2$ (see Sec. 10.4). The measurement of the latter is higher than the SM prediction, and its inclusion in the fit favors a larger $\alpha(M_Z)$ and a lower M_H from the precision data (currently by 2.3 GeV).

The weak mixing angle can be determined from Z pole observables, M_W, and a variety of neutral-current processes spanning a very wide Q^2 range. The results (for older low energy neutral-current data see Refs. [310–313], as well as earlier editions of this *Review*) shown in Table 10.8 are in reasonable agreement with each other, indicating the quantitative success of the SM. One of the largest discrepancies is the value $\widehat{s}^2_Z = 0.23176 \pm 0.00027$ from $A^{(0,b)}_{FB}$ and $A^{(0,c)}_{FB}$, which is 2.0 σ above the value 0.23121 ± 0.00004 from the global fit to all data. Similarly, $\widehat{s}^2_Z = 0.23064 \pm 0.00028$ from the SLD asymmetries (in both cases when combined with M_Z, Γ_Z, and m_t) is 2.0 σ low.

The extracted Z pole value of $\alpha_s(M_Z)$ is based on a formula with negligible theoretical uncertainty if one assumes the exact validity of the SM. One should keep in mind, however, that this value, $\alpha_s(M_Z) = 0.1221 \pm 0.0027$, which increased after the updated analysis in Ref. [275], is very sensitive to certain types of new physics such as non-universal vertex corrections. In contrast, the value derived from τ decays, $\alpha_s(M_Z) = 0.1170^{+0.0019}_{-0.0017}$, is theory dominated but less sensitive to new physics. The agreement between the two values is only marginal, but the latter does agree well with the averages deduced from DIS and global PDF fits (0.1161 ± 0.0018), hadronic final states of e^+e^- annihilations (0.1171 ± 0.0031), hadron colliders (0.1159 ± 0.0034), as well as lattice QCD simulations (0.1182 ± 0.0008). For more details, other determinations, and references, see the Section on "Quantum Chromodynamics" in this *Review*.

Using $\alpha(M_Z)$ and $\widehat{s}^2_Z$ as inputs, one can predict $\alpha_s(M_Z)$ assuming grand unification. One finds $\alpha_s(M_Z) = 0.13 \pm 0.01$ [317, 318] for the simplest theories based on the minimal supersymmetric extension of the SM, where the uncertainty is from the unknown particle thresholds. This is slightly larger, but consistent with $\alpha_s(M_Z) = 0.1185 \pm 0.0016$ from our fit and most other determinations, while minimal non-supersymmetric theories predict much lower and excluded values (see the Section on "Grand Unified The-

Table 10.8: Values of $\widehat{s}^2_Z$, s^2_W, α_s, m_t and M_H for various data sets. In the fit to the LHC data, the α_s constraint is from a combined NNLO analysis of inclusive electroweak boson production cross-sections at the LHC [315]. Likewise, for the Tevatron fit we use the α_s result from the inclusive jet cross-section at DØ [316].

ories" in this *Review*).

Most of the parameters relevant to ν-hadron, ν-e, e-hadron, and e-e processes are determined uniquely and precisely from the data in "model-independent" fits, *i.e.*, fits allowing for an arbitrary EW gauge theory. The values for the parameters defined in Eq. (10.21) are given in Table 10.9 along with the predictions of the SM. The agreement is very good. (The ν-hadron results including NuTeV [134] and other ν-DIS data can be found in the 2006 edition of this *Review*, and fits with modified NuTeV constraints in the 2008 and 2010 editions.)

10.7 Constraints on new physics

The masses and decay properties of the electroweak bosons and low energy data can be used to search for and set limits on deviations from the SM. We will mainly discuss the effects of exotic particles (with heavy masses $M_{\rm new} \gg M_Z$ in an expansion in $M_Z/M_{\rm new}$) on the gauge boson self-energies. (Brief remarks are made on new physics which is not of this type.) Most of the effects on precision measurements can be described by three gauge self-energy parameters S, T, and U. We will define these, as well as the related parameters ρ_0, ϵ_i, and $\widehat{\epsilon}_i$, to arise from new physics only. In other words, they are equal to zero ($\rho_0 = 1$) exactly in the SM, and do not include any (loop induced) contributions that depend on m_t or M_H, which are treated separately. Our treatment differs from most of the original papers.

The dominant effect of many extensions of the SM can be described by the ρ_0 parameter,

$$\rho_0 \equiv \frac{M_W^2}{M_Z^2\, \widehat{c}^{\,2}_Z\, \widehat{\rho}} \,, \tag{10.66}$$

which describes new sources of SU(2) breaking that cannot be accounted for by the SM Higgs doublet or by m_t effects. $\widehat{\rho}$ is calculated as in Eq. (10.18) assuming the validity of the SM. In the presence of $\rho_0 \neq 1$, Eq. (10.66) generalizes the second Eq. (10.18) while the first remains unchanged. Provided that the new physics which yields $\rho_0 \neq 1$ is a small perturbation which does not significantly affect other radiative corrections, ρ_0 can be regarded as a phenomenological parameter which multiplies G_F in Eqs. (10.21) and (10.41), as well as Γ_Z in Eq. (10.60c). There are enough data to determine ρ_0, M_H, m_t, and α_s, simultaneously. From the global fit,

$$\rho_0 = 1.00038 \pm 0.00020 \,, \tag{10.67a}$$

$$\alpha_s(M_Z) = 0.1188 \ \ \pm 0.0017 \,, \tag{10.67b}$$

where as before the uncertainty is from the experimental inputs and includes an estimate of the error from unknown higher-order electroweak corrections. The result in Eq. (10.67a) is 1.9 σ above the SM expectation, $\rho_0 = 1$. It can be used to constrain higher-dimensional Higgs representations to have vacuum expectation values of less than a few percent of those of the doublets. Indeed, the relation between M_W and M_Z is modified if there are Higgs multiplets with weak isospin $> 1/2$ and significant vacuum expectation values. For a general (charge-conserving) Higgs structure,

$$\rho_0 = \frac{\sum_i [t_i(t_i+1) - t_{3i}^2]|v_i|^2}{2\sum_i t_{3i}^2 |v_i|^2} \,, \tag{10.68}$$

where v_i is the expectation value of the neutral component of a Higgs multiplet with weak isospin t_i and third component t_{3i}. In order to calculate to higher orders in such theories one must define a set of four fundamental renormalized parameters which one may conveniently choose to be α, G_F, M_Z, and M_W, since M_W and M_Z are directly measurable. Then $\widehat{s}^2_Z$ and ρ_0 can be considered dependent parameters.

Eq. (10.67a) can also be used to constrain other types of new physics. For example, non-degenerate multiplets of heavy fermions or scalars break the vector part of weak SU(2) and lead to a decrease in the value of M_Z/M_W. Each non-degenerate SU(2) doublet $\binom{f_1}{f_2}$ yields a positive contribution to ρ_0 [319–321] of

$$\frac{N_C\, G_F}{8\sqrt{2}\pi^2}\Delta m^2 \ , \tag{10.69}$$

where

$$\Delta m^2 \equiv m_1^2 + m_2^2 - \frac{4m_1^2 m_2^2}{m_1^2 - m_2^2}\ln\frac{m_1}{m_2} \geq (m_1 - m_2)^2 \ , \tag{10.70}$$

and $N_C = 1$ (3) for color singlets (triplets). Eq. (10.67a) taken together with Eq. (10.69) implies the following constraint on the mass splitting at the 90% CL,

$$(14\text{ GeV})^2 < \sum_i \frac{N_C^i}{3}\Delta m_i^2 < (48\text{ GeV})^2 \ , \tag{10.71}$$

where the sum runs over all new-physics doublets, for example fourth-family quarks or leptons, $\binom{t'}{b'}$ or $\binom{\nu'}{\ell'^-}$, vector-like fermion doublets (which contribute to the sum in Eq. (10.71) with an extra factor of 2), and scalar doublets such as $\binom{\tilde{t}}{\tilde{b}}$ in Supersymmetry (in the absence of L–R mixing).

Non-degenerate multiplets usually imply $\rho_0 > 1$. Similarly, heavy Z' bosons decrease the prediction for M_Z due to mixing and generally lead to $\rho_0 > 1$ [322]. On the other hand, extra Higgs doublets participating in spontaneous symmetry breaking [323–325] or heavy lepton doublets involving Majorana neutrinos [326], both of which have more complicated expressions, and the v_i of higher-dimensional Higgs representations can contribute to ρ_0 with either sign.

A number of authors [327–329] have considered the general effects on neutral-current, Z and W boson observables of various types of heavy (*i.e.*, $M_{\rm new} \gg M_Z$) physics which contribute to the W and Z self-energies but which do not have any direct coupling to the ordinary fermions (an alternative formulation is given by Ref. [330]). In addition to non-degenerate multiplets, which break the vector part of weak SU(2), these include heavy degenerate multiplets of chiral fermions which break the axial generators.

Such effects can be described by just three parameters, S, T, and U [331], at the (EW) one-loop level[15]. T is proportional to the difference between the W and Z self-energies at $Q^2 = 0$ (*i.e.*, vector SU(2)-breaking), while S ($S + U$) is associated with the difference between the Z (W) self-energy at $Q^2 = M_{Z,W}^2$ and $Q^2 = 0$ (axial SU(2)-breaking). Denoting the contributions of new physics to the various self-energies by $\Pi_{ij}^{\rm new}$, we have

$$\widehat{\alpha}(M_Z)T \equiv \frac{\Pi_{WW}^{\rm new}(0)}{M_W^2} - \frac{\Pi_{ZZ}^{\rm new}(0)}{M_Z^2} \ , \tag{10.72a}$$

$$\frac{\widehat{\alpha}(M_Z)}{4\,\widehat{s}_Z^2\widehat{c}_Z^2}S \equiv \frac{\Pi_{ZZ}^{\rm new}(M_Z^2) - \Pi_{ZZ}^{\rm new}(0)}{M_Z^2} - \frac{\widehat{c}_Z^2 - \widehat{s}_Z^2}{\widehat{c}_Z\widehat{s}_Z}\frac{\Pi_{Z\gamma}^{\rm new}(M_Z^2)}{M_Z^2} - \frac{\Pi_{\gamma\gamma}^{\rm new}(M_Z^2)}{M_Z^2} \ , \tag{10.72b}$$

$$\frac{\widehat{\alpha}(M_Z)}{4\,\widehat{s}_Z^2}(S+U) \equiv \frac{\Pi_{WW}^{\rm new}(M_W^2) - \Pi_{WW}^{\rm new}(0)}{M_W^2} - \frac{\widehat{c}_Z}{\widehat{s}_Z}\frac{\Pi_{Z\gamma}^{\rm new}(M_Z^2)}{M_Z^2} - \frac{\Pi_{\gamma\gamma}^{\rm new}(M_Z^2)}{M_Z^2} \ . \tag{10.72c}$$

S, T, and U are defined with a factor proportional to $\widehat{\alpha}$ removed, so that they are expected to be of order unity in the presence of new physics. In the $\overline{\rm MS}$ scheme as defined in Ref. [71], the last two terms in Eqs. (10.72b) and (10.72c) can be omitted, as was done in some earlier editions of this *Review*. These parameters are related to other parameter sets, S_i [71], $\widehat{\epsilon}_i$ [335], and h_i [336], by

$$T = h_V = \frac{\widehat{\epsilon}_1}{\widehat{\alpha}(M_Z)} \ , \tag{10.73a}$$

$$S = h_{AZ} = S_Z = 4\,\widehat{s}_Z^2\frac{\widehat{\epsilon}_3}{\widehat{\alpha}(M_Z)} \ , \tag{10.73b}$$

$$U = h_{AW} - h_{AZ} = S_W - S_Z = -4\,\widehat{s}_Z^2\frac{\widehat{\epsilon}_2}{\widehat{\alpha}(M_Z)} \ . \tag{10.73c}$$

A heavy non-degenerate multiplet of fermions or scalars contributes positively to T as

$$\rho_0 - 1 = \frac{1}{1 - \widehat{\alpha}(M_Z)T} - 1 \approx \widehat{\alpha}(M_Z)T \ , \tag{10.74}$$

where $\rho_0 - 1$ is given in Eq. (10.69). The effects of non-standard Higgs representations cannot be separated from heavy non-degenerate multiplets unless the new physics has other consequences, such as vertex corrections. Most of the original papers defined T to include the effects of loops only. However, we will redefine T to include all new sources of SU(2) breaking, including non-standard Higgs, so that T and ρ_0 are equivalent by Eq. (10.74).

A multiplet of heavy degenerate chiral fermions yields

$$S = \frac{N_C}{3\pi}\sum_i\left(t_{3i}^L - t_{3i}^R\right)^2 \ , \tag{10.75}$$

where $t_{3i}^{L,R}$ is the 3rd component of weak isospin of the left-(right-) handed component of fermion i. For example, a heavy degenerate ordinary or mirror family would contribute $2/3\pi$ to S. In models with warped extra dimensions [337], sizeable corrections to the S parameter are generated through mixing between the SM gauge bosons and their Kaluza-Klein (KK) excitations, and one finds $S \approx 30\,v^2 M_{KK}^{-2}$ [338], where M_{KK} is the mass scale of the KK gauge bosons. Large positive values of S can also be generated in models with dynamical electroweak symmetry breaking, where the Higgs boson is composite. In simple composite Higgs models, the dominant contribution stems from heavy spin-1 resonances of the strong dynamics leading to $S \approx 4\pi v^2(M_V^{-2} + M_A^{-2})$, where $M_{V,A}$ are the masses of the lightest vector and axial-vector resonances, respectively [339].

Negative values of S are possible, for example, in models of walking Technicolor [340–347], or from loops involving scalars or Majorana particles [348, 349]. The simplest origin of $S < 0$ would probably be an additional heavy Z' boson [322]. Supersymmetric extensions of the SM [350, 351] generally give very small effects. For more details and references, see Refs. [352–361] and the Sections on "Supersymmetry" in this *Review*. Most simple types of new physics yield $U = 0$, although there are counter-examples, such as the effects of anomalous triple gauge vertices [335].

The SM expressions for observables are replaced by,

$$M_Z^2 = M_{Z0}^2\,\frac{1 - \widehat{\alpha}(M_Z)T}{1 - G_F M_{Z0}^2 S/2\sqrt{2}\pi} \ , \tag{10.76a}$$

$$M_W^2 = M_{W0}^2\,\frac{1}{1 - G_F M_{W0}^2(S+U)/2\sqrt{2}\pi} \ , \tag{10.76b}$$

where M_{Z0} and M_{W0} are the SM expressions (as functions of m_t and M_H) in the $\overline{\rm MS}$ scheme. Furthermore,

$$\Gamma_Z = \frac{M_Z^3\beta_Z}{1 - \widehat{\alpha}(M_Z)T} \ , \tag{10.77a}$$

$$\Gamma_W = M_W^3\beta_W \ , \tag{10.77b}$$

$$A_i = \frac{A_{i0}}{1 - \widehat{\alpha}(M_Z)T} \ , \tag{10.77c}$$

[15] Three additional parameters are needed if the new physics scale is comparable to M_Z [332]. Further generalizations, including effects relevant to LEP 2 and Drell-Yan production at the LHC, are described in Refs. [333] and [334], respectively.

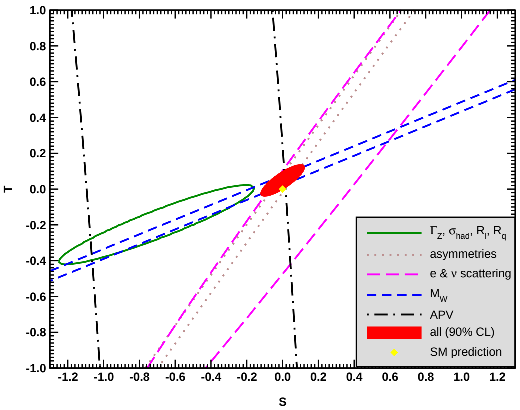

Figure 10.6: 1 σ constraints (39.35% for the closed contours and 68% for the others) on S and T (for $U = 0$) from various inputs combined with M_Z. S and T represent the contributions of new physics only. Data sets not involving M_W or Γ_W are insensitive to U. With the exception of the fit to all data, we fix $\alpha_s = 0.1185$. The black dot indicates the Standard Model values $S = T = 0$.

where $\beta_{Z,W}$ are the SM expressions for the reduced widths Γ_{Z0}/M_{Z0}^3 and Γ_{W0}/M_{W0}^3, M_Z and M_W are the physical masses, and A_i (A_{i0}) is a neutral-current amplitude (in the SM).

The data allows for a simultaneous determination of M_H and m_t (from the hadron colliders), S (from M_Z), T (mainly from Γ_Z), U (from M_W), $\widehat{s}_Z^2 = 0.23112 \pm 0.00013$ (from the Z pole asymmetries), and $\alpha_s(M_Z) = 0.1189 \pm 0.0018$ (from R_ℓ, $\sigma_{\rm had}$, and τ_τ), giving,

$$S = -0.01 \pm 0.10 \; , \tag{10.78a}$$

$$T = 0.03 \pm 0.12 \; , \tag{10.78b}$$

$$U = 0.02 \pm 0.11 \; , \tag{10.78c}$$

with little correlation among the SM parameters, where the uncertainties are from unknown higher orders in the SM predictions and the inputs. The parameters in Eq. (10.78), which by definition are due to new physics only, are in excellent agreement with the SM values of zero. Fixing $U = 0$, which is motivated by the fact that U is suppressed by an additional factor $M_{\rm new}^2/M_Z^2$ compared to S and T [362], greatly improves the precision on S and particularly T,

$$S = 0.00 \pm 0.07 \; , \tag{10.79a}$$

$$T = 0.05 \pm 0.06 \; . \tag{10.79b}$$

If only any one of the three parameters is allowed, then this parameter would deviate at the 1.6 to 1.9 σ level, reflecting the deviation in M_W. Using Eq. (10.74), the value of ρ_0 corresponding to T in Eqs. (10.78) is 1.0002 ± 0.0009, while the one corresponding to Eqs. (10.79) is 1.0004 ± 0.0005. Thus, the multi-parameter fits are consistent with $\rho_0 = 1$, in contrast to the fit with $S = U = 0$ in Eq. (10.67a). There is a strong correlation (92%) between the S and T parameters. The U parameter is -80% (-93%) anti-correlated with S (T). The allowed regions in $S{-}T$ (for $U = 0$) are shown in Fig. 10.6. From Eq. (10.78) one obtains $S < 0.14$ and $T < 0.22$ at 95% CL, where the former puts the constraint $M_{KK} \gtrsim 3.6$ TeV on the masses of KK gauge bosons in warped extra dimensions. In minimal composite Higgs models, the bound on S requires $M_V \gtrsim 4$ TeV [363], but this constraint can be relaxed, *e.g.*, if the fermionic sector is also allowed to be partially composite [364, 365].

The S parameter can also be used to constrain the number of fermion families, *under the assumption* that there are no new contributions to T or U and therefore that any new families are degenerate; then an extra generation of SM fermions is excluded at the 8 σ level corresponding to $N_F = 2.75 \pm 0.15$. This can be compared to the fit to the number of light neutrinos given in Eq. (10.63), $N_\nu = 3.0026 \pm 0.0061$, but the S parameter fits are valid even for a very heavy fourth family neutrino. Allowing T to vary as well, the constraint on a fourth family is weaker [366]. However, a heavy fourth family would increase the Higgs production cross-section through gluon fusion by a factor of about 9 [367], which is in considerable tension with the observed Higgs signal at the LHC [368]. Combining the limits from electroweak precision data with the measured Higgs production rate and limits from direct searches for heavy quarks [369], a fourth family of chiral fermions is now excluded by more than five standard deviations [370, 371]. Similar remarks apply to a heavy mirror family [372] involving right-handed SU(2) doublets and left-handed singlets. In contrast, new doublets that receive most of their mass from a different source than the Higgs vacuum expectation value, such as vector-like fermion doublets or scalar doublets in Supersymmetry, give small or no contribution to S, T, U, and the Higgs production cross-section and are therefore still allowed. Partial or complete vector-like fermion families are predicted in many Grand Unified Theories [373] (see the Section on “Grand Unified Theories” in this *Review*), and many other models including supersymmetric and superstring inspired ones [374–377].

As discussed in Sec. 10.6, there is a 3.6% deviation in the asymmetry parameter A_b. Assuming that this is due to new physics affecting preferentially the third generation, we can perform a fit allowing additional $Z \to b\bar{b}$ vertex corrections ρ_b and κ_b as in Eq. (10.42) (here defined to be due to new physics only with the SM contributions removed), as well as S, T, U, and the SM parameters, with the result,

$$\rho_b = 0.058 \pm 0.020 \; , \tag{10.80a}$$

$$\kappa_b = 0.185 \pm 0.067 \; , \tag{10.80b}$$

with an almost perfect correlation of 99% (because R_b is much better determined than A_b). The central values of the oblique parameters are consistent with their SM values of zero, and there is little change in the SM parameters, except that the value of $\alpha_s(M_Z)$ is lower by 0.0008 compared to the SM fit. Given that an $\mathcal{O}(20\%)$ correction to κ_b would be necessary, it would be difficult to account for the deviation in A_b by new physics that enters only at the level of radiative corrections. Thus, if it is due to new physics, it is most likely of tree-level type affecting preferentially the third generation. Examples include the decay of a scalar neutrino resonance [378], mixing of the b quark with heavy exotics [379], and a heavy Z' with family non-universal couplings [380, 381]. It is difficult, however, to simultaneously account for R_b without tuning, which has been measured on the Z peak and off-peak [382] at LEP 1.

There is no simple parametrization to describe the effects of every type of new physics on every possible observable. The S, T, and U formalism describes many types of heavy physics which affect only the gauge self-energies, and it can be applied to all precision observables. However, new physics which couples directly to ordinary fermions cannot be fully parametrized in the S, T, and U framework. Examples include heavy Z' bosons [322], mixing with exotic fermions [9, 383, 384], leptoquark exchange [260, 385, 386], supersymmetric models, strong EW dynamics [364], Little Higgs models [387, 388], and TeV-scale extra spatial dimensions [389–392] (for more details and references, see the Section on “Extra Dimensions” in this *Review*). These types of new physics can be parametrized in a model-independent way by using an effective field theory description [393–396]. Here the SM is extended by a set of higher-dimensional operators, denoted $\mathcal{O}_i$,

$$\mathcal{L} = \mathcal{L}_{\rm SM} + \sum_{d>4} \sum_i \frac{C_i}{\Lambda^{d-4}} \mathcal{O}_i \; , \tag{10.81}$$

where Λ is the characteristic scale of the new physics sector, which is assumed to satisfy $\Lambda \gg v$. For EW precision observables, the leading new operators enter at dimension $d = 6$. Note that S and T can be identified with two of these operators (or linear combinations thereof, depending on the chosen operator basis), while U corresponds to a dimension-8 operator [362, 397]. With current data on M_W and Z pole observables, Λ is constrained to be larger than $\mathcal{O}$(TeV) if the Wilson coefficients C_i are of order unity [398–402].

An alternate formalism [403] defines parameters, ϵ_1, ϵ_2, ϵ_3, and ϵ_b in terms of the specific observables M_W/M_Z, $\Gamma_{\ell\ell}$, $A_{FB}^{(0,\ell)}$, and R_b. The definitions coincide with those for $\widehat{\epsilon}_i$ in Eqs. (10.72) and (10.73c) for physics which affects gauge self-energies only, but the ϵ's now parametrize arbitrary types of new physics. However, the ϵ_i are not related to other observables unless additional model-dependent assumptions are made.

Limits on new four-Fermi operators and on leptoquarks using LEP 2 and lower energy data are given in Refs. [260, 404–406], while constraints on various types of new physics are addressed in Refs. [9, 151, 277, 407, 408]. For a particularly well motivated and explored type of physics beyond the SM, see the Section on "Z'-Boson Searches" in this *Review*.

Acknowledgments

It is a pleasure to thank Rodolfo Ferro-Hernández for discussions, for performing some of the calculations and checks, and for producing the plot in Fig. 10.2. J.E. is supported by the German–Mexican research collaboration grant SP 778/4–1 (DFG) and 278017 (CONACyT). A.F. is supported in part by the National Science Foundation under grant no. PHY–1820760.

11.1 Introduction

Understanding the mechanism that breaks the electroweak symmetry and generates the masses of the known elementary particles has been one of the fundamental endeavours in particle physics for several decades. The discovery in 2012 by the ATLAS [1] and the CMS [2] collaborations of a new resonance with a mass of approximately 125 GeV and the subsequent studies of its properties with the full data set from Run 1, from 2009 to 2012, with a centre-of-mass energy of 7 TeV and 8 TeV, conclusively provided a first portrait of the Electroweak Symmetry Breaking (EWSB) mechanism. The data collected during the LHC Run 2, from 2015 to 2018, with a higher centre-of-mass energy of 13 TeV and more conspicuous dataset, put in solid grounds the compatibility of the measured resonance with the Higgs boson of the Standard Model (SM) [3].

In the SM, the electroweak interactions are described by a gauge field theory invariant under the $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ symmetry group. The mechanism of EWSB [4] provides a general framework to keep untouched the structure of these gauge interactions at high energies and still generate the observed masses of the W and Z gauge bosons. The EWSB mechanism posits a self-interacting complex EW doublet scalar field, whose CP-even neutral component acquires a vacuum expectation value (VEV) $v \approx 246$ GeV, which sets the scale of the symmetry breaking. Three massless Goldstone bosons are generated and are absorbed to give masses to the W and Z gauge bosons. The remaining component of the complex doublet becomes the Higgs boson – a new, and so far unique, fundamental scalar particle. The masses of all fermions are also a consequence of EWSB since the Higgs doublet is postulated to couple to the fermions through Yukawa interactions

The initial measurements during the LHC Run 1 were accessible mainly through production and decay channels related to the couplings of the Higgs boson to the vector gauge bosons (the mediators of the electroweak interactions, $W^{\pm}$, Z and γ, as well as the gluons, g, mediators of the strong interactions).

The outstanding performance of the LHC Run 2, made it possible for the ATLAS and CMS experiments to independently and unambiguously establish the couplings of the Higgs boson to the charged fermions of the third generation (the top quark, the bottom quark, and the tau). These observations of fundamental importance were made with partial Run 2 datasets.

In all observed production and decay modes measured so far, the rates and differential measurements are found to be consistent, within experimental and theoretical uncertainties, with the SM predictions. In high resolution decay channels, such as the ones with four leptons (electrons or muons) or diphoton final states, the mass of the Higgs boson has been measured at the permill precision level.

Nevertheless, several channels are still out of reach experimentally and the couplings of the Higgs boson to light fermions are yet to be proven. Moreover, within the current precision, a more complex sector with additional states is not ruled out, nor has it been established whether the Higgs boson is an elementary particle or whether it has an internal structure like any other scalar particles observed before it.

Without the Higgs boson, the calculability of the SM would have been spoiled. In particular, perturbative unitarity [5] would be lost at high energies since the longitudinal W/Z boson scattering amplitude would grow with the centre-of-mass energy. In addition, the radiative corrections to the gauge boson self-energies would exhibit dangerous logarithmic divergences that would be difficult to reconcile with EW precision data. With the discovery of the Higgs boson, the SM is a spontaneously broken gauge theory and, as such, it could a priori be consistently extrapolated well above the masses of the W and Z bosons. Hence, formally there is no need for new physics at the EW scale. However, as the SM Higgs boson is a scalar particle, at the quantum level it has sensitivity to possible new physics scales. Quite generally, the Higgs boson mass is affected by the presence of heavy particles and receives quantum corrections which destabilise the weak scale barring a large fine tuning of unrelated parameters. This is known as the Higgs naturalness or hierarchy problem [6]. It has been the prime argument for expecting new physics right at the TeV scale. New theoretical paradigms have been imagined, such as a new fermion-boson symmetry called supersymmetry (SUSY) [7] (for recent reviews, see Refs. [8,9]), or the existence of strong interactions at a scale of the order of a TeV from which the Higgs boson would emerge as a composite state [10] (see Refs. [11,12] for recent reviews). Alternatively, new agents stabilising the weak scale could also be light but elusive, like in models of neutral naturalness [13,14]. Other more recent scenarios [15], instead, rely on the cosmological evolution of the Universe to drive the Higgs boson mass to a value much smaller than the cutoff of the theory and aim at alleviating the hierarchy problem without the need for TeV scale new physics, even thought there might still be interesting and spectacular signatures [15,16]. Beyond the naturalness problem, extensions of the SM Higgs sector without other low-energy particles have been proposed, for example, to provide explanations for the fermion mass hierarchies, see e.g. Ref. [17], to account for the Dark Matter abundance, see e.g. Ref. [18], or to modify the properties of the electroweak phase transition [19]. Such models with additional scalars provide grounds to explore new Higgs boson signals in concrete and complete scenarios, with different types of coupling structure to fermions and gauge bosons.

The Higgs boson is anyway special and, in the eight years since its discovery, it became a powerful tool to explore the manifestations of the SM and to probe the physics landscape beyond it. It might offer direct insights on what comes beyond the weak scale through possible sizeable effects on the Higgs boson properties. The Higgs boson couplings, however, are observed to be in good agreement with their SM predictions. This, together with the strong bounds from precision electroweak and flavour data, leaves open the possibility that the Higgs boson may well be elementary, weakly coupled and solitary up to the Planck scale, rendering the EW vacuum potentially metastable [20].

After completion of the first two runs, the LHC has only gathered approximately 5% of its projected full dataset. During the second long shut down currently underway, the LHC is undergoing important upgrades in order to prepare for its high luminosity phase. The foreseen larger datasets to be collected during Run 3 and ultimately during the High Luminosity LHC (HL-LHC), will enable yet more fundamental and challenging measurements to explore new physics.

This review is organised as follow. Section 11.2 is a theoretical review of the SM Higgs boson, its properties, production mechanisms and decay rates. In Section 11.3, the experimental measurements are described. In Section 11.4, the combination of the main Higgs boson production and decay channels is presented. In Section 11.5, measurements of the main quantum numbers and CP properties of the Higgs boson are reported and the bounds on its total width are discussed. In Section 11.6, a general theoretical framework to describe the deviations of the Higgs boson couplings from the SM predictions is introduced and the experimental measurements of these Higgs couplings is reviewed. Measurements of differential cross sections are outlined. Section 11.7 presents, in detail, some interesting models proposed for extensions of the SM Higgs sector, addressing the hierarchy problem or not, and considers their experimental signatures. Section 11.8 provides a short summary and a brief outlook.

11.2 The Standard Model and the mechanism of electroweak symmetry breaking

In the SM [3], electroweak symmetry breaking [4] is responsible for generating mass for the W and Z gauge bosons rendering the weak interactions short ranged. The SM scalar potential reads:

$$V(\Phi) = m^2\Phi^\dagger\Phi + \lambda(\Phi^\dagger\Phi)^2 \tag{11.1}$$

with the Higgs field Φ being a self-interacting $\mathrm{SU}(2)_L$ complex doublet (four real degrees of freedom) with weak hypercharge $Y{=}1$ (the hypercharge is normalised such that $Q = T_{3L} + Y/2$, Q being the electric charge and T_{3L} the eigenvalue of the diagonal generator of $\mathrm{SU}(2)_L$):

$$\Phi = \frac{1}{\sqrt{2}}\begin{pmatrix}\sqrt{2}\phi^+\\ \phi^0 + ia^0\end{pmatrix}, \tag{11.2}$$

where ϕ^0 and a^0 are the CP-even and CP-odd neutral components, and ϕ^+ is the complex charged component of the Higgs doublet, respectively. $V(\Phi)$ is the most general renormalisable scalar potential. If the quadratic term is negative, the neutral component of the scalar doublet acquires a non-zero vacuum expectation value (VEV)

$$\langle\Phi\rangle = \frac{1}{\sqrt{2}}\begin{pmatrix}0\\ v\end{pmatrix}, \tag{11.3}$$

with $\phi^0 = H + \langle\phi^0\rangle$ and $\langle\phi^0\rangle \equiv v$, inducing the spontaneous breaking of the SM gauge symmetry $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ into $\mathrm{SU}(3)_C \times \mathrm{U}(1)_{\mathrm{em}}$. The global minimum of the theory defines the ground state, and spontaneous symmetry breaking implies that there is a (global and/or local) symmetry of the system that is not respected by the ground state. From the four generators of the $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ SM gauge group, three are spontaneously broken, implying that they lead to non-trivial transformations of the ground state and indicate the existence of three massless Goldstone bosons identified with three of the four Higgs field degrees of freedom. The Higgs field couples to the W_μ and B_μ gauge fields associated with the $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ local symmetry through the covariant derivative appearing in the kinetic term of the Higgs Lagrangian,

$$\mathcal{L}_{\mathrm{Higgs}} = (D_\mu\Phi)^\dagger(D^\mu\Phi) - V(\Phi)\,, \tag{11.4}$$

where $D_\mu\Phi = (\partial_\mu + ig\sigma^a W^a_\mu/2 + ig'YB_\mu/2)\Phi$, g and g' are the $\mathrm{SU}(2)_L$ and $\mathrm{U}(1)_Y$ gauge couplings, respectively, and $\sigma^a, a = 1,2,3$ are the usual Pauli matrices. As a result, the neutral and the two charged massless Goldstone degrees of freedom mix with the gauge fields corresponding to the broken generators of $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ and become, in the unitarity gauge, the longitudinal components of the Z and W physical gauge bosons, respectively. The Z and W gauge bosons acquire masses,

$$m_W^2 = \frac{g^2v^2}{4}\,, \quad m_Z^2 = \frac{(g'^2 + g^2)v^2}{4}. \tag{11.5}$$

The fourth generator remains unbroken since it is the one associated to the conserved $\mathrm{U}(1)_{\mathrm{em}}$ gauge symmetry, and its corresponding gauge field, the photon, remains massless. Similarly the eight color gauge bosons, the gluons, corresponding to the conserved $\mathrm{SU}(3)_C$ gauge symmetry with 8 unbroken generators, also remain massless (though confined inside hadrons and mesons as the result of the asymptotic freedom behaviour of QCD). Hence, from the initial four degrees of freedom of the Higgs field, two are absorbed by the $W^\pm$ gauge bosons, one by the Z gauge boson, and there is one remaining degree of freedom, H, that is the physical Higgs boson — a new scalar particle first imagined by P. Higgs [4]. The Higgs boson is neutral under the electromagnetic interactions and transforms as a singlet under $\mathrm{SU}(3)_C$ and hence does not couple at tree level to the massless photons and gluons.

The fermions of the SM acquire mass through renormalisable interactions between the Higgs field and the fermions: the Yukawa interactions,

$$\mathcal{L}_{\mathrm{Yukawa}} = -\hat{h}_{d_{ij}}\bar{q}_{L_i}\Phi\, d_{R_j} - \hat{h}_{u_{ij}}\bar{q}_{L_i}\tilde{\Phi}u_{R_j} - \hat{h}_{l_{ij}}\bar{l}_{L_i}\Phi\, e_{R_j} + h.c., \tag{11.6}$$

which respect the symmetries of the SM but generate fermion masses once EWSB occurs. In the Lagrangian above, $\tilde{\Phi} = i\sigma_2\Phi^*$ and q_L (l_L) and u_R, d_R (e_R) are the quark (lepton) $\mathrm{SU}(2)_L$ doublets and singlets, respectively, while in each term, $\hat{h}_{X_{ij}}$ is parametrised by a 3×3 matrix in family space. The mass term for neutrinos is omitted, but could be added in an analogous manner to the up-type quarks when right-handed neutrinos are supplementing the SM particle content (neutrinos can also acquire Majorana masses via non-renormalisable dimension-5 interactions with the Higgs field [21]). Once the Higgs field acquires a VEV, and after rotation to the fermion mass eigenstate basis that also diagonalises the Higgs-fermion interactions, $\hat{h}_{f_{ij}} \to h_{f_i}\delta_{ij}$, all fermions acquire a mass given by $m_{f_i} = h_{f_i}v/\sqrt{2}$. The indices $i,j = 1,2,3$ refer to the three families in the up-quark, down-quark or charged lepton sectors. It should be noted that the EWSB mechanism provides no additional insight on possible underlying reasons for the large variety of masses of the fermions, often referred to as the flavour hierarchy. The fermion masses, accounting for a large number of the free parameters of the SM, are simply translated into Yukawa couplings.

11.2.1 *The SM Higgs boson mass, couplings and quantum numbers*

The SM Higgs boson is a CP-even scalar of spin 0. Its mass is given by $m_H = \sqrt{2\lambda}\ v$, where λ is the self coupling parameter in $V(\Phi)$. The expectation value of the Higgs field, $v = (\sqrt{2}G_F)^{-1/2} \approx 246\,\mathrm{GeV}$, is fixed by the Fermi coupling G_F, which is determined with a precision of 0.6 ppm from muon decay measurements [22]. The quartic coupling λ is a free parameter in the SM, and hence, there is no a priori prediction for the Higgs mass. Moreover the sign of the mass parameter $m^2 = -\lambda v^2$ has to be negative for the EW symmetry breaking to take place, but there is no a priori understanding of what decides of this sign. The experimentally measured Higgs boson mass, $m_H = 125.10 \pm 0.14\,\mathrm{GeV}$ [22], implies that $\lambda \simeq 0.13$ and $|m| \simeq 88.4\,\mathrm{GeV}$.

The Higgs boson couplings to the fundamental particles are set by their masses. This is a new type of interaction; very weak for light particles, such as up and down quarks, and electrons, but strong for heavy particles such as the W and Z bosons and the top quark. More precisely, the SM Higgs couplings to fundamental fermions are linearly proportional to the fermion masses, whereas the couplings to bosons are proportional to the square of the boson masses. The SM Higgs boson couplings to gauge bosons and fermions, as well as the Higgs boson self coupling, are summarised in the following Lagrangian:

$$\begin{aligned}\mathcal{L} = -g_{Hf\bar{f}}\bar{f}fH + \frac{g_{HHH}}{6}H^3 + \frac{g_{HHHH}}{24}H^4 \\ + \delta_V V_\mu V^\mu \left(g_{HVV}H + \frac{g_{HHVV}}{2}H^2\right)\end{aligned} \tag{11.7}$$

with

$$\begin{aligned} g_{Hf\bar{f}} = \frac{m_f}{v},\ g_{HVV} = \frac{2m_V^2}{v},\ g_{HHVV} = \frac{2m_V^2}{v^2}, \\ g_{HHH} = \frac{3m_H^2}{v},\ g_{HHHH} = \frac{3m_H^2}{v^2}, \end{aligned} \tag{11.8}$$

where $V = W^\pm$ or Z and $\delta_W = 1, \delta_Z = 1/2$. As a result, the dominant mechanisms for Higgs boson production and decay involve the coupling of H to W, Z and/or the third generation quarks and leptons. The Higgs boson coupling to gluons [23,24] is induced at leading order by a one-loop process in which H couples to a virtual $t\bar{t}$ pair (with minor contributions from the other lighter quarks). Likewise, the Higgs boson coupling to photons is also generated via loops, although in this case the one-loop graph with a virtual W^+W^- pair provides the dominant contribution [25] and it is interfering with the smaller contribution involving a virtual $t\bar{t}$ pair (as such, the Higgs coupling to photons is sensitive to the relative phase of the interactions between bosons and fermions).

11.2.2 *The SM custodial symmetry*

The SM Higgs Lagrangian, $\mathcal{L}_{\text{Higgs}} + \mathcal{L}_{\text{Yukawa}}$ of Eq. (11.4) and Eq. (11.6), is, by construction, $\text{SU}(2)_L \times \text{U}(1)_Y$ gauge invariant, but it also has an approximate global symmetry. In the limit $g' \to 0$ and $h_f \to 0$, the Higgs sector has a global $\text{SU}(2)_R$ symmetry, and hence it is invariant under a global $\text{SU}(2)_L \times \text{SU}(2)_R$ symmetry, with $\text{SU}(2)_L$ just being the global variant of the SM chiral gauge symmetry. This symmetry is preserved for non-vanishing Yukawa couplings, provided $h_u = h_d$. Once the Higgs acquires a VEV, both the $\text{SU}(2)_L$ and $\text{SU}(2)_R$ symmetry groups are broken but the diagonal subgroup $\text{SU}(2)_{L+R}$ remains unbroken and it is the subgroup that defines the custodial symmetry of the SM [26].

In the limit $g' \to 0$, the W and Z gauge bosons have equal mass and form a triplet of the $\text{SU}(2)_{L+R}$ unbroken global symmetry. Using the expressions for the W and Z gauge boson masses in term of the gauge couplings, one obtains at tree level

$$\frac{m_W^2}{m_Z^2} = \frac{g^2}{g'^2 + g^2} = \cos^2\theta_W \quad \text{or} \quad \rho \equiv \frac{m_W^2}{m_Z^2\cos^2\theta_W} = 1. \tag{11.9}$$

The custodial symmetry protects the above relation from large radiative corrections. All corrections to the ρ parameter are therefore proportional to terms that break the custodial symmetry. For instance, radiative corrections involving the Higgs boson are proportional to $\sin^2\theta_W$, $\delta\rho = -11G_F m_Z^2 \sin^2\theta_W \log(m_H^2/m_Z^2)/(24\sqrt{2}\pi^2)$, and vanish in the limit $g' \to 0$. Since $m_t \neq m_b$, there are also relevant radiative corrections generated by massive fermions. They are proportional to $m_t^2 + m_b^2 - 2(m_t^2 m_b^2)\log(m_t^2/m_b^2)/(m_t^2 - m_b^2)$ and would indeed vanish for $m_t = m_b$ [27].

11.2.3 *Stability of the Higgs potential*

The discovery of the Higgs boson with $m_H \approx 125$ GeV has far reaching consequences within the SM framework. In particular, the precise value of m_H determines the value of the quartic coupling λ at the electroweak scale and makes it possible to study its behavior up to high energy scales. A larger value of m_H would have implied that the self coupling λ would become non-perturbative at some scale Λ that could be well below the Planck scale [28].

However, for the value of Higgs boson mass experimentally measured, the EW vacuum of the Higgs potential is most likely metastable [20]. The high energy evolution of λ shows that it becomes negative at energies $\Lambda = \mathcal{O}(10^{11})$ GeV (even though λ could remain positive till higher energy, maybe all the way to the Planck scale, if the top quark mass exceeds its current measured value by 3σ). When this occurs, the SM Higgs potential develops an instability and the long term existence of the EW vacuum is challenged. This behaviour may call for new physics at an intermediate scale before the instability develops, i.e., below M_{Planck}, even though new physics at M_{Planck} could influence the stability of the EW vacuum and possibly modify this conclusion [29]. The consequences of the instability of the EW vacuum on high-scale inflation have been discussed in Ref. [30]. It was also noticed that Higgs field fluctuations during inflation could seed the formation of primordial black holes, possibly making up the Dark Matter relic abundance [31] or they could produce a stochastic background of gravitational waves with characteristic structures [32], offering a probe of the EW vacuum near criticality.

The lifetime of the EW metastable vacuum is determined by the rate of quantum tunnelling from this vacuum into the true vacuum of the theory (for the most recent computation of the EW vacuum lifetime within the SM, see Ref. [33]). Within the SM, the running of the Higgs self coupling slows down at high energies with a cancellation of its β-function at energies just one to two orders of magnitude below the Planck scale [34]. This slow evolution of the quartic coupling is responsible for saving the EW vacuum from premature collapse. It might also help the Higgs boson to play the role of an inflaton [35] (see, however, Ref. [36] for potential issues with this Higgs-boson-as-an-inflaton idea).

11.2.4 *Higgs boson production and decay mechanisms*

Reviews of the SM Higgs boson's properties and phenomenology, with an emphasis on the impact of loop corrections to the Higgs boson decay rates and cross sections, can be found in Refs. [37–44].

11.2.4.1 *Production mechanisms at hadron colliders*

The main production mechanisms at the Tevatron collider and the LHC are gluon fusion (ggF), weak-boson fusion (VBF), associated production with a gauge boson (VH), and associated production with a pair of $t\bar{t}$ quarks ($t\bar{t}H$) or with a single top quark (tHq). Figure 11.1 depicts representative diagrams for these dominant Higgs boson production processes.

The state-of-the-art of the theoretical calculations in the main different production channels is summarized in Table 11.1.

The cross sections for the production of a SM Higgs boson as a function of $\sqrt{s}$, the center of mass energy, for pp collisions, including bands indicating the theoretical uncertainties, are summarised in Fig. 11.2 (left) [45]. A detailed discussion, including uncertainties in the theoretical calculations due to missing higher-order effects and experimental uncertainties on the determination of SM parameters involved in the calculations, can be found in Refs. [41–44]. These references also contain state-of-the-art discussions on the impact of PDF uncertainties, QCD scale uncertainties and uncertainties due to different procedures for including higher-order corrections matched to parton shower simulations, as well as uncertainties due to hadronisation and parton-shower events.

Table 11.2 summarises the Higgs boson production cross sections and relative uncertainties for a Higgs boson mass of 125 GeV, for $\sqrt{s} = 7$, 8, 13 and 14 TeV. The Higgs boson production cross sections in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV for the Tevatron are obtained from Ref. [46].

i. *Gluon fusion production mechanism*

At high-energy hadron colliders, the Higgs boson production mechanism with the largest cross section is the gluon-fusion process, $gg \to H + X$, mediated by the exchange of a virtual, heavy top quark [47]. Contributions from lighter quarks propagating in the loop are suppressed proportionally to m_q^2. QCD radiative corrections to the gluon-fusion process are very important and have been studied in detail. Including the full dependence on the

The theoretical uncertainties are indicated as bands. (Right) The branching ratios for the main decays of the SM Higgs boson near $m_H = 125\,\text{GeV}$ [43,44]. The theoretical uncertainties are indicated as bands.

(top, bottom, charm) quark and Higgs boson masses, the cross section has been calculated at the next-to-leading order (NLO)

Table 11.2: The SM Higgs boson production cross sections for $m_H = 125$ GeV in pp collisions ($p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV for the Tevatron), as a function of the center of mass energy, $\sqrt{s}$. The predictions for the LHC energies are taken from Refs. [41–44], the ones for the Tevatron energy are from Ref. [46]. The predictions for the ggF channel at the LHC include the latest N3LO results leading to reduced theoretical uncertainties by a factor around 2 compared to the NNLO+NLL results. The total uncertainties are estimated assuming no correlations between α_S and PDF uncertainties.

$\sqrt{s}$ (TeV)	Production cross section (in pb) for $m_H = 125$ GeV					
	ggF	VBF	WH	ZH	$t\bar{t}H$	total
1.96	$0.95^{+17\%}_{-17\%}$	$0.065^{+8\%}_{-7\%}$	$0.13^{+8\%}_{-8\%}$	$0.079^{+8\%}_{-8\%}$	$0.004^{+10\%}_{-10\%}$	1.23
7	$16.9^{+4.4\%}_{-7.0\%}$	$1.24^{+2.1\%}_{-2.1\%}$	$0.58^{+2.2\%}_{-2.3\%}$	$0.34^{+3.1\%}_{-3.0\%}$	$0.09^{+5.6\%}_{-10.2\%}$	19.1
8	$21.4^{+4.4\%}_{-6.9\%}$	$1.60^{+2.3\%}_{-2.1\%}$	$0.70^{+2.1\%}_{-2.2\%}$	$0.42^{+3.4\%}_{-2.9\%}$	$0.13^{+5.9\%}_{-10.1\%}$	24.2

in α_s [48, 49]. To a very good approximation, the leading top-quark contribution can be evaluated in the limit $m_t \to \infty$ by matching the SM to an effective theory. The gluon-fusion amplitude is then evaluated from an effective Lagrangian containing a local $HG^a_{\mu\nu}G^{a\,\mu\nu}$ operator [23, 24]. In this approximation, the cross section is known at next-to-next-to-next-to-leading order (N3LO) [50]. The validity of the effective theory with infinite m_t is greatly enhanced by rescaling the result by the exact LO result: $\sigma = (\sigma^{\rm LO}_{m_t}/\sigma^{\rm LO}_{m_t=\infty})\times\sigma_{m_t=\infty}$ [44]. The large top-quark mass approximation, after this rescaling of the cross section, yields a NNLO result that has been established to be at the percent level accuracy [51]. Further progress is made to include full top mass dependence at NNLO [52].

The LO and NLO QCD corrections [53] amount to about 80% of the total N3LO cross section. The NNLO corrections [54] further enhance the cross section by approximately 30% of the LO plus NLO result (at $\mu_f = \mu_r = m_H/2$). Electroweak radiative corrections have been computed at NLO and increase the LO cross section by about 5% for $m_H \simeq 125$ GeV [55]. Mixed QCD-EW corrections are now being investigated with encouraging results on the computation of the exact 3-loop amplitude [56] complementing the results obtained in either limit of heavy [57] or massless [58] gauge bosons.

At N3LO, the perturbation series is rather stable with a mere enhancement of 3% of the total cross section, with a central value quite insensitive to threshold resummation effects with the scale choice mentioned above [44, 50, 59]. At the LHC with a center-of-mass energy of 13 TeV, the most up-to-date value for the production cross section of a 125 GeV Higgs boson amounts to [44]

$$\sigma^{\rm N3LO}_{\rm ggF} = 48.6\,{\rm pb}^{+2.2\,{\rm pb}\,(+4.6\%)}_{-3.3\,{\rm pb}\,(-6.7\%)}\,({\rm theory})\pm 1.6\,{\rm pb}\,(3.2\%)\,({\rm PDF}+\alpha_s). \tag{11.10}$$

Besides considering the inclusive Higgs boson production cross section at the LHC, it is important to study differential distributions in order to probe the properties of the Higgs boson in a detailed way. A more exclusive account of Higgs boson production is also required because experimental analyses often impose cuts on the final states in order to improve the signal-to-background ratio. To this end, it is useful to define benchmark cuts and compare the differential distributions obtained at various levels of theoretical accuracy (i.e., at NLO or NNLO) with Monte-Carlo generators. In the infinite top mass limit, the Higgs boson p_T distribution is known at NNLO [60, 61] (see Ref. [62] for a recent reappraisal) and heavy quark mass effects, including top-bottom interferences, have been computed at NLO [63], revealing a non-trivial logarithmic structure that will make resummation difficult [64]. A programatic approach for a fixed-order/resummation matching of the top-bottom interferences has been proposed [65]. Many search modes for the Higgs boson are carried out by separating the events according to the number of jets or the transverse momentum and rapidity of the Higgs boson. For $p_T < 35$ GeV, predictions for the transverse-momentum distribution can only be trusted after large logarithms of the form $\alpha_s^n \ln^k(m_H/p_T^{\rm veto})$, $k \leq 2n-1$, and (non-Sudakov) double logarithms of the form $g_{Hq\bar{q}}\, m_q/m_H[\ln^2(m_H/m_q), \ln^2(p_T/m_q)]$ have been resummed. This has been accomplished with N3LL accuracy [66] and the results have been matched onto the fixed-order prediction at NNLO [67]. In addition, impressive progress is made to improve the calculation of the Higgs boson production cross section with a jet veto (the "0-jet bin" or in the presence of a veto bounding the transverse momentum of the hardest accompanying jet) [68], reaching N2LL accuracy matched to N3LO. These accurate predictions for the jet-veto cross section are required, e.g., to suppress the $t\bar{t}$ background in the $H \to WW$ channel [69]. Electroweak corrections have been studied in Ref. [70]. Note that in the boosted regime, at $p_T \sim 1$ TeV, VH takes over ggF as the dominant channel [71].

ii. *Vector boson fusion production mechanism*

The SM Higgs boson production mode with the second-largest cross section at the LHC is vector boson fusion. At the Tevatron collider, VBF also occurred, but for $m_H = 125$ GeV had a smaller cross section than Higgs boson production in association with a W or Z boson. Higgs boson production via VBF, $qq \to qqH$, proceeds by the scattering of two (anti-)quarks, mediated by t- or u-channel exchange of a W or Z boson, with the Higgs boson radiated off the weak-boson propagator. The scattered quarks give rise to two back-to-back hard jets in the forward and backward regions of the detector [72]. Because of the color-singlet nature of the weak-gauge boson exchange, gluon radiation from the central-rapidity regions is strongly suppressed. These characteristic features of VBF processes can be exploited to distinguish them from overwhelming QCD backgrounds, including gluon-fusion induced Higgs boson + 2 jet production, and from s-channel WH or ZH production with a hadronically decaying weak gauge boson. After the application of specific selection cuts, the VBF channel provides a clean environment, not only for the Higgs boson searches originally performed, but also for the subsequent determination of Higgs boson couplings at the LHC.

At the inclusive level, the cross-section is known at N3LO [73], with a residual uncertainty of the order of few permill. However, this result is obtained in the DIS/factorised approximation [74] where the fusing gauge bosons are emitted from the two quark legs independently. While, the exact NNLO VBF calculation will remain out-of-reach in the near future, the leading non-factorisable contributions with two forward jets have been estimated [75]. They give some corrections, also of the order of few permill, to inclusive quantities, but they are an order of magnitude larger for differential observables. Full NNLO QCD and NLO EW results in the DIS approximation are known [76] and the residual uncertainty is of the order of a few percent but is quite sensitive to the tagging jet cuts and jet radius modelling [77].

iii. *WH and ZH associated production mechanism*

The next most relevant Higgs boson production mechanisms after ggF and VBF at the LHC, and the most relevant ones after ggF at the Tevatron collider, are associated production with W and Z gauge bosons. The cross sections for the associated production processes, $pp \to VH + X$, with $V = W^\pm, Z$ receive contributions at NLO given by NLO QCD corrections to the Drell–Yan cross section [78, 79] and from NLO EW corrections. The latter, unlike the QCD corrections, do not respect the factorisation into Drell–Yan production since there are irreducible box contributions already at one loop [80]. At NNLO, the Drell–Yan-like corrections to WH production also give the bulk of the corrections to ZH production [81]. For ZH production there are, however, gluon-gluon induced contributions that do not involve a virtual Z gauge boson but are such that the Z gauge boson and H boson couple to gluons via top-quark loops [82], see diagram (d) in Fig. 11.1. In addition, WH and ZH production receive non Drell–Yan-like corrections in the $q\bar{q}'$ and $q\bar{q}$ initiated channels, respectively, at the NNLO level, where the Higgs boson is radiated off top-quark loops [83]. The full QCD corrections up to NNLO order, the NLO EW corrections and the NLO corrections to the gluon-gluon channel are available in `VH@NNLO` [84].

As neither the Higgs boson nor the weak gauge bosons are stable particles, their decays also have to be taken into account. Providing full kinematical information for the decay products can furthermore help in the suppression of large QCD backgrounds. Differential distributions for the processes $pp \to WH \to \bar{\nu}_\ell \ell H$ and $pp \to ZH \to \ell^+\ell^- H/\nu_\ell\bar{\nu}_\ell H$, including NLO QCD and EW corrections, have been presented in Ref. [85]. The NNLO QCD corrections to differential observables for WH production at the LHC, including the leptonic decays of the W boson and the decay of the Higgs boson into a $b\bar{b}$ pair, are presented in Ref. [86]. Calculations at the same level, including also the ZH process have been performed [87]. The WH production mode has also been matched to a parton shower at NNLO accuracy [88]. Full NNLO results for both the production and decay are available [89] and show a large impact of radiation from the final-state bottoms. The WH and ZH production modes, especially in the boosted regime, provide a relatively clean environment for studying the decay of the Higgs boson into bottom quarks [90].

iv. *Higgs boson production in association with $t\bar{t}$*

Higgs boson radiation off top quarks, $pp \to t\bar{t}H$, provides a direct probe of the top-Higgs Yukawa coupling. The LO cross section for this production process was computed in Ref. [91]. Later, the NLO(+NNLL) QCD [92] and NLO EW corrections [93] were evaluated yielding a moderate increase in the total cross section of at most 20%, but significantly reducing the scale dependence of the inclusive cross section. The EW corrections can be enhanced by large electroweak Sudakov logarithms in particular in the boosted regime often used in the phenomenological analyses [94]. The total theoretical errors, estimated by combining the uncertainties from factorisation and renormalisation scales, strong gauge coupling, and parton distributions, amount to 10–15% of the corresponding inclusive cross section. Interfaces between NLO QCD calculations for $t\bar{t}H$ production with parton-shower Monte-Carlo programs have been provided in Ref. [95]. These programs provide the most flexible tools to date for the computation of differential distributions, including experimental selection cuts and vetoes on the final-state particles and their decay products. The fixed-order NLO QCD calculation have been interfaced with the standard Parton Shower Monte-Carlo generators, allowing an accurate description of the $t\bar{t}H$ signal, from the energy scale of the hard scattering to the hadronisation energy scale. The exploitation of this channel requires, however, a proper description of the background, in particular $t\bar{t}b\bar{b}$, which exhibits a huge k-factor[1] enhancement from shower effects, see Ref. [44] for a detailed discussion.

v. *Other single Higgs boson production mechanisms at the LHC*

The Higgs boson production in association with a single top quark, though subdominant, can bring valuable information, in particular regarding the sign of the top Yukawa coupling. This is due to an almost totally destructive interference between two large contributions, one where the Higgs boson couples to a space-like W boson and the other where it couples to the top quark. This process has been computed at NLO in a five-flavour scheme [96] and amounts to about 90 fb at $\sqrt{s} = 14\,\mathrm{TeV}$ (with the opposite sign of the top Yukawa coupling, the cross section increases by one order of magnitude while the cross section for associated production with a pair of top quarks is unaffected).

The Higgs boson production in association with a pair of bottom quarks ($b\bar{b}H$) is known at NNLO in the case of five quark flavours [97–99]. The coupling of the Higgs boson to a b-quark is suppressed in the SM by the bottom-quark mass over the Higgs VEV, m_b/v, implying that associated production of a SM Higgs boson with b-quarks is small at the LHC. Yet, at high energy, large logarithms are present and need to be resummed, leading to an enhancement of the inclusive cross section. At $\sqrt{s} = 14\,\mathrm{TeV}$, the $b\bar{b}H$ cross section can be as large as 550 fb, still two orders of magnitude below the ggF production cross section. In a two Higgs doublet model or a SUSY model, which will be discussed in Section 11.7, this coupling is proportional to the ratio of neutral Higgs boson vacuum expectation values, $\tan\beta$, and can be significantly enhanced for large values of this ratio. Consequently, the $b\bar{b}H$ mode can even become the dominant production process for the Higgs boson, unlike in the SM.

The Higgs boson production in association with charm quarks is also known at NNLO and its cross section is approximately 85 fb at $\sqrt{s} = 13\,\mathrm{TeV}$ [44].

vi. *Double Higgs boson production at the LHC*

The main interest in the double Higgs boson production is that it can provide invaluable information on the Higgs potential. In particular, it gives access to the Higgs trilinear self coupling. The dominant production is via gluon fusion $gg \to HH$. It accounts for more than 90% of the total inclusive cross-section, the subleading production mechanisms are VBF $HHjj$ (around 1.7 fb at 13 TeV), HHW (0.50 fb), HHZ (0.36 fb) and $t\bar{t}HH$ (0.8 fb). The fixed order QCD corrections, computed in the infinite top mass limit, are large, typically doubling the cross section from LO to NLO [100] and further enhancing it by 20% from NLO to NNLO [101] to reach at 13 TeV [45]

$$\sigma(gg \to HH)^{\mathrm{NNLO,\ FTa}}_{\mathrm{ggF}} = 31.05\,\mathrm{fb}^{+2.2\%}_{-5.0\%}\,(\mathrm{theory}) \pm 3\%\,(\mathrm{PDF} + \alpha_s) \pm 2.6\%\,(m_t). \tag{11.11}$$

Recently, the complete NLO corrections with all top quark mass effects also became available numerically [102, 103], intriguingly revealing a k-factor much less flat than predicted in the large top mass approximations. The non-trivial dependence of the results on the renormalisation scheme and scale for the top quark mass [103] questions the assessment of the scale uncertainty and would warrant a proper NNLO computation that will however remain out of reach for quite some time. At the differential level, the destructive interference between the box and the triangle contributions complicates the predictions made in the infinite top mass limit for both the HH invariant mass and the leading Higgs boson p_T distributions. With an inclusive cross section of about 35 fb at $\sqrt{s} = 13\,\mathrm{TeV}$ and a difficult signal vs background discrimination, the double Higgs boson production remains a challenging channel to probe and will greatly benefit from the high-luminosity run of the LHC [104].

11.2.4.2 *Production mechanisms at e^+e^- colliders*

The dominant Higgs boson production cross sections at an e^+e^- collider are from the Higgs-strahlung process [23, 105], $e^+e^- \to ZH$, and the WW fusion process [106], $e^+e^- \to \bar{\nu}_e\nu_e W^*W^* \to \bar{\nu}_e\nu_e H$. The cross-section for the Higgs-strahlung process scales as s^{-1} and is predominant at low energies, while the cross-section for the WW fusion process scales as $\ln(s/m_H^2)$ and dominates at high energies [107]. The ZZ fusion mechanism, $e^+e^- \to e^+e^-Z^*Z^* \to e^+e^-H$, also contributes to the Higgs boson production, with a cross-section suppressed by an order of magnitude with respect to that of WW fusion. The process $e^+e^- \to t\bar{t}H$ [108] becomes important for $\sqrt{s} \geq 500\,\mathrm{GeV}$. For a more detailed discussion of Higgs boson production properties at lepton colliders, see for example Ref. [109].

[1] the k-factor is defined as the ratio of a physical quantity with and without radiative corrections included.

11.2.4.3 *SM Higgs boson branching ratios and total width*

For the understanding and interpretation of the experimental results, the computation of all relevant Higgs boson decay widths is essential, including an estimate of their uncertainties and, when appropriate, the effects of Higgs boson decays into off-shell particles with successive decays into lighter SM ones. A Higgs boson mass of about 125 GeV allows to explore the Higgs boson couplings to many SM particles. In particular the dominant decay modes are $H \to b\bar{b}$ and $H \to WW^*$, followed by $H \to gg$, $H \to \tau^+\tau^-$, $H \to c\bar{c}$ and $H \to ZZ^*$. With much smaller rates follow the Higgs boson decays into $H \to \gamma\gamma$, $H \to \gamma Z$ and $H \to \mu^+\mu^-$. Since the decays into gluons, diphotons and $Z\gamma$ are loop induced, they provide indirect information on the Higgs boson couplings to WW, ZZ and $t\bar{t}$ in different combinations. The uncertainties in the branching ratios include the missing higher-order corrections in the theoretical calculations as well as the errors in the SM input parameters, in particular fermion masses and the QCD gauge coupling, involved in the decay. In the following the state-of-the-art of the theoretical calculations will be discussed and the reader is referred to Refs. [41–44, 110] for detail.

The evaluation of the radiative corrections to the fermionic decays of the SM Higgs boson are implemented in HDECAY [111] at different levels of accuracy. The computations of the $H \to b\bar{b}$ and $H \to c\bar{c}$ decays include the complete massless QCD corrections up to N4LO, with a corresponding scale dependence of about 0.1% [112]. Both the electroweak corrections to $H \to b\bar{b}$, $c\bar{c}$ as well as $H \to \tau^+\tau^-$ are known at NLO [113] providing predictions with an overall accuracy of about 1–2% for $m_H \simeq 125$ GeV.

The loop induced decays of the SM Higgs boson are known fully at NLO and partially beyond that approximation. For $H \to gg$, the QCD corrections are known up to N3LO in the limit of heavy top quarks [49,114] and the uncertainty from the scale dependence is about 3%. For the $H \to \gamma\gamma$, the full NLO QCD corrections are available [49, 115] and the three-loop QCD corrections have also been evaluated [116]. The NLO electroweak corrections to $H \to gg$ and $H \to \gamma\gamma$ have been computed in Ref. [117]. All these corrections are implemented in HDECAY [111]. For $m_H \simeq$ 125 GeV, the overall impact of known QCD and EW radiative effects turns out to be well below 1%. In addition, the contribution of the $H \to \gamma e^+e^-$ decay via virtual photon conversion has been computed in Ref. [118]. The partial decay width $H \to Z\gamma$ is only implemented at LO in HDECAY, including the virtual W, top-, bottom-, and τ-loop contributions. The QCD corrections have been calculated and are at the percent level [119]. The theoretical uncertainty due to unknown electroweak corrections is estimated to be less than 5%, an accuracy that will be hard to achieve in the measurement of this process at the LHC.

Table 11.3: The branching ratios and the relative uncertainty [43, 44] for a SM Higgs boson with $m_H = 125$ GeV.

Decay channel	Branching ratio	Rel. uncertainty
$H \to \gamma\gamma$	2.27×10^{-3}	2.1%
$H \to ZZ$	2.62×10^{-2}	$\pm 1.5\%$
$H \to W^+W^-$	2.14×10^{-1}	$\pm 1.5\%$
$H \to \tau^+\tau^-$	6.27×10^{-2}	$\pm 1.6\%$
$H \to b\bar{b}$	5.82×10^{-1}	${}^{+1.2\%}_{-1.3\%}$
$H \to c\bar{c}$	2.89×10^{-2}	${}^{+5.5\%}_{-2.0\%}$
$H \to Z\gamma$	1.53×10^{-3}	$\pm 5.8\%$
$H \to \mu^+\mu^-$	2.18×10^{-4}	$\pm 1.7\%$

The decays $H \to WW/ZZ \to 4f$ can be simulated with the `Prophecy4f` Monte-Carlo generator [120] that includes complete NLO QCD and EW corrections for Higgs decays into any possible four-fermion final state. All calculations are consistently performed with off-shell gauge bosons, without any on-shell approximation. For the SM Higgs boson, the missing higher-order corrections are estimated to be roughly 0.5%. Such uncertainties will have to be combined with the parametric uncertainties, in particular those associated to the bottom-quark mass and the strong gauge coupling, to arrive at the full theory uncertainty. A detailed treatment of the differential distributions for a Higgs boson decay into four charged leptons in the final state is discussed in Refs. [43,121].

The total width of a 125 GeV SM Higgs boson is $\Gamma_H = 4.07 \times 10^{-3}$ GeV, with a relative uncertainty of ${}^{+4.0\%}_{-3.9\%}$. The branching ratios for the most relevant decay modes of the SM Higgs boson as a function of m_H, including the most recent theoretical uncertainties, are shown in Fig. 11.2 (right) and listed for $m_H = 125$ GeV in Table 11.3. Further details of these calculations can be found in the reviews [41–44] and references therein.

11.3 The experimental profile of the Higgs boson

The observation [1, 2] at the LHC of a narrow resonance with a mass of about 125 GeV was an important landmark in the decades-long direct search [46, 122] for the SM Higgs boson. This was followed by a detailed exploration of properties of the Higgs boson at the different runs of the LHC at $\sqrt{s} = 7$, 8 and 13 TeV.

The dataset at $\sqrt{s}$ =13 TeV in the Run 2 phase of the LHC operation corresponds to an integrated luminosity of about 156 fb^{-1} see Table 11.4. The datasets effectively useful for analysis need to take into account the data-taking efficiency with fully operational detectors and the data quality efficiency. The typical total inefficiency for both ATLAS and CMS is approximately 10%, where approximately half is due to the data taking inefficiency and half from data quality.

In this section, most of the references for the Run 1 measurements that have been updated at the Run 2 are given in the previous version of this review [123] and are not repeated herein.

Table 11.4: The LHC *pp* collision centre-of-mass energies and delivered data samples.

Year	$\sqrt{s}$ (TeV)	$\int$ L.dt (fb^{-1})	Period
2010	7	0.04	Run 1
2011	7	6.1	Run 1
2012	8	23.3	Run 1
2015	13	4.2	Run 2
2016	13	40.8	Run 2
2017	13	50.2	Run 2
2018	13	60.6	Run 2

11.3.1 *The principal decay channels to vector bosons*

For a given m_H, the sensitivity of a channel depends on the production cross section of the Higgs boson, its decay branching fraction, the reconstructed mass resolution, the selection efficiency and the level of background in the final state. For a low-mass Higgs boson (110 GeV $< m_H <$ 150 GeV) for which the SM width would be only a few MeV, five decay channels play an important role at the LHC. In the $H \to \gamma\gamma$ and $H \to ZZ^* \to 4\ell$ channels, all final state particles can be very precisely measured and the reconstructed m_H resolution is excellent (typically 1-2%). While the $H \to W^+W^- \to \ell^+\nu_\ell \ell'^- \bar{\nu}_{\ell'}$ channel has relatively large branching fraction, however, due to the presence of neutrinos which are not reconstructed in the final state, the m_H resolution, obtained through observables sensitive to the Higgs boson mass such as the transverse mass, is poor (approximately 20%). The $H \to b\bar{b}$ and the $H \to \tau^+\tau^-$ channels suffer from large backgrounds and lead to an intermediate mass resolution of about 10% and 15% respectively.

With the increase in the size of datasets, measurements in the most sensitive channels are now carried out differentially or in exclusive modes depending on specific production characteristics. These measurements are discussed in Section 11.6.2.4.

The candidate events in each Higgs boson decay channel are split into several mutually exclusive categories (or event tags) based on the specific topological, kinematic or other features present in the event. The categorization of events increases the sensitivity of the overall analysis and allows a separation of different Higgs boson production processes. Most categories are dominated by signal from one Higgs boson decay mode but contain an admixture of various Higgs boson production processes. For example, a typical VBF selection requires Higgs boson candidates to be accompanied by two energetic jets (≥ 30 GeV) with a large dijet mass (≥ 400 GeV) and separated by a large pseudo-rapidity ($\Delta\eta_{jj} \geq 3.5$) [124]. While such a category is enriched in Higgs bosons produced via VBF, the contamination from the ggF production mechanism can be significant. Hence, a measurement of the signal rate in the VBF category does not imply a measurement of VBF production cross section since one cannot resolve the contamination from ggF. Simulations are used to determine the relative contributions of the various Higgs boson production modes in each specific categories.

An important difference between the Run 1 and Run 2 results, in particular when comparing signal strengths, and therefore in the measurement of the couplings of the Higgs boson as discussed in Section 11.4, is that values and errors of the predicted cross sections have been improved (mostly the scale and PDF uncertainties). The theoretical predictions are however compatible and therefore, the signal strengths can be compared on a sound basis.

11.3.1.1 $H \to \gamma\gamma$

In the $H \to \gamma\gamma$ channel, a search is performed for a narrow peak over a smoothly falling background in the invariant mass distribution of two high p_T photons. The background in this channel is conspicuous and stems from prompt $\gamma\gamma$ processes for the irreducible backgrounds, and the γ+jet and dijet processes for the reducible backgrounds where one jet fragments typically into a leading π^0. In order to optimise search sensitivity and also to separate the various Higgs boson production modes, ATLAS and CMS split events into several mutually exclusive categories. Diphoton events containing a high p_T muon or electron, or missing energy (E_T^{miss}) consistent with the decay of a W or Z boson, are tagged in the VH production category. Diphoton events containing energetic dijets with a large mass and pseudo-rapidity difference are assigned to the VBF production category, and the remaining events are considered either in the VH category when the two jets are compatible with the hadronic decay of a W or a Z, or in the ggF production category. While the leptonic VH category is relatively pure, the VBF category has significant contamination from the gluon fusion process. Events which are not picked by any of the above selections are further categorised according to their expected $m_{\gamma\gamma}$ resolution and signal-to-background ratio. Categories with good m_H resolution and larger signal-to-background ratio contribute most to the sensitivity of the search.

Both ATLAS and CMS have studied in detail the calibration of the energy response of photons, in particular using $Z \to e^+e^-$, $Z \to \mu^+\mu^-\gamma$ and the response of muons in the calorimeter (for ATLAS) from $Z \to \mu^+\mu^-$ events. This information is used to correct the simulated signal mass line-shapes. In each category, parametric signal models are adjusted to these line-shapes to provide a functional form for the signal. Simple monotonic functional forms of the backgrounds are determined by a fit to the $m_{\gamma\gamma}$ distribution in each category (typically exponential, Bernstein polynomials, Laurent series or power laws). All categories are fitted simultaneously to determine the signal yield at the measured combined Run 1 mass of 125.09$\pm$ GeV [127] discussed in Section 11.3.2. The $m_{\gamma\gamma}$ distribution after combining all categories is shown in Fig. 11.3, using the full ATLAS Run 2 dataset.

The signal strength, $\mu = (\sigma \cdot \text{BR})_{\text{obs}}/(\sigma \cdot \text{BR})_{\text{SM}}$, which is the observed product of the Higgs boson production cross section (σ) and its branching ratio (BR) normalised to the corresponding SM values, is 1.17 ± 0.27 for ATLAS in Run 1 and 1.02 ± 0.14 in Run 2 [128] (where this signal strength measurement is estimated from the measured fiducial cross sections and thus neglects acceptance systematic uncertainties, which are not expected to be dominant in particular given that the measurement is inclusive). The signal strengths [2] measured in Run 1 and Run 2 by the CMS collaboration are $1.18^{+0.26}_{-0.23}$ and $1.18^{+0.17}_{-0.14}$ [129] respectively.

11.3.1.2 $H \to ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$

In the $H \to ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ channel, a search is performed for a narrow mass peak over a small continuous background dominated by non-resonant ZZ^* production from $q\bar{q}$ annihilation and gg fusion processes. The contribution and the shape of this irreducible background is taken from simulation. The subdominant and reducible backgrounds stem from $Z+b\bar{b}$, $t\bar{t}$ and Z+jets events. Their contribution is suppressed by requirements on lepton isolation and lepton impact parameter and their yield is estimated from control samples in data.

To help to distinguish the Higgs boson signal from the dominant non-resonant ZZ^* background, both ATLAS and CMS [130] use a matrix element likelihood approach to construct a kinematic discriminant built for each 4ℓ event based on the ratio of complete leading-order matrix elements $|\mathcal{M}_{\text{sig}}{}^2/\mathcal{M}_{\text{bkg}}{}^2|$ for the signal ($gg \to H \to 4\ell$) and background ($q\bar{q} \to ZZ \to 4\ell$) hypotheses. To further enhance the sensitivity, experiments also use multivariate techniques.

To improve the sensitivity to more exclusive production processes such as VBF, VH and $t\bar{t}H$, the experiments divide 4ℓ events into mutually exclusive categories. Events are categorised in terms of the number of reconstructed jets, the number of additional leptons (from the decay of a vector boson in the associated production mode), number of jet tagged as containing a b-hadron, the transverse momentum of the Higgs boson (or e.g. its associated vector boson) and missing transverse momentum. The exclusive processes are also further separated in different kinematic regions in a framework referred to as Simplified Template Cross Sections (see Section 11.6.2.4). Dijets with a large mass and pseudo-rapidity difference populate the VBF category. ATLAS requires the presence of an additional lepton in the VH category. In events with less than two jets, CMS uses the $p_T^{4\ell}$ to distinguish between production via the gluon fusion and the VH/VBF processes.

Since the $m_{4\ell}$ resolutions and the reducible background levels are different in the 4μ, $4e$ and $2e2\mu$ sub-channels, they are analysed separately and the results are then combined. The distribution of the reconstructed invariant mass of the four leptons for CMS [126] is given in Fig. 11.3 (right), showing a clear excess at a mass of approximately $m_H = 125$ GeV. Both experiments also observe a clear peak at $m_{4\ell} = 91$ GeV from the production of a Z boson on-mass-shell and decaying to four leptons due typically to the emission of an off-shell photon from one of the primary leptons from the Z boson decay.

The signal strengths μ for the inclusive $H \to 4\ell$ production measured by ATLAS and CMS are $1.44^{+0.40}_{-0.33}$ at $m_H = 125.36$ GeV and $0.93^{+0.29}_{-0.25}$ at $m_H = 125.6$ GeV respectively, in Run 1. The signal strengths measured by ATLAS and CMS in Run 2 are 1.04 ± 0.10 [131] and 0.94 ± 0.10 [126] respectively (the ATLAS measurement is made at the combined Run 1 Higgs boson mass of $m_H = 125.09$ GeV while the m_H is profiled in the CMS analysis). The dominant uncertainty in these measurements remains the statistical uncertainty.

11.3.1.3 *Measurement of the Higgs boson mass*

To measure the mass of the Higgs boson, ATLAS and CMS collaborations rely on the two high mass-resolution and sensitive channels, $\gamma\gamma$ and $ZZ^*/4\ell$. The ATLAS and CMS approaches are very similar in these two analyses with small differences on the usage of categories, additional discriminating variables and per-event errors. In these two channels, the mass resolutions range from 1.4 GeV to 2 GeV for ATLAS and from 1.0 GeV to 2.8 GeV for CMS (see Ref. [127] and the reconstruction-performance references therein). The best mass resolution is obtained for both experiments in the diphoton channel for central diphoton pairs (typically for events where both photons are not converted). The signal strengths in the $\gamma\gamma$ and ZZ channels are assumed to be

[2] The Run 1 results for ATLAS and CMS are at fixed values of m_H = 125.4 GeV and 124.7 GeV, respectively.

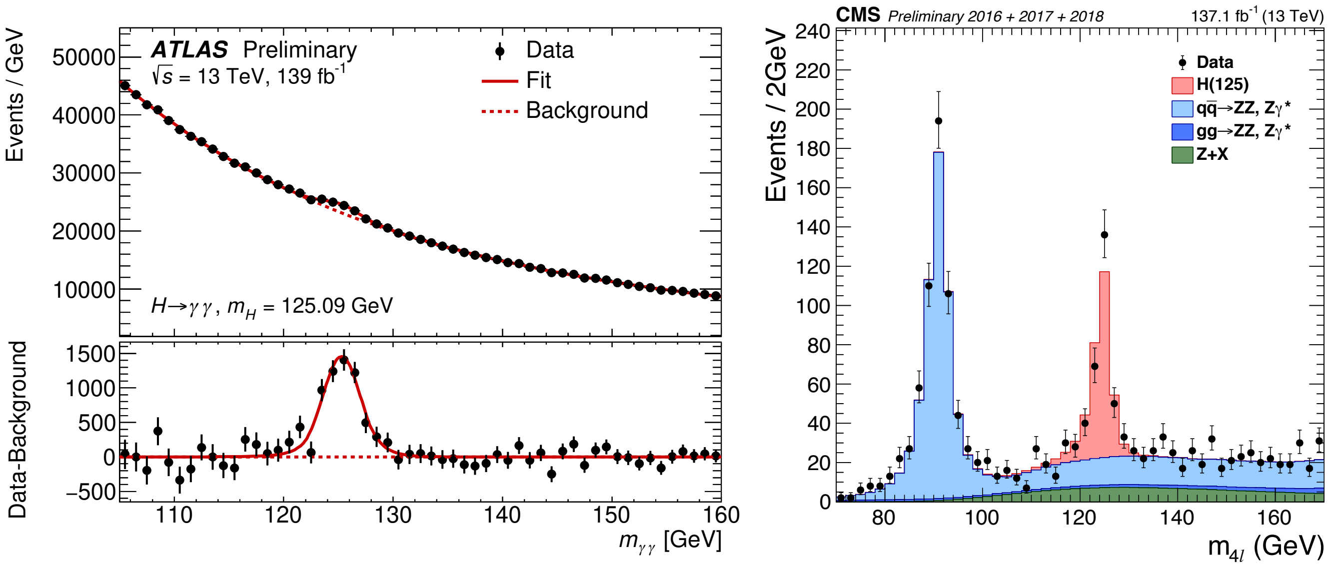

Figure 11.3: (Left) The invariant mass distribution of diphoton candidates, with each event weighted by the ratio of signal-to-background in each event category, observed by ATLAS [125] at Run 2. The residuals of the data with respect to the fitted background are displayed in the lower panel. (Right) The $m_{4\ell}$ distribution from CMS [126] Run 2 data.

independent and not constrained to the expected rate ($\mu = 1$) for the SM Higgs boson.

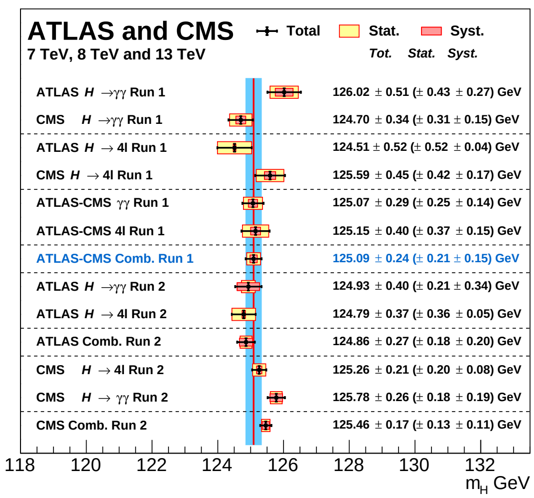

Figure 11.4: Summary of the CMS and ATLAS mass measurements in the $\gamma\gamma$ and ZZ channels in Run 1 and Run 2.

Figure 11.4 summarizes all measurements of the Higgs boson mass, including the individual and combined Run 1 measurements [127] and the Run 2 measurement by ATLAS [132] and CMS [130, 133] for both the diphoton and the 4ℓ channels.

In the diphoton channel, as discussed in Section 11.5.3.2, a mass shift is expected to be induced by the deformation of the mass line-shape of the signal in presence of background, from the interference between the Higgs boson production and the continuum irreducible background. It is a small but non negligible effect of approximately 35 MeV [134] for a Higgs boson width close to that of the SM. This effect could be larger if the width of the Higgs boson were to be substantially larger. This effect estimated by ATLAS with a full simulation is still relatively small with respect to the total uncertainty on the mass and is therefore neglected.

11.3.1.4 $H \to W^+W^- \to \ell^+\nu\ell^-\overline{\nu}$

In this intricate channel, experiments search for an excess of events with two leptons of opposite charge accompanied by missing energy and/or jets. A typical event selection is described below in order to give an idea of the main challenges. Specific selections vary between experiments and between Run 1 and Run 2 analyses. Events are divided into several categories depending on the lepton flavour combination (e^+e^-, $\mu^+\mu^-$and $e^\pm\mu^\mp$) and the number of accompanying jets ($N_{\rm jet} = 0, 1, \geq 2$). In the ATLAS analysis, the $N_{\rm jet} \geq 2$ category is optimised for the VBF production process by selecting two leading jets with a large pseudo-rapidity difference and with a large mass ($m_{jj} > 500$ GeV).

Backgrounds contributing to this channel are numerous and depend on the category of selected events. Reducing them and accurately estimating the remainder is a major challenge in this analysis. For events with opposite-flavour leptons and no accompanying high p_T jets, the dominant background stems from non-resonant WW production. Events with same-flavour leptons suffer from large Drell–Yan contamination (note that also the opposite-flavour leptons analysis has Drell–Yan $\tau\bar{\tau}$ background in 0-jet category). The $t\bar{t}$, tW and $W +$jets (with the jet misidentified as a lepton) events contaminate all categories. Non-resonant WZ, ZZ and $W\gamma$ processes also contribute to the background at a sub-leading level.

A requirement of large missing transverse energy ($E_T^{\rm miss}$) is used to reduce the Drell–Yan and multijet backgrounds. In the e^+e^- and $\mu^+\mu^-$ categories, events with $m_{\ell\ell}$ consistent with the Z mass are vetoed. The $t\bar{t}$ background is suppressed by a veto against identified b-jets or low p_T muons assumed to be coming from semi-leptonic b-hadron decays within jets (this soft muon veto was not applied anymore in Run 2 analysis) and tight isolation requirements diminish the W+jets background. The scalar nature of the Higgs boson and the $V - A$ nature of the W boson decay implies that the two charged leptons in the final state are preferentially emitted at small angles with respect to each other. Therefore the dilepton invariant mass ($m_{\ell\ell}$) and the azimuthal angle difference between the leptons ($\Delta\phi_{\ell\ell}$) are used to discriminate between the signal and non-resonant WW events [135]. The transverse mass, constructed from the dilepton p_T ($p_T^{\ell\ell}$), $E_T^{\rm miss}$ and the azimuthal angle between $E_T^{\rm miss}$ and $p_T^{\ell\ell}$, is defined as $m_T = \sqrt{2p_T^{\ell\ell}E_T^{\rm miss}(1 - \cos\Delta\phi_{E_T^{\rm miss}\ell\ell})}$ and serves as an effective discriminant against backgrounds. The transverse mass variable also tracks the Higgs boson mass but with a poor mass resolution. Background rates except for the small contributions typically from non-resonant WZ, ZZ and $W\gamma$ are evaluated from data control samples with floating normalisation.

ATLAS fitted the m_T distributions and observed an excess at $m_H = 125.36$ GeV with a local significance of 6.1σ similar to that expected from a 125 GeV SM Higgs boson. The measured inclusive signal strength is $\mu = 1.09^{+0.23}_{-0.21}$. In the VBF category, an excess with a significance of 3.2σ corresponding to a signal strength of $\mu = 1.27^{+0.53}_{-0.45}$ is observed. The CMS analysis of 0- and 1-jet categories, using all lepton flavour combinations, shows an excess with an observed significance of 4.3σ, lower than the expected sensitivity of 5.8σ for a 125.6 GeV SM Higgs boson. CMS observes no significant excess in the VBF production mode and sets a 95% CL limit on the signal strength of $\mu_{\rm VBF} < 1.7$ for $m_H = 125.6$ GeV.

ATLAS and CMS have also searched for the associated Higgs boson production in this channel. The signal consists of up to three (WH) or four (ZH) high p_T isolated leptons with missing transverse energy and low hadronic activity. The major backgrounds stem from triboson and diboson production where each boson decays leptonically. ATLAS observes [136] an excess at $m_H = 125.36$ GeV with a local significance of 2.5σ corresponding to a $\mu_{VH} = 3.0^{+1.6}_{-1.0}$. CMS instead sets a 95% CL limit of $\mu_{VH} < 4.7$.

In this difficult channel, the full Run 2 dataset has not yet been analysed by ATLAS nor CMS. There have been partial analyses made with Run 2 data at 13 TeV by both ATLAS and CMS. ATLAS has analysed the $WW \to e\nu\mu\nu$ decay mode in the gluon fusion, the VBF and VH production modes with 2015 and 2016 datasets [137,138]. With this limited dataset the measured gluon fusion signal strength yielded [138] $\mu_{\rm ggF} = 1.10 \pm 0.20$, with the largest uncertainties being the experimental systematic uncertainties.

CMS has performed a more complete analysis with the full 2016 dataset, with most production channels covering both the opposite- and same-flavour final states of opposite charge leptons (electrons or muons), obtaining a combined signal strength of $\mu_{\rm WW} = 1.28 \pm 0.18$ [139]. This analysis aims at several production modes (ggF, VBF and VH – with the vector boson reconstructed both in jet and leptonic decay modes).

11.3.2 *Decays to third generation fermions ($b\bar{b}$ and $\tau^+\tau^-$)*

In the SM, fermions acquire a mass through gauge invariant interactions with the Higgs field which is also responsible for the electroweak symmetry breaking and thus for generating the masses of gauge bosons (see Section 11.2 for more details). While this minimal solution is very elegant, there is no fundamental reason for it to be the case, and probing the couplings of the Higgs boson to fermions is therefore of fundamental importance, in particular since BSM physics can largely change the SM predictions.

The discovery of the Higgs boson was made essentially through bosonic final states. These decays probed mostly the couplings of the Higgs boson to vector bosons (the decay of the Higgs boson to photons occurring only through loops is also dominated in the SM by the coupling of the Higgs boson to W bosons). However, the predominant Higgs boson production mode is the gluon fusion, occurring only through loops dominated by the coupling of the Higgs boson to fermions. The observation of the Higgs boson in the two photons or two gluons decay modes is also an indirect evidence for the coupling of the Higgs boson to fermions (and in particular to the top quark). Nevertheless, the observation of either decays to fermions or production modes which unambiguously proceed through fermion couplings provide direct probes of the coupling of the Higgs boson to fermions and is thus of fundamental importance.

At hadron colliders, the most promising channel for probing the coupling of the Higgs field to the quarks and leptons are $H \to b\bar{b}$ and $H \to \tau^+\tau^-$, respectively. For a Higgs boson with $m_H \approx 125$ GeV, the branching fraction to $b\bar{b}$ is about 58% and to $\tau^+\tau^-$ is about 6%. Nevertheless, the presence of very large backgrounds makes the isolation of a Higgs boson signal in these channels quite challenging.

One of the most prominent goals of the LHC Run 2 for ATLAS and CMS was the direct observation of the Yukawa coupling of the Higgs boson to fermions of the third generation (bottom quarks, tau leptons and top quarks). This goal has been reached independently by both ATLAS and CMS and with only partial Run 2 datasets.

11.3.2.1 $H \to \tau^+\tau^-$

In the $H \to \tau^+\tau^-$ search, τ leptons decaying to electrons (τ_e), muons (τ_μ) and hadrons (τ_{had}) are considered. The $\tau^+\tau^-$ invariant mass ($m_{\tau\tau}$) is reconstructed from a kinematic fit of the visible products from the two τ leptons and the missing energy observed in the event. Due to the presence of missing neutrinos, the $m_{\tau\tau}$ resolution is poor ($\approx 15\%$). As a result, a broad excess over the expected background in the $m_{\tau\tau}$ distribution is searched for. The major sources of background stem from Drell–Yan $Z \to \tau^+\tau^-$ and $Z \to e^+e^-$, W+jets, $t\bar{t}$ and multijet production. Events in all sub-channels are divided into categories based on the number and kinematic properties of additional energetic jets in the event and the transverse momentum of the reconstructed Higgs boson and the distance ΔR distance between the two τ's. The sensitivity of the search is generally higher for categories with one or more additional jets. The VBF category, consisting of a τ pair with two energetic jets separated by a large pseudo-rapidity, has the best signal-to-background ratio and search sensitivity, followed by the $\tau^+\tau^-$+1 jet category. The signal to background discrimination relies in part on the $m_{\tau\tau}$ resolution, which improves with the boost of the Higgs boson. The non-VBF categories are further subdivided according to the observed boost of the $\tau^+\tau^-$ system. CMS primarily uses the reconstructed $m_{\tau\tau}$ as the final discriminating variable while ATLAS combines various kinematic properties of each event categories with multivariate techniques to build the final discriminant [140].

Searches for $H \to \tau^+\tau^-$ decays in the VH production mode are also performed in final states where the W or Z boson decays into leptons or jets. The irreducible background in this search arises from non-resonant WZ and ZZ diboson production. The reducible backgrounds originate from W, Z, and $t\bar{t}$ events that contain at least one fake lepton in the final state due to a misidentified jet. The shape and yield of the major backgrounds in each category are estimated from control samples in data. Contributions from non-resonant WZ and ZZ diboson production are estimated from simulations but corrected for reconstruction efficiency using control samples formed from observed data.

For CMS, the significance of the observed excess at $m_H = 125$ GeV in Run 1 is 3.2σ, close to the expected 3.7σ sensitivity, and corresponds to a signal strength of $\mu = 0.86 \pm 0.29$. The observed (expected) deviation from the background-only hypothesis in ATLAS corresponds to a local significance of 4.5σ (3.4σ) and the best fit value of the signal strength is $\mu = 1.43^{+0.43}_{-0.37}$ [140].

When the ATLAS and CMS $H \to \tau\tau$ Run 1 measurements are combined [141], the significance of the observed excess corresponding to $m_H = 125.09$ GeV is 5.5σ and the combined signal strength is $\mu = 1.11^{+0.24}_{-0.22}$, consistent with the SM expectation.

The Run 1 evidence was strong only through the combination of the two experiments. The Run 2 larger dataset at a greater centre-of-mass energy is essential to further confirm this observation and perform first precision measurements in this important channel.

ATLAS has analysed its 2015 and 2016 dataset so far, providing further evidence at the 4.4σ level with an expected significance of 4.1σ. When combined with the Run 1 data the single experiment observation significance is 6.4σ (5.4σ expected) [142].

In the CMS analysis of the 2016 data [143], the strategy was improved using additional categories aiming at the inclusive production of the Higgs boson and binned in transverse momentum of the $\tau^+\tau^-$ system, and for the VBF production, the analysis is binned as a function of the dijet mass. This analysis reached a sensitivity of 4.7σ with a dataset corresponding to an integrated luminosity of 35.9 fb^{-1}. CMS observes an excess with a significance of 4.9σ. In combination with the Run 1 results, this provides an unambiguous observation of the direct coupling of the Higgs boson to taus, in the VBF production mode.

CMS has then also extended to additional production modes via the associated production with a vector boson [144] and analysed a larger dataset corresponding to an integrated luminosity of almost 80 fb^{-1} of data collected in 2016 and 2017, providing results which complete the Run 1 search for an unambiguous observation of the direct decay of the Higgs bosons to a pair of taus (and measurements of cross sections times branching-fractions) [145].

11.3.2.2 $H \to b\bar{b}$

In the search for the decay of the Higgs boson to a pair of b-quarks, the most sensitive production modes are the associated WH and ZH processes allowing use of the leptonic W and Z decays for triggering, and to purify the signal and reject QCD backgrounds. The W bosons are reconstructed via their leptonic decay $W \to \ell\bar{\nu}_\ell$ where $\ell = e, \mu$ or τ. The Z bosons are reconstructed via their decay into $e^+e^-, \mu^+\mu^-$or $\nu\bar{\nu}$. The Higgs boson candidate mass is reconstructed from two b-tagged jets in the event. Backgrounds arise from production of W and Z bosons in association with gluon, light and heavy-flavoured jets (V+jets), $t\bar{t}$, diboson (ZZ and WZ with $Z \to b\bar{b}$) and QCD multi-jet processes. Due to the limited $m_{b\bar{b}}$ mass resolution, a SM Higgs boson signal is expected to appear as a broad enhancement in the reconstructed dijet mass distribution. The crucial elements in this search are b-jet tagging with high efficiency and low fake rate, accurate estimate of b-jet momentum and estimate of backgrounds from various signal depleted control samples constructed from data.

At the Tevatron, the $H \to b\bar{b}$ channel contributes the majority of the Higgs boson search sensitivity below $m_H = 130$ GeV. To separate signal from background, CDF and D0 use multivariate analysis (MVA) techniques that combine several discriminating variables into a single final discriminant. Each channel is divided into exclusive sub-channels according to various lepton, jet multiplicity, and b-tagging characteristics in order to group events with similar signal-to-background ratio and thus optimise the overall search sensitivity. The combined CDF and D0 data show [46,146] an excess of events with respect to the predicted background in the 115–140 GeV mass range in the most sensitive bins of the discriminant distributions suggesting the potential presence of a signal. At $m_H = 125$ GeV, the observed signal strength is $\mu = 1.59^{+0.69}_{-0.72}$.

At the LHC, in order to reduce the dominant V+jets background, following Ref. [90], experiments select a region in the VH production phase space where the vector boson is significantly boosted and recoils from the $H \to b\bar{b}$ candidate with a large azimuthal angle $\Delta\phi_{VH}$. For each channel, events are categorised into different $p_T(V)$ regions with varying signal/background ratios. Events with higher $p_T(V)$ have smaller backgrounds and better $m_{b\bar{b}}$ resolution. CMS uses MVA classifiers based on kinematic, topological and quality of b-jet tagging and trained on different values of m_H to separate Higgs boson signal in each category from backgrounds. The MVA outputs for all categories are then fit simultaneously.

The nominal results from ATLAS are also based on a combination of (i) a multivariate analysis of their 8 TeV data, incorporating various kinematic variables in addition to $m_{b\bar{b}}$ and b-tagging information and (ii) a statistical analysis of their 7 TeV data centred on $m_{b\bar{b}}$ as the main discriminant. In both cases, customised control samples devised from data are used to constrain the contributions of the dominant background processes.

The direct observation of the Higgs boson decaying to a pair of b-quarks, a major result of Run 2, was obtained by both ATLAS and CMS independently after the update of their search with similar analyses as those performed at Run 1 but with a larger dataset of approximately 80 fb^{-1} of data collected in 2015, 2016 and 2017. The increase in signal cross sections of nearly a factor of 3 at the centre-of-mass energy of 13 TeV with respect to 7 TeV, has also been instrumental in bringing the two experiments to the required sensitivity to claim an evidence for this decay mode in the VH production mode (in the high transverse momentum of the vector boson fiducial region of interest for this channel). The expected significance for a SM Higgs boson is 4.3σ for ATLAS [147] and 4.9σ for CMS [148]. Both ATLAS and CMS observe significant excesses corresponding to 4.9σ and 4.8σ respectively with Run 2 data only. When combined with results obtained in Run 1, the observed (expected) significance of the excesses are 5.4σ (5.5σ) and 5.6σ (5.5σ) respectively. These results provide direct evidence for the Higgs boson decay to a $b\bar{b}$ through the VH production mode. All these results are summarised in Table 11.5. It should be noted that the sensitivity of these analyses are already limited by systematic uncertainties.

This channel has also been exploited by ATLAS to produce a measurement at higher transverse momentum of the vector boson in the framework of Simplified Template Cross Sections (STXS) discussed in Section 11.6.2.4 [149]. In this case, at higher transverse momentum, the statistical uncertainty still dominates.

Also, the LHCb collaboration has performed a search for the VH production with subsequent decay of the Higgs boson to a pair of b-quarks [150] with 1.98 fb^{-1} of data taken at a centre-of-mass energy of 8 TeV. The final state is required to have two reconstructed b quarks and one lepton in the LHCb acceptance of $2 < \eta < 5$. The sensitivity of this search is an expected 95% CL exclusion of 84 times the SM production rate. This analysis is also used to set a limit on the VH production with the subsequent decay of the Higgs boson in a pair of c quarks with a 95% CL limit at 6.4×10^3 times the SM production rate, while the expected sensitivity corresponds to an exclusion of 7.9×10^3 times the SM production rate.

ATLAS and CMS have also searched for $H \to b\bar{b}$ in the VBF production mode. The event topology consists of two VBF-tagging energetic light-quark jets in the forward and backward direction relative to the beam direction and two b-tagged jets in the central region of the detector. Due to the electroweak nature of the process, for the signal events, no additional energetic jet activity (excluding that from the Higgs boson) is expected in the rapidity gap between the two VBF-tagging jets. The dominant background in this search stems from QCD production of multi-jet events and the hadronic decays of vector bosons accompanied by additional jets. A contribution of Higgs boson events produced in the ggF process but with two or more associated jets is expected in the signal sample. The signal is expected as a broad enhancement in the $m_{b\bar{b}}$ distribution over the smoothly falling contribution from the SM background processes. Both ATLAS [151] and CMS [152] have produced results in this channel with Run 1 data, but with limited sensitivity. Both experiments performed a similar analysis with Run 2 data [153]. The results are summarised in Table 11.5.

Two of the main difficulties for the VBF production mode are the large QCD background and the difficulty in triggering events fully hadronic events. Both difficulties are addressed, by the proposal made in Ref. [154], where the requirement of an additional photon in the final state reduces the background through an interference effect and enhances the possibilities for triggering. This analysis has been carried out by ATLAS at Run 2 [153] (see Table 11.5).

The sensitivity in the inclusive search for the Higgs boson in the ggF production mode with $H \to b\bar{b}$ is limited by the overwhelming background from the inclusive production of $pp \to b\bar{b} + X$ via the strong interaction. For this reason, no meaningful results exist with the Run 1 dataset for this production mode. With the increase in centre-of-mass energy to 13 TeV, and by taking advantage of the harder transverse momentum spectrum of the $gg \to H$ production mode with respect to the QCD background, a search for high p_T Higgs boson decaying to a pair of b quarks in association with an energetic Initial State Radiation (ISR) jet, has been performed by ATLAS [155] and CMS [156]. For this analysis with the Run 2 data, ATLAS and CMS require jets clustered with the anti-k_T algorithm [157] with a distance parameter of 1.0 and 0.8 respectively, with a transverse momentum in excess of 480 GeV and 450 GeV respectively. As in the case of VH production mode, this analysis is sensitive also to the $VZ, Z \to b\bar{b}$ production, which is an important step in the validation of the analysis chain. The $Z \to b\bar{b}$ decay is observed with a significance of 5.8σ, in good agreement with the expected sensitivity of 5.1σ. CMS provides an expected sensitivity to the observation of a Higgs boson of 0.7σ. This estimate has a non negligible uncertainty from the precise estimate of the fiducial signal cross section in the specific acceptance of this analysis. Both ATLAS and CMS observe small and non significant excesses at $m_H = 125$ GeV of 1.6σ and 1.5σ respectively. These results are reported in Table 11.5.

Another important production mode sensitive to the decay of the Higgs boson to bottom quarks, is the associated production with a pair of top quarks. The results of the searches for this process have been combined with the channels described above, to provide an additional constraint on the Yukawa coupling of

Table 11.5: Summary of the results of measurements for a Higgs boson decaying to a pair of b-quarks by ATLAS and CMS. The results are given in terms of measured signal strength. When available, the statistical and systematic contributions to the total uncertainty are reported separately and in this order.

$H \to b\bar{b}$	Tevatron	ATLAS Run 1	CMS Run 1	ATLAS Run 2	CMS Run 2
VH	1.6 ± 0.7	$0.52 \pm 0.32 \pm 0.24$	1.0 ± 0.5	$1.16 \pm 0.16\,^{+0.21}_{-0.19}$	1.01 ± 0.22
VBF (γ)	—	-0.8 ± 2.3	$2.8 \pm 1.4 \pm 0.8$	2.5 ± 1.3	1.3 ± 1.2

the Higgs boson to bottom quarks. The channels corresponding to this production mode are described in Section 11.3.3. The results are, however, also reported in Table 11.5.

11.3.3 *Higgs boson production in association with top quarks or in top decays*

11.3.3.1 *The associated production with top quark pairs*

As discussed in Section 11.2, the coupling of the Higgs boson to top quarks plays a special role in the electroweak symmetry breaking mechanism in the SM, as well as in its possible extensions. Substantial indirect evidence of this coupling is provided by the compatibility of observed rates of the Higgs boson in the principal discovery channels, given that the main production process – the gluon fusion – is dominated by a top quark loop. Direct evidence of this coupling at the LHC and the future e^+e^- colliders will be mainly available through the $t\bar{t}H$ final state and will permit a clean measurement of the top quark-Higgs boson Yukawa coupling. The $t\bar{t}H$ production cross section at the LHC is small in comparison with the ggF or even VH production modes. The production cross section for a 125 GeV Higgs boson in pp collisions at $\sqrt{s} = 8$ TeV of about 130 fb made it challenging to measure the $t\bar{t}H$ process with the LHC Run 1 dataset. However, in Run 2, the increase in cross section at $\sqrt{s} = 13$ TeV is substantial, reaching approximately 500 fb. For a sensitive search, at Run 1, it was important to target as many accessible experimental signatures as possible. The analysis channels for such complex final states can be separated in four classes according to the decays of the Higgs boson. In each of these classes, most of the decay final states of the top quarks are considered (fully hadronic, semi-leptonic and dilepton decay final states).

The first analysis in this ensemble is the search for $t\bar{t}H$ production in the $H \to \gamma\gamma$ channel. This analysis relies on the search for a narrow mass peak in the $m_{\gamma\gamma}$ distribution. The background is estimated from the $m_{\gamma\gamma}$ sidebands. The sensitivity in this channel is mostly limited by the available statistics. The second analysis is the search for the Higgs boson decaying to ZZ^* and subsequently to four leptons (electrons and/or muons). This channel is currently limited by the low statistics due to the small branching fraction of the Z decays to leptons. The third analysis is the search in the $H \to b\bar{b}$ channel. This search is intricate due to the large backgrounds, both physical and combinatorial in resolving the $b\bar{b}$ system from the Higgs boson decay, in events with six jets and four b-tagged jets. Already with the Run 1 dataset, the sensitivity of this analysis was strongly impacted by the systematic uncertainties on the background predictions. The fourth analysis channel is a specific search for $\tau^+\tau^-$ where the two tau leptons decay to hadrons. Finally, the W^+W^- , $\tau^+\tau^-$ and ZZ^* final states can be searched for inclusively in multilepton event topologies (not including the resonant $H \to 4\ell$ channel that is covered in a more specific analysis). The corresponding $t\bar{t}H$ modes can be decomposed in terms of the decays of the Higgs boson and those of the top quarks as having two b-quarks and four W bosons (or two W and two taus, or two W and two Z) in the final state.

ATLAS and CMS have provided a complete set of results in these channels and their combination with the Run 1 data [158, 159]. Results for most of these channels have been updated with Run 2 data.

With the large increase in production cross section for the $t\bar{t}H$ associated production process of a factor of 3.9 from 7 TeV to 13 TeV, an outstanding goal of the Run 2 physics program was the direct observation of the top Yukawa coupling through this production mode. As could be seen in the Run 1 results, the $H \to b\bar{b}$ channel sensitivity was already dominated by systematic uncertainties and the multilepton channel had already large systematic uncertainties, while channels such as the $H \to \gamma\gamma$ had very limited sensitivity due to the low statistics. With a conspicuous amount of data, the hierarchy of channels was therefore bound to change.

ATLAS and CMS have analysed Run 2 data in all the sensitive decay channels for this production mode, with datasets of variable size of up to the full Run 2 dataset in the case where it matters the most, i.e., the $t\bar{t}(H \to \gamma\gamma)$ channel. With this partial analysis of the Run 2 data, ATLAS and CMS were able to independently observe the production of the Higgs boson in association with a pair of top quarks, and therefore the Yukawa coupling of the Higgs boson to the top quark [160]. This observation is particularly important in comparison to the indirect evidence through the gluon fusion production process dominated by the top quark loop.

The observation made independently by the two experiments was based on all the channels that were studied at the Run 1. ATLAS used up to 79.8 fb^{-1} of Run 2 data and CMS has used its 2016 dataset of 35.9 fb^{-1}. ATLAS reached an expected sensitivity of 4.9σ and an observed significance of 5.8σ with the Run 2 partial dataset alone, and 6.3σ (with 5.1σ expected) in combination with the Run 1 results. CMS reached a sensitivity of 4.2σ and observed an excess with respect to the background-only hypothesis of 5.2σ, combining the Run 1 and Run 2 results.

With the larger Run 2 dataset, the dominant mode is the $t\bar{t}(H \to \gamma\gamma)$ channel, where a narrow peak over a continuous background is searched for. At Run 2, this channel has reached a signal-to-background ratio in excess of 1 in the most signal-like categories. This is in contrast with the inclusive diphoton channel Higgs channels where the signal-to-background ratios are of the order of a few percent. ATLAS has analysed the entire Run 2 dataset reaching an observed (expected) sensitivity of 4.9σ (4.2σ) [161] and CMS has utilised 77.4 fb^{-1} of Run 2 data for this channel with an observed (expected) sensitivity of 4.1σ (2.7σ) [162], providing nearly unambiguous observations in this channel alone. These results are largely dominated by statistical uncertainty and are therefore expected to improve significantly with more data. These results with the full dataset from ATLAS [161] and with a larger Run 2 dataset for CMS [162] are not part of the ATLAS and CMS combinations and therefore provide substantially more evidence for the direct coupling of the Higgs boson to the top quark.

The resonant search for the resonant Higgs boson decay to four leptons in the associated production with a pair of top quarks has also been updated in ATLAS [131] with the full Run 2 dataset and reported in Table 11.6, but it is also not included in the combination.

An update of the $H \to b\bar{b}$ channel made by CMS with a partial Run 2 dataset of 41.5 fb^{-1} [163], using in particular the fully hadronic channel, is not in combination either. It is nevertheless reported in Table 11.5.

For the so-called "multi-lepton" channels which cover mostly the WW, ZZ and $\tau\tau$ decay modes, ATLAS and CMS have analysed only part of the Run 2 datasets [164].

All results are summarized in Table 11.6.

11.3.3.2 *The associated production with a single top quark*

An additional production mode of the Higgs boson in association with a top quark is the single top associated production mode. There is an interesting similarity between this production mode and the $H \to \gamma\gamma$ decay mode. Both processes proceed through either the top Yukawa coupling or the interaction of the Higgs boson with the W boson, with a negative interference between the two. Representative Feynman diagrams for this production process are shown in Fig. 11.1. Contrary to the diphoton decay channel, in this production mode the interference occurs at the tree level and is dominant. This process can therefore be used to further discriminate a negative relative sign between the couplings of the Higgs boson to fermions and its couplings to gauge bosons [165].

ATLAS and CMS have produced specific searches for the tH production mode with the Run 1 and Run 2 data exploiting a variety of Higgs boson decay modes resulting in final states with photons, bottom quarks, and multiple charged leptons, including tau leptons. In particular, with the Run 2 data, CMS has searched for multi-leptonic decay signatures from the $H \to WW^*$, $H \to \tau^+\tau^-$ and $H \to ZZ^*$ modes [166]. This analysis restricts values of κ_t, the top-Higgs coupling normalized to its SM value, to $[-1.25, 1.60]$ at 95% CL. CMS has also performed an analysis of the 2015 dataset to search for the $H \to b\bar{b}$ mode [167], yielding much less stringent constraints.

The diphoton channel has also been used to search specifically for this production mode by ATLAS using Run 1 data, yielding the restricted range of allowed values of κ_t at the 95% CL to $[-1.3, 8]$.

The strongest constraint on the negative (relative) sign of κ_t was obtained by CMS with a recent analysis of the 2016 dataset [168] in the multilepton ($H \to WW$, $H \to ZZ$, $H \to \tau\tau$) and $H \to bb$ channels, all combined with a reinterpretation of the $H \to \gamma\gamma$ analysis channel aiming at measuring the $pp \to t\bar{t}H$ production mode. Negative values of κ_t are disfavoured at approximately 1.5σ and values of κ_t below -0.9 are excluded at 95% CL.

11.3.3.3 *Flavour changing neutral current decays of the top quark*

The discovery of the Higgs boson at a mass smaller than the top quark mass opened a new decay channel for the top quark. The decays of the top quark to a Higgs boson and a charm or an up quark proceed through a Flavour Changing Neutral Current (FCNC) which are forbidden at tree level and suppressed at higher orders through the Glashow–Iliopoulos–Maiani (GIM) mechanism [3]. The SM prediction for these branching fractions is $\mathrm{BR}(t \to Hc) = 10^{-15}$ and two orders of magnitude less for the Hu final state. These decay channels of the top quark are, therefore, very interesting to probe possible FCNC interactions in the Yukawa couplings to the quark sector, see Section 11.7.

ATLAS has searched for FCNC top decays specifically in channels involving a Higgs boson with subsequent decays to two photons and a pair of b-quarks [169]. It has also reinterpreted a search for the $t\bar{t}H$ production in the multilepton final state (discussed in Section 11.3.6.1) [159]. The latter channel covers Higgs boson decays to a pair of W bosons and a pair of taus. No significant excess was observed in any of the specific channels (as discussed in Section 11.3.6.1, a slight excess is observed in the $t\bar{t}H$ multilepton channel) and 95% CL upper limits are set on $\mathrm{BR}(t \to Hc) < 0.46\%$ with an expected sensitivity of 0.25% and $\mathrm{BR}(t \to Hu) < 0.45\%$ with an expected sensitivity of 0.29%. CMS has performed a search for these FCNC top decays in the diphoton and multi-lepton channels [170], placing a 95% CL upper limit on $\mathrm{BR}(t \to Hc) < 0.40\%$ with an expected sensitivity of 0.43%.

From these limits on branching fractions, constraints on non-flavour-diagonal Yukawa couplings of a FCNC Lagrangian of the form:

$$\mathcal{L}_{\mathrm{FCNC}} = \lambda_{tcH}\bar{t}Hc + \lambda_{tuH}\bar{t}Hu + h.c. \tag{11.12}$$

can be derived. The 95% CL observed (expected) upper limits from ATLAS on the $|\lambda_{tcH}|$ and $|\lambda_{tuH}|$ couplings are 0.13 (0.10) and 0.13 (0.10), respectively.

The results above are derived from the combination of several channels for searches performed with Run 1 data. Both ATLAS and CMS have produced updates of individual channels with Run 2 data. ATLAS has searched for FCNC top decays with subsequent decays of the Higgs boson to a pair of photons [171], yielding a 95% CL upper limit on $\mathrm{BR}(t \to Hc) < 0.22\%$ with an expected sensitivity of 0.16%. CMS has searched for FCNC top decays with subsequent decays of the Higgs boson to a pair of b-quarks [172], yiedling a 95% CL upper limit on $\mathrm{BR}(t \to Hc) < 0.47\%$ with an expected sensitivity of 0.44%.

11.3.4 *Higgs boson pair production*

Higgs boson pair production in the SM is a rare but very important mode to measure and search for. The measurement of Higgs boson pair production is essential to directly constrain the trilinear Higgs boson self coupling and the search for Higgs boson pair resonances is key in a variety of BSM models. The latter searches are discussed in Section 11.7.7.

In the SM, the main non-resonant production mode of two Higgs bosons proceeds through a loop, mainly of top quarks, see Fig. 11.5 (a). Another production mode is via the trilinear coupling of the Higgs boson, see Fig. 11.5 (b), whose amplitude is not negligible compared to the former. These diagrams interfere negatively, making the overall production rate smaller than what would be expected in the absence of a trilinear coupling.

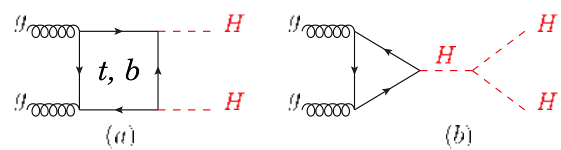

Figure 11.5: Feynman diagrams contributing at leading order to Higgs boson pair production through (a) a top- and bottom-quark loop and (b) through the self coupling of the Higgs boson.

11.3.4.1 *Searches for Higgs boson pair production*

The searches for Higgs boson pair production both resonant and non-resonant are very interesting probes for a variety of BSM theories, and they can be done in a large number of Higgs boson decay channels. At Run 1, ATLAS and CMS have searched for both resonant and non resonant Higgs boson pair production in the following channels: (i) $HH \to b\bar{b}\gamma\gamma$; (ii) $HH \to b\bar{b}\tau^+\tau^-$; (iii) $HH \to b\bar{b}b\bar{b}$; (iv) $HH \to WW^*\gamma\gamma$; (v) in final states containing multiple leptons (electrons or muons) covering the WW^*WW^*, WW^*ZZ^*, ZZ^*ZZ^*, $ZZ^*\tau^+\tau^-$, $WW^*\tau^+\tau^-$, $ZZ^*b\bar{b}$, $\tau^+\tau^-\tau^+\tau^-$ channels; and (vi) $\gamma\gamma\tau^+\tau^-$ channels.

At Run 2, similarly to the $t\bar{t}H$ production process, the di-Higgs production gains a substantial increase in production cross section of a factor in excess of 3 from 8 TeV to 13 TeV, and most of these channels have been updated both by ATLAS [173] and CMS [174] using the 2016 datasets with the addition of the (vii) $HH \to b\bar{b}b\bar{b}$ channels. The detailed description of the analyses can be found in references within the combination results published by the collaborations [173, 174]. All the results and their combinations are summarised in Table 11.7.

11.3.4.2 *The Higgs boson self coupling*

The Higgs boson self coupling is an extremely important direct probe of the Higgs potential with implications on our understanding of the electroweak phase transition. Constraints on the trilinear self coupling from HH processes is an outstanding long term goal of the LHC and the reach in sensitivity has been reappraised in the light of the recent HH analyses from ATLAS and CMS, shedding a different light on the achievable sensitivity [104]. Constraints from the HHH final state on the quartic Higgs boson self coupling are out of reach at the LHC due mostly to the very small production rates and intricate final states.

In the SM, the Higgs boson pair production through the trilinear Higgs boson self coupling has an on-shell component and a large off-shell component. The on-shell $H \to H^*H^*$ is strongly disfavoured, requiring two off-shell Higgs bosons in the final state.

Table 11.6: Summary of the results of searches for a Higgs boson in association with a top quark pair by ATLAS and CMS. The results are given in terms of a measured signal strength. When available, the statistical and systematic contributions to the total uncertainty are reported separately and in this order. The ATLAS [161] and CMS [162] diphoton results indicated by (∗) are not included in the overall combinations which include versions of the diphoton analyses with smaller Run 2 datasets. The combination includes the $t\bar{t}(H \to b\bar{b})$ channels reported in Table 11.5.

$t\bar{t}H$	ATLAS Run 1	CMS Run 1	ATLAS Run 2	CMS Run 2
$H \to \gamma\gamma$	$1.3\ ^{+2.6}_{-1.7}\ ^{+2.5}_{-1.7}$	$1.2\ ^{+2.5}_{-1.7}\ ^{+2.6}_{-1.8}$	$1.38\ ^{+0.33}_{-0.31}\ ^{+0.26}_{-0.18}$ (∗)	$2.27^{+0.86}_{-0.74}$ (∗)
$H \to 4\ell$	—	—	$1.2\ ^{+1.4}_{-0.8}$ (∗)	0.0 ± 1.2 (∗)
$WW/\tau\tau/ZZ$	$1.4\ \pm 0.6\ \pm 1.0$	3.3 ± 1.4	$1.56\ ^{+0.30}_{-0.29}\ ^{+0.30}_{-0.27}$	$0.96\ ^{+0.34}_{-0.31}$
Comb.	$1.7\ \pm 0.5\ \pm 0.8$	$2.6\ ^{+1.0}_{-0.9}$	$1.32\ \pm 0.18\ ^{+0.21}_{-0.19}$	$1.49\ \pm 0.16\ ^{+0.27}_{-0.21}$

Table 11.7: Summary of the final states investigated in the search for Higgs boson pair production by ATLAS and CMS, most analyses make use of the 2016 Run 2 dataset corresponding to integrated luminosities of up to 36 fb^{-1}. For ATLAS, the result indicated by (*) uses mostly the $b\bar{b}W^+W^-$ channel. Results are 95% CL upper limits on the observed (expected) SM signal strengths.

Channel	ATLAS	CMS
$b\bar{b}\gamma\gamma$	20.3 (26)	23.6 (18.8)
$b\bar{b}b\bar{b}$	12.9 (21)	74.6 (36.9)
$b\bar{b}\tau^+\tau^-$	12.5 (15)	31.4 (25.1)
$W^+W^-W^+W^-$	160 (120)	–
$W^+W^-\gamma\gamma$	230 (170)	–
$b\bar{b}VV$	305 (305)*	79 (89)
Combination	6.9 (10)	22.2 (12.8)

The sensitivity region to the trilinear coupling production as in Fig. 11.5 (b), is mainly in the kinematic region where the two Higgs boson in the final state are on-shell and the Higgs boson acts as a propagator (off-shell). As discussed in the introduction to this section, this process interferes negatively with the background Higgs boson pair production (Fig. 11.5 (a)).

The measurement of the trilinear coupling requires separating the contributions of the diagram of Fig. 11.5 (b) from the box diagram of Fig. 11.5 (b), and therefore a precise knowledge of the top-Yukawa coupling is needed. Each diagram alone would produce rather distinct m_{HH} distribution. And, for values of the trilinear coupling close to the SM value, an additional discriminating feature of the signal with respect to one obtained with the box contribution alone is a deficit in the number of events. With large variations of the trilinear coupling, an excess of events over the SM prediction would be observed (for a value of the trilinear coupling about 6 times larger than its SM value, the number of events is equal to the SM expectation). Additional sensitivity to the trilinear coupling is also obtained from the kinematical distributions of the signal taking in particular into account the effect of the HH mass distribution which discriminates the main contributions of Fig. 11.5. This further discrimination is instrumental in resolving the degeneracy in the total cross section mentioned above. The bounds obtained by ATLAS [173] and CMS [174] are the following:

$$\begin{aligned} &(\text{ATLAS}) \; -5.0 < \kappa_\lambda < 12.0\,(\text{observed}), \\ &\qquad\quad -5.8 < \kappa_\lambda < 12.0\,(\text{expected}), \\ &(\text{CMS}) \; -11.8 < \kappa_\lambda < 18.8\,(\text{observed}), \\ &\qquad\quad -7.1 < \kappa_\lambda < 13.6\,(\text{expected}), \end{aligned} \tag{11.13}$$

where κ_λ is the ratio between the trilinear coupling value left free in the fit and its expected value in the SM ($\kappa_\lambda = 1$ corresponds to the SM). These results are also illustrated in Fig. 11.6.

The analyses performed at Run 2 bring substantial improvements from those of Run 1, and they were used to reappraise the sensitivity of the LHC in the High Luminosity regime in the framework of the update of the European Strategy for Particle Physics [104]. The result in terms of bounds on the trilinear coupling are shown in Fig. 11.6, indicating that the significance of the observation of the HH process reaches 4σ. It is also apparent that the degeneracy of secondary minimum at intermediate values of κ_λ is resolved by the use of the kinematic discriminants. Indeed, this secondary minimum is expected to be excluded at 99.4% CL. This is very important to allow the measurement in the vicinity of the SM value at one standard deviation and to provide a meaningful confidence interval. At HL-LHC, the foreseen precision on κ_λ is approximately 50%.

Significantly higher precisions can be reached at pp colliders (and e^+e^- colliders) at higher centre-of-mass energies. The foreseen precision for a High-Energy (HE) LHC at a centre-of-mass energy of 27 TeV is expected to be within 10% to 20% [104]. At a very large hadron collider at a centre-of-mass energy of 100 TeV, a 5% sensitivity is expected to be reached, provided that the theoretical and parametric uncertainties are kept at the 1% level.

Indirect constraints on the Higgs boson trilinear coupling from single Higgs boson production processes will be discussed in Section 11.6.2.5.

11.3.5 *Searches for rare decays of the Higgs boson*

11.3.5.1 *$H \to Z\gamma$ and the Dalitz $H \to \ell^+\ell^-\gamma$ decay*

The search for $H \to Z\gamma$ is performed in the final states where the Z boson decays into opposite sign and same flavour leptons ($\ell^+\ell^-$), ℓ here refers to e or μ. While the branching fraction for $H \to Z\gamma$ is comparable to $H \to \gamma\gamma$ (about 10^{-3}) at $m_H = 125$ GeV, the observable signal yield is brought down by the small branching ratio of $Z \to (e^+e^- + \mu^+\mu^-) = 6.7 \times 10^{-2}$. In these channels, the $m_{\ell\ell\gamma}$ mass resolution is excellent (1–3%), therefore the analyses search for a narrow mass peak over a continuous background. The major backgrounds arise from the $Z+\gamma$ final state radiation in Drell–Yan decays and from the $Z+$ jets processes where a jet is misidentified as a photon. The ratio of signal over background in this channel is typically of the order of 0.5%. In a narrow window of a few GeV around 125 GeV, several hundreds of events are expected in a Run 2 dataset corresponding to approximately 36 fb^{-1}.

Events are divided into mutually exclusive categories on the basis of the expected $m_{Z\gamma}$ resolution and the signal-to-background ratio. A VBF category is formed for $H \to Z\gamma$ candidates which

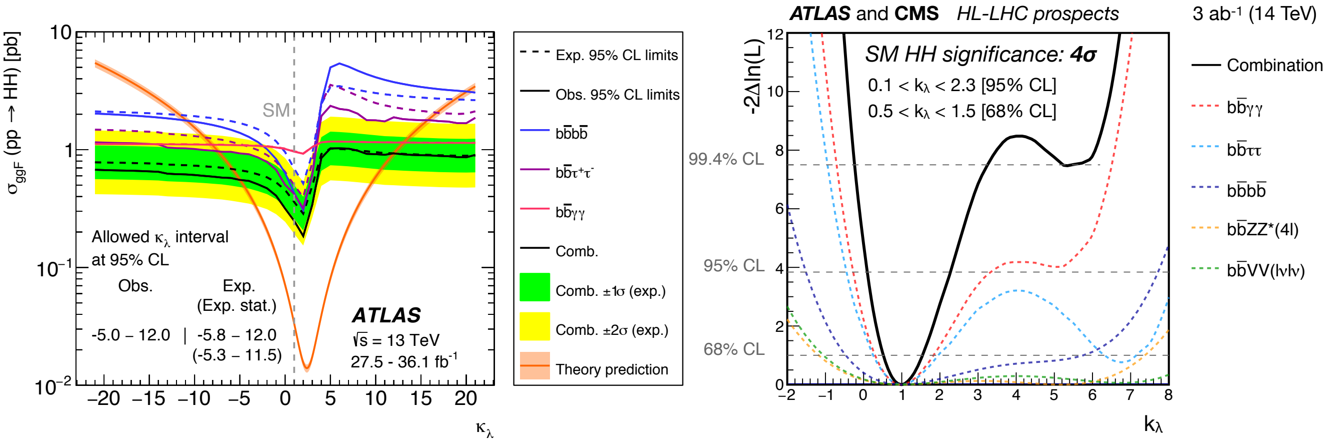

Figure 11.6: (Left) Upper limit obtained by ATLAS on the total $pp \to HH$ production cross section as a function of the trilinear coupling modifier κ_λ. The variation of the limit corresponds to variations in the signal acceptance. The expected total production cross section is also illustrated (red). (Right) Expected combined ATLAS and CMS likelihood for the searches for the $pp \to HH$ production at the High Luminosity LHC. The channels used in the combination are indicated in the figure.

are accompanied by two energetic jets separated by a large pseudo-rapidity. While this category contains only about 2% of the total event count, the signal-to-noise ratio is about an order of magnitude higher. The search for a Higgs boson is conducted independently in each category and the results from all categories are then combined.

No excess of events is observed in either ATLAS or CMS in the Run 1 data. The CMS expected and observed 95% CL upper limits for $m_H = 125$ GeV on the signal strength μ are 10.0 and 9.5 respectively. The ATLAS expected and observed upper limits on the signal strength μ are 9.0 and 11.0 respectively, for $m_H = 125.5$ GeV.

The CMS analysis also extended the search for the so-called Dalitz Higgs boson decays $H \to \gamma^*\gamma \to \ell^+\ell^-\gamma$ in the low mass γ^* range of $m_{\ell\ell} < 20$ GeV. This decay mode has a substantially larger branching fraction compared to the $Z\gamma$ decay, as $\Gamma(H \to \gamma^*\gamma \to e^+e^-\gamma) \sim 3.5\% \times \Gamma(H \to \gamma\gamma)$ and $\Gamma(H \to \gamma^*\gamma \to \mu^+\mu^-\gamma) \sim 1.7\% \times \Gamma(H \to \gamma\gamma)$, while $\Gamma(H \to Z\gamma) = 2.3\% \times \Gamma(H \to \gamma\gamma)$ (which does not account for the subsequent decay of the Z boson to electrons or muons). The limits in this channel are therefore stronger and CMS has observed an upper limit of 6.7 times the SM branching ratio [175].

ATLAS has performed an analysis of the full 2015 and 2016 Run 2 data to search for the $Z\gamma$ decay mode [176]. No significant excess was observed and 95% CL observed (expected) upper limits on the signal strength are 6.6 (5.2).

CMS has repeated its $Z\gamma$ and $\gamma^*\gamma$ analyses with the 2016 dataset and obtained much more stringent observed limits on cross section times the corresponding branching fractions of 1.4 and 4.0 (6.1 and 11.4) times the SM cross section for $H \to \gamma^*\gamma$ ($H \to Z\gamma$) [177]. CMS also performed a combination of the two modes, obtaining a combined observed (expected) limit of 3.9 (2.0) times the SM branching fractions.

11.3.5.2 $H \to \mu^+\mu^-$

The branching fraction in the $H \to \mu^+\mu^-$ channel for a 125 GeV SM Higgs boson is 2.2×10^{-4}, about ten times smaller than that for $H \to \gamma\gamma$. The dominant and irreducible background arises from the $Z/\gamma^* \to \mu^+\mu^-$ process which has a rate several orders of magnitude larger than that from the SM Higgs boson signal. Due to the precise muon momentum measurement achieved by ATLAS and CMS, the $m_{\mu^+\mu^-}$ mass resolution is very good ($\approx$ 2–3% for ATLAS and $\approx$ 1–3% for CMS depending on the selected categories; a better resolution is expected for CMS due its higher field in the inner detector). A search is performed for a narrow peak over a large but smoothly falling background. For optimal search sensitivity, events are divided into several categories. Either taking advantage of the superior muon momentum measurement in the central region, events can be subdivided by the pseudo-rapidity of the muons, or designing selections aiming at specific production processes such in particular as the vector boson fusion.

No excess in the $m_{\mu^+\mu^-}$ spectrum is observed near 125 GeV. From an analysis of the Run 1 data, ATLAS sets an observed (expected) 95% CL upper limit on the signal strength $\mu < 7.0$ (7.2). The CMS analysis of its 7 and 8 TeV data sets an observed (expected) limit of $\mu < 7.4$ (6.5).

ATLAS performed a reoptimised analysis using the full Run 2 dataset and categorising events in number of jets including VBF-topology specific categories [178]. The data showed a non-significance excess with a best-fit value of the signal strength for Higgs boson with a mass of 125 GeV, $\mu = 0.5 \pm 0.7$. The data subsequently yielded an observed (expected) 95% CL upper limit on the signal strength of 1.7 (1.3) , assuming $\mathrm{BR}(H \to \mu\mu) = 0$, (while the expected limit assuming the SM value for $\mathrm{BR}(H \to \mu\mu)$ is 2.2).

CMS, having analysed its 2016 dataset of Run 2, has obtained an observed (expected) limit on the production cross section times the branching fraction to a pair of muons of 3.0 (2.5) times the SM expectation [179]. In combination with the Run 1 data, the limit improves to 2.2 times the SM expectation. A non significant excess is also observed (with a significance of approximately 1σ) and the best fit signal strength is 1.0 ± 1.0 (stat) $\pm$ 0.1 (syst).

11.3.5.3 $H \to e^+e^-$

A search similar to the $H \to \mu^+\mu^-$ is performed by CMS in the di-electron channel. In this search channel, the contribution from the peaking background from Higgs boson decays to diphotons mis-identified as di-electrons (when mostly converted photons are faking electrons) needs to be assessed. The sensitivity to the SM Higgs decays is negligible given the extremely small branching fraction to e^+e^-, approximately 40'000 times smaller than the branching fraction to dimuons. It is nevertheless interesting to probe this decay channel to search for potential large anomalous couplings. Assuming a SM Higgs boson production cross section, the observed limit on the branching fraction at the 95% CL is 0.0019, five orders of magnitude larger than the expected SM prediction. It is also important to note that processes not depending on the electron Yukawa coupling such as the $H \to e^+e^-\gamma$ (where the photon is soft), are sizeably larger than the direct Yukawa coupling process, but also much smaller than the current constraints, making any interpretation in terms of constraint on the electron Yukawa couplings far from straightforward.

At Run 2, ATLAS has also performed a search for the $H \to e^+e^-$ decay mode with the full dataset, improving the current limit by a factor of approximately 5, with a limit of 3.6×10^{-4} on the branching fraction [180].

11.3.5.4 *Lepton flavour violating (LFV) Higgs boson decays*

Given the Yukawa suppression of the couplings of the Higgs boson to quarks and leptons of the first two generations and the small total width of the Higgs boson, new physics contributions could easily have sizable branching fractions. One very interesting possibility is the Lepton Flavour Violating (LFV) decays of the Higgs boson, in particular in the $\tau\mu$ and τe modes. These decays are suppressed in the SM but they could easily be enhanced in theories such as two-Higgs-doublet models (discussed in Section 11.7).

There are already constraints on LFV Yukawa couplings $|Y_{\tau\mu}|$ from channels such as the $\tau \to 3\mu$ or $\tau \to \mu\gamma$, or a re-interpretation of the search for Higgs boson decays to $\tau^+\tau^-$. A direct search at the LHC, however, complements these indirect limits. The search for LFV decays in the $\tau\mu$ channel have been done with the Run 1 dataset in several channels according to the subsequent decay of the τ. The results from CMS [181] and from ATLAS for the hadronic [182], the leptonic [183] decays of the tau, and their combination [183] are reported in Table 11.8. It is interesting to note that the analysis strategies at Run 1 for the di-lepton $\tau_{\rm lep}\mu$ channel are very different between ATLAS [183] and CMS [181].

As shown in Table 11.8, an excess was observed in this channel by CMS with a significance of 2.5σ, while in ATLAS analysis, the excess is smaller, about 1σ at Run 1. CMS has performed the search again with the full 2016 Run 2 dataset [184], relying on a multivariate analysis. The observed best fit branching fraction is $(0.00 \pm 0.12)\%$. These limits are reported in Table 11.8.

ATLAS and CMS have also performed a search for the LFV Higgs boson decays in the τe and μe channels [183–185]. No significant excess was observed and 95% CL limits are reported in Table 11.8, for the τe channel only. For the μe channel, the constraints from the $\mu \to e\gamma$ experiments [186] are much stronger than those from the direct LFV Higgs boson decay search. However these indirect constraints can be relaxed by the cancellation of LFV effects from new physics.

At Run 2, ATLAS has performed searches for LFV decays of the Higgs boson in the $e\tau$ and $\mu\tau$ channels [187] as well as in the $e\mu$ channel [180]. The searches for the $H \to e\tau$ and $H \to \mu\tau$ decays where done with the 2016 data only and yielded upper limits on the LFV decay branching fraction of 0.47% (0.34%) and 0.28% (0.37%), respectively.

CMS has also searched for LFV decays with the 2016 dataset at Run 2 and obtained observed (expected) limits on the LFV branching fraction of $\mathrm{BR}(H \to \mu\tau) < 0.25\%$ (0.25%) and $\mathrm{BR}(H \to e\tau) < 0.61\%$ (0.37%), at the 95% CL [188]. These limits were also interpreted in terms of constraints on the corresponding off-diagonal Yukawa couplings.

The results obtained by ATLAS and CMS at Run 2 do not confirm the excesses observed at Run 1.

11.3.5.5 *Probing charm- and light-quark-Yukawa couplings*

Probing the Yukawa couplings to quarks of the second or even the first generation is extremely challenging given the overwhelming backgrounds and very small rates.

The possibility of probing the Yukawa coupling to the charm has been discussed in Ref. [189] where indirect bounds are estimated from a combined fit to the Higgs data and the importance of using charm tagging is emphasised. Searches in the VH production mode have then been carried out, in the channels very similarly to those aiming at the b-quark Yukawa coupling, by both ATLAS [190] and CMS [191] with Run 2 data. The upper limits obtained (expected) on the VH production cross section times the charm quark decay branching fraction of the Higgs boson are:

$$\text{(ATLAS)}\ \ \sigma(ZH) \times \mathrm{BR}(H \to c\bar{c}) < 2.7\ \ (3.9^{+2.1}_{-1.1})\,\mathrm{pb}, \quad (11.14)$$

$$\text{(CMS)}\ \ \frac{\sigma(VH) \times \mathrm{BR}(H \to c\bar{c})}{\sigma(VH)_{SM} \times \mathrm{BR}(H \to c\bar{c})_{SM}} < 70\ \ (37^{+16}_{-10}). \quad (11.15)$$

The ATLAS search [190] was done in the ZH channel where the Z boson decays to a pair of leptons (electrons or muons) only. The expected cross section times branching fraction $\sigma(ZH) \times \mathrm{BR}(H \to c\bar{c})$ is $26\,\mathrm{fb}^{-1}$.

Another possibility to access the charm Yukawa coupling has been discussed in Ref. [192]. It relies on the decays of the Higgs boson to a final state with charmonium: $H \to J/\Psi\gamma$. Higgs boson decays in this final state have been searched for by ATLAS [193]. The sensitivity of this analysis is, however, several orders of magnitude above the branching fraction estimated in the SM: $\mathrm{BR}(H \to J/\Psi\gamma) = (2.8 \pm 0.2) \times 10^{-6}$. ATLAS [193] has also searched for Higgs boson decays to $\Upsilon(nS)\gamma$ where $(n = 1, 2, 3)$, a channel with much lower sensitivity than the $H \to b\bar{b}$ to the Yukawa coupling to b-quarks.

More recently, ATLAS has searched, , with a specific trigger, for another quarkonia final state where the Higgs boson decays to $\phi\gamma$ [194] at the LHC Run 2 and a center-of-mass energy of 13 TeV. This channel could probe deviations from the strange-quark Yukawa coupling. Its sensitivity is several orders of magnitude above the SM expectation. Other quarkonia final states, such as the $\rho\gamma$, which could potentially probe the Yukawa coupling to light quarks, can also be searched for.

CMS has also performed a search of the decays of the Higgs boson in the $J/\Psi J/\Psi$ and $\Upsilon\Upsilon$ decay to cover the cases where the photon in the $J/\Psi\gamma$ decay is virtual and transforms into a J/Ψ meson, These decays provide an additional channel potentially sensitive to BSM phenomena [195].

11.3.5.6 *Rare decays outlook*

Rare decays such as those described in the above sections have clearly a limited sensitivity. However, they already deliver interesting messages. For example, if the coupling of the Higgs boson to muons was as strong as it is to top quarks, this mode should have been observed. Therefore, it can be concluded that the observed couplings of the Higgs boson are manifestly non-universal. Further developing these rare decay modes is an important component of the High Luminosity program of the LHC in order to directly probe the couplings of the Higgs boson, and to potentially measure the Yukawa coupling to the fermions of the second generation, in particular to muons. It is also an integral part of the physics program of the discussed potential future Higgs boson factories.

11.3.6 *Searches for non-SM decay channels*

The main decay and production properties of the observed Higgs boson are consistent with the SM predictions. The Higgs boson may, however, have other decay channels beyond those anticipated in the SM. Among these, and of great interest, are the invisible decays into stable particles, such as DM particle candidates, that interact very weakly with the detector, and that remain undetected. Other non standard decay channels that have been investigated are the decays of the Higgs particle to hidden valley or dark particles.

11.3.6.1 *Invisible decays of the Higgs boson*

The discovery of the Higgs boson immediately raised the question of its couplings to DM and how it could be used to reveal at colliders the existence of a dark sector coupled to the SM via the Higgs boson portal, see Ref. [196] and references therein. If kinematically accessible and with a sufficiently large coupling to the Higgs boson, DM particles, such as, e.g., neutralinos in SUSY models, graviscalars in models with extra dimensions or heavy neutrinos in the context of four-generation fermion models, would manifest themselves as invisible decays of the Higgs boson, thus strongly motivating searches for the invisible decays of the Higgs boson.

To identify an invisibly decaying Higgs boson at the LHC, it must be produced in association with other particles. Searches for invisible decays of the Higgs particle at the LHC have been carried out in the three associated production modes of the Higgs boson with the highest SM cross sections and target events with large missing energy.

The ggF production mode has the largest SM cross section but it usually results in the Higgs boson being created alone and hence leaving no characteristic signature in the detector of its invisible decay. One way to search for invisible decays in ggF production mode is to look for events with the monojet topology arising from initial state gluon radiation and containing missing energy. The major irreducible background in such searches stems from Z + jets

Table 11.8: Summary of the results of searches for lepton flavour violating decays of the Higgs boson in the $\tau\mu$ and τe channels from ATLAS and CMS. For the result with *, the expected sensitivity was not reported but appears consistent with the observed one.

	ATLAS (Run 1)	CMS (Run 1)	CMS (Run 2)
$\mathrm{BR}(H \to \tau\mu)$	$(0.53 \pm 0.51)\%$	$(0.84^{+0.39}_{-0.37})\%$	$(0.00 \pm 0.12)\%$

$H \to \tau e$ 95% CL Obs. (Exp.)	1.02% (1.21%)	0.69%*	0.61% (0.37%)

events where the Z boson decays into a pair of neutrinos [197]. The analysis with the best sensitivity targets the VBF production topology but it suffers from large backgrounds arising from events with two jets and large missing energy. The VH mode has much smaller cross section but the presence of a W or Z boson allows a variety of final states that can be tagged with relatively low background.

ATLAS and CMS have searched for such final states at Run 1 and have observed no significant excess over the predicted backgrounds (for references, see the previous edition of this review [123]). Table 11.9 summarizes the 95% CL limits on the invisible decays of the Higgs boson assuming a SM Higgs boson production cross section and the corresponding detector acceptances.

ATLAS has performed the search for invisible decays of the Higgs boson at Run 2 with the 2015 and 2016 datasets, corresponding to an integrated luminosity of approximately 36 fb^{-1}, in the VBF production [198], the ZH associated production where the Z boson subsequently decays to a pair of leptons [199], and the VH associated production where the vector boson (a W or a Z) subsequently decays hadonically [200]. The most stringent constraint is obtained through the VBF channel. All results and their combination [201] are reported in Table 11.9. Combined with the Run 1 results, the ATLAS limit on the invisible branching fraction reaches 26%, with an expected sensitivity of 17% [201].

CMS has updated the search for invisible decays of the Higgs boson in the vector boson fusion and the associated production with a vector boson channels (both with subsequent leptonic [202] and hadronic decays [203]) using Run 2 data collected in 2016 [204]. It has produced a combination with Run 1 channels, yielding a limit on the invisible branching fraction of 19%, with an expected sensitivity of 15% [204].

CMS has also reinterpreted a search for scalar top quarks in the all-hadronic, semi-leptonic and fully leptonic final state with the 2016 data of Run 2 to set limits on the invisible Higgs decays through the $pp \to t\bar{t}H$ production mode [205]. The results of the search are reported in Table 11.9.

This constraint can then be further used to probe Higgs portal models to DM [196], where an additional weakly interacting particle χ with mass lower than $m_H/2$ is introduced as DM candidate and where the Higgs boson is considered as the only mediator between the SM particles and DM. In this model, it is interesting to express the limit on the invisible branching fraction in terms of strength of interaction of DM with standard matter, i.e., in terms of it interaction cross section with nucleons $\sigma_{\chi-N}$. In this model, the couplings of the Higgs boson to SM particles are assumed to be those of the SM and the interaction of the Higgs boson with the nucleon is parametrised in a Higgs-Nucleon form factor estimated using lattice QCD calculations [196]. The exclusion limits from the constraints on invisible Higgs boson decays, both direct and indirect from the measurement of the coupling properties of the Higgs boson can be compared to direct detection experiments. For comparison, the limit at 90% CL on the invisible branching fraction of $\mathrm{BR}_{\mathrm{inv}} < 19\%$ [204] is used and converted into limits on $\sigma_{\chi-N}$ under several hypotheses on the nature of DM particles depending mainly on their spin (scalar- or fermion-like). The vector DM hypothesis is not included since (renormalisable) models of vectorial DM require an extended dark sector that could imply modifications of the signal. The results are shown in Fig. 11.7.

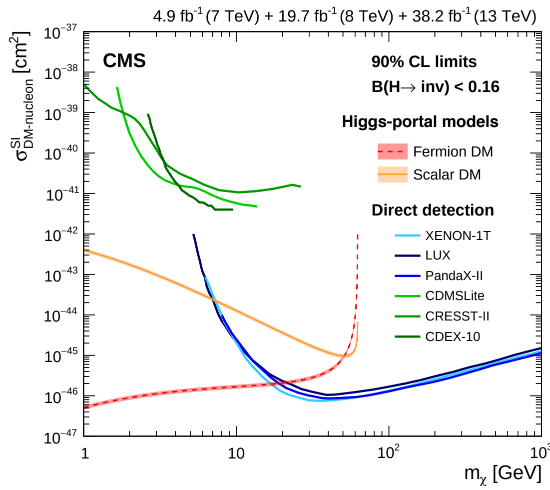

Figure 11.7: 90% CL upper limits on the WIMP-nucleon scattering cross section as a function of the DM particle mass. Spin-independent results excluded and favored regions from direct detection experiments are also shown.

11.3.6.2 *Exotic Higgs boson decays*

The 125 GeV Higgs boson serves not only as a probe for potential DM candidates, but also to search for other exotic particles arising from fields associated with a low-mass hidden sector. Such hidden sectors are composed of fields that are singlet under the SM gauge group $\mathrm{SU}(3) \times \mathrm{SU}(2) \times U(1)$. These models are referred to as hidden valley models [206]. Since a light Higgs boson is a particle with a narrow width, even modest couplings to new states can give rise to a significant modification of the Higgs boson phenomenology through exotic decays. Simple hidden valley models exist in which the Higgs boson decays to an invisible fundamental particle, which has a long lifetime to decay back to SM particles through a small mixing with the SM Higgs boson, see Ref. [206] for a concrete example. The Higgs boson may also decay to a pair of hidden valley "v-quarks," which subsequently hadronise in the hidden sector, forming "v-mesons." These mesons often prefer to decay to the heaviest state kinematically available, so that a possible signature is $H \to 4b$. Some of the v-mesons may be stable, implying a mixed missing energy plus heavy flavour final state. In other cases, the v-mesons may decay to leptons, implying the presence of low mass lepton resonances in high-H_T events [207]. Other scenarios have been studied [208] in which the Higgs boson decays predominantly into light hidden sector particles, either directly, or through light SUSY states, and with subsequent cascades that increase the multiplicity of hidden sector particles. In such scenarios, the high-multiplicity hidden-sector particles, after decaying back into the SM, appear in the detector as clusters of collimated leptons known as "lepton jets".

A variety of models have been investigated searching for final states involving dark photons and hidden valley scalars. The resulting topologies typically have leptons or light hadrons which in some cases can be prompt (i.e., originating from the hard process interaction point) or not and are in some cases collimated and reconstructed as jets [209, 210], and long lived weakly interacting particles. The latter occur not only in hidden valley scenarios, but also in gauge-mediated extensions of the minimal SUSY standard model (MSSM), the MSSM with R-parity violation, and inelastic DM scenarios [211]. Finally, CMS has performed a search for pair production of light bosons [212]. Such a scenario can occur in SUSY models with additional hidden (or dark) valleys.

Table 11.9: Summary of the channels searched for and the corresponding 95% CL limits from ATLAS and CMS on the branching fraction for the Higgs boson decay to invisible particles assuming a SM Higgs boson production cross section. The results in parentheses are the expected exclusions.

11.4 Combining the main channels

The analysis strategy used by the LHC experiments to perform the searches for the Higgs boson has been based on the Higgs boson decay modes. It is a natural choice given that it focusses on the decay products of the object searched for. However, for each channel, exclusive sub-channels have been defined according to the Higgs boson production processes and, in the results presented, these sub-channels have been combined. The natural extension of this approach in order to probe further the production and decay modes of the Higgs boson is to combine the analysis channels together. Such a combination is also used in Section 11.6 to further measure the coupling properties of the Higgs boson.

At the LHC, the total cross section cannot be measured in any of the production modes. As a consequence, neither the absolute branching fractions nor the total width of the Higgs boson can be directly measured, at least if the width is of the SM size. However, a combined measurement of the large variety of categories described in Section 11.3, with different sensitivities to various production and decay modes, permits a wide variety of measurements of the production, decay and coupling properties. These measurements require, in general, a limited but nevertheless restrictive number of assumptions.

In this section, three sets of results will be given. The first one is the ATLAS and CMS Run 1 combination [141]. The other two are the individual combinations of ATLAS and CMS independently with partial Run 2 dataset. It is important to note that, between the Run 1 and the Run 2 results, the signal theoretical systematic uncertainties have improved significantly.

The Run 1 full combination results were derived by the two collaborations, taking rigorously into account all correlations in the systematic uncertainties and in the large number of channels and their categories.

At Run 2, ATLAS [213] and CMS [214] have already produced combined measurements of the coupling properties of the Higgs boson with partial datasets, of up to 80 fb^{-1} and up to 36 fb^{-1} respectively.

In this section, only the results on the main Higgs boson production and decay modes will be discussed. Only a brief presentation of the combination framework is given here (a more detailed description is given in Ref. [215]). This framework will also be used in Section 11.6 to discuss the measurements of the coupling properties of the Higgs boson.

11.4.1 *Principles of the combination*

The combination of the Higgs boson analysis channels in each experiment and for the two experiments together was done using a fit of a signal and background model to the data. As described above, the data was made of a large number of categories, aiming at reconstructing exclusive production and decay modes. In the combination of ATLAS and CMS [141], there were approximately 600 categories. The combination was a simultaneous fit to all these categories, using a reduced number of parameters of interest and a Higgs boson mass fixed at its measured value (see Section 11.3.2). The much larger number of categories present in the ATLAS and CMS combination [141] is due to additional separation in terms of finer exclusive production regions, decay channels of the Z and the W bosons, and taus, control regions where little-to-no signal is present, and different center-of-mass energies. It should be noted that the individual combination performed by ATLAS [216] included two additional decay channels: the $\mu^+\mu^-$ and $Z\gamma$. For the sake of simplicity these channels were omitted in the ATLAS–CMS combination. In addition, a $H \to b\bar{b}$ analysis performed by CMS, see the reference in Ref [123], and included in its own combination, has been omitted from the ATLAS–CMS combination.

In their Run 2 individual combinations, ATLAS and CMS have not considered the $Z\gamma$ channel. The CMS experiment has included the $\mu\mu$ channel.

The key to understand how the combination of channels works relies on the combination master formula, which expresses for each category, indexed by c, of a given channel (typically a category covers mostly one decay mode, but possibly various production modes), the measured number of signal events n_s^c as a function of a limited number of parameters as follows:

$$n_s^c = \left(\sum_{i,f} \mu_i \, \sigma_i^{\mathrm{SM}} \times A_{if}^c \times \varepsilon_{if}^c \times \mu_f \, \mathrm{BR}_f^{\mathrm{SM}} \right) \times \mathcal{L}^c. \quad (11.16)$$

The production index is defined as $i \in \{\mathrm{ggF}, \mathrm{VBF}, VH, t\bar{t}H\}$ and the decay index is defined as $f \in \{\gamma\gamma, WW, ZZ, bb, \tau\tau\}$, while σ_i^{SM} and $\mathrm{BR}_f^{\mathrm{SM}}$ are the corresponding production cross sections and decay branching fractions, estimated as described in Section 11.2, assuming that the Higgs boson is that of the SM. A_{if}^c and ε_{if}^c are the signal acceptance and the reconstruction efficiency for the given production and decay modes in the category c. $\mathcal{L}^c$ is the integrated luminosity used for that specific category. For the purpose of this review, these parameters can be considered as fixed[3].

The parameters of interest in the master formula are the signal strength parameters μ_i and μ_f. It is important to note that the formula relies on the factorisation of the production cross section and decay branching fraction, which assumes the narrow width approximation. The width of the Higgs boson will be discussed in Section 11.5, however, for the precision needed here, the fact that the Higgs boson has been observed in decay channels with high mass resolution as a resonance is sufficient to validate this hypothesis. It is also manifest in the above equation that the ten parameters for the production modes (μ_i) and decay modes (μ_f) cannot be determined simultaneously. This illustrates that total cross sections or branching fractions cannot be measured without further assumptions in this fit.

The master formula also illustrates an important caveat to the measurement of signal strength parameters. In case these are interpreted as scale factors of the production cross sections or branching fractions, then all the other quantities such as the acceptances and efficiencies, A_{if}^c and ε_{if}^c, need to be assumed as independent and fixed to their estimated values for the SM Higgs boson. An additional important caveat to note concerning these combined results is that only the normalisation is varied, while the discriminating variables for the signal are not modified and

[3] In the combination performed by ATLAS and CMS, the systematic uncertainties on these parameters are taken into account by allowing these parameters to vary in the fit.

Table 11.10: Summary of the observation significances (with respect to the background only hypothesis) for the main production and decay processes at the LHC. Measured signal strengths are reported when the observation has been established unambiguously. Measured signal strengths are reported with the uncertainty of statistical nature first and systematic last, ATLAS has not reported these results in its Run 2 combination (NR). *The Run 2 VH significances reported in this table are obtained from the observation of the Higgs boson decays to b quarks, while the Run 1 combination corresponds to combination of all channels.

	Decay modes			
	ATLAS (Run 1)	CMS (Run 1)	ATLAS (Run 2)	CMS (Run 2)
$\gamma\gamma$	4.6σ (5.3σ)	5.2σ (4.6σ)	NR	$1.20\,^{+0.13}_{-0.11}\,^{+0.12}_{-0.09}$
ZZ	6.2σ (6.3σ)	8.1σ (6.5σ)	NR	$1.06\,^{+0.16}_{-0.15}\,^{+0.11}_{-0.08}$
WW	5.9σ (5.4σ)	6.5σ (4.7σ)	NR	$1.28\,^{+0.09}_{-0.09}\,^{+0.14}_{-0.13}$
$\tau^+\tau^-$	3.4σ (3.9σ)	4.5σ (3.8σ)	6.4σ (5.4σ)	5.9σ (5.9σ)
	Comb. 5.0σ (5.5σ)			
$b\bar{b}$	2.6σ (2.5σ)	1.4σ (2.1σ)	5.4σ (5.5σ)	5.5σ (5.6σ)
	Comb. 3.7σ (2.6σ)			
	Production modes			
	ATLAS and CMS (Run 1)		ATLAS (Run 2)	CMS (Run 2)
$qq \to qqH$ (VBF)	Comb. 5.4σ (4.6σ)		$1.21\,^{+0.18}_{-0.17}\,^{+0.16}_{-0.13}$	$0.73\,^{+0.24}_{-0.23}\,^{+0.17}_{-0.15}$
$pp \to VH$	Comb. 3.5σ (4.2σ)		5.3σ (4.8σ)*	4.8σ (4.9σ)*
$pp \to t\bar{t}H$	Comb. 4.4σ (2.2σ)		5.8σ (4.9σ)	5.2σ (4.2σ)

are still used in the fit. These caveats are of particular importance in the use of the combination to measure the coupling properties of the Higgs boson, as discussed in Section 11.6. For relatively small perturbations of the couplings of the Higgs boson from the SM values, this hypothesis is valid.

However, the products $\mu_i \times \mu_f$ can be considered as free parameters and in principle measurable (if there is sufficient sensitivity from specific categories). Measuring the products of signal strengths can be viewed as measuring the cross sections times the branching fraction, $\sigma \cdot \mathrm{BR}$. An illustration of the results for the Run 2 combinations of ATLAS and CMS is presented in Fig. 11.8 for the combination of ATLAS and CMS.

A coherent picture emerges (including the Run 1 results, see Ref. [123]) where an excellent consistency between the observation in each channel and the SM expectation. This multi-parameter fit quantifies the current experimental knowledge of the main production and decays modes. Run 2 results are also available [213,214]. These are not included in the figure for the sake of simplicity. The Run 2 results are already competitive with the Run 1 results. In Fig. 11.8, the Run 1 results are kept for illustration purposes. The theoretical uncertainty in the aforementioned fit is not included in the measured values of the signal strengths but is illustrated on the unit value corresponding to the SM expectation.

Other fits involving ratios of cross sections, which are less sensitive to theory uncertainties, are performed and reported in Ref. [215].

The most constrained fit in the combination allows for only one single parameter to vary, i.e., $\forall(i,f), \mu_i = \mu_f = \mu$. This global-signal-strength model provides the simplest probe of the compatibility of the signal with the SM Higgs boson. Indeed, it is sensitive to any deviation from the SM Higgs boson couplings provided that these deviations do not cancel overall. The full Run 1 combination determines the global signal strength to be

$$\begin{aligned}\mu = 1.09 \pm 0.11 =& 1.09 \pm 0.07\,(\text{stat.}) \pm 0.04\,(\text{expt.})\\ &\pm 0.03\,(\text{th. bkg.}) \pm 0.07\,(\text{th. sig.}),\end{aligned} \tag{11.17}$$

where the statistical, experimental uncertainties as well as the theoretical uncertainties on the background and on the signal are reported separately. The ATLAS Run 2 combination of the global signal strength yields [213]:

$$\begin{aligned}\mu = 1.11^{+0.09}_{-0.08} = 1.11 &\pm 0.05\,(\text{stat.}) \,^{+0.05}_{-0.04}\,(\text{expt.})\\ &\pm 0.03\,(\text{th. bkg.}) \,^{+0.05}_{-0.04}\,(\text{th. sig.}),\end{aligned} \tag{11.18}$$

while the CMS Run 2 combination yields [214]:

$$\begin{aligned}\mu = 1.17 \pm 0.10 = 1.17 &\pm 0.06\,(\text{stat.}) \,^{+0.06}_{-0.05}\,(\text{th. sig.})\\ &\pm 0.06\,(\text{other. syst.}).\end{aligned} \tag{11.19}$$

These overall signal strengths are fully compatible with the SM expectation, $\mu = 1$, with a precision of 10%. It is interesting to note that the main uncertainty in these measurements arises from the limited precision in the theoretical predictions for the signal production processes. The precision reached with the individual experiments combinations using partial Run 2 data sets have already exceeded the full Run 1 ATLAS and CMS combination precision.

11.4.2 *Main decay modes*

Despite the large number of decay channels, since the cross sections cannot be independently measured, from the measurements described in this section it is impossible to measure the decay branching fractions without a loss of generality. The simplest assumption that can be made is that the production cross sections are those of the SM, which is equivalent to assume that, for all i indices, $\mu_i = 1$. All branching fractions μ_f can then be measured in a simple 5 parameter fit. The results of these fits are reported in Table 11.10 in terms of significances to highlight their unambiguous observations: all the measured branching fractions are compatible with the SM values.

For the $\tau^+\tau^-$ channel, ATLAS and CMS were both only mildly sensitive at the Run 1 and have observed excesses in their data. The individual results were not sufficiently significant to claim an observation, however, in combination the evidence was very strong. It is really with the addition of the Run 2 data that the decay of the Higgs boson to tau pairs has been established by the two experiments independently and unambiguously (see Table 11.10 and Section 11.3.2).

As illustrated in Table 11.10, ATLAS and CMS were both less sensitive in the $H \to b\bar{b}$ decay mode. The available sensitivity

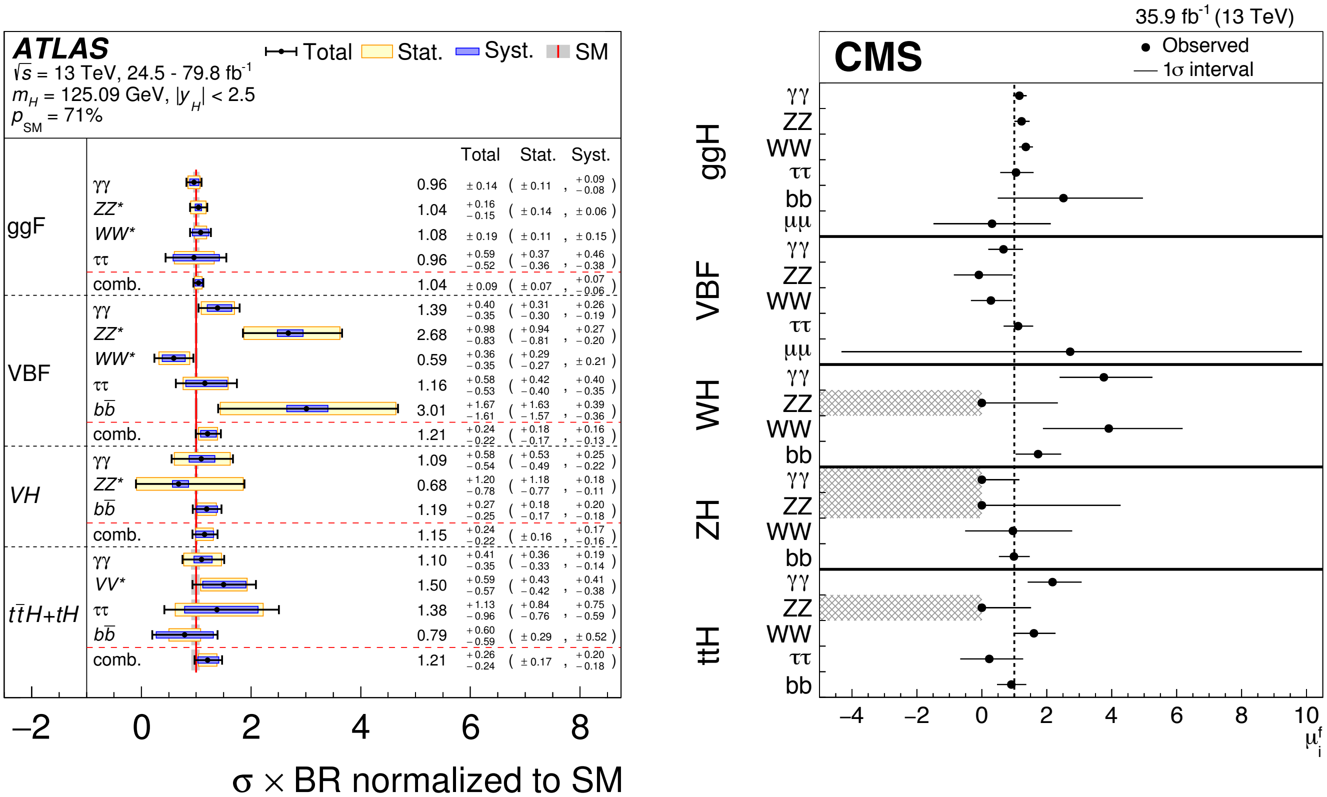

Figure 11.8: Combined measurements of the products $\sigma \cdot \mathrm{BR}$, normalised to the SM predictions, for the five main production and five main decay modes. The hatched combinations require more data for a meaningful confidence interval to be provided.

came mostly from the VH process. The combined significance of 3.7σ at Run 1 was sufficient to suggest evidence, however ATLAS and CMS observations were both low with respect to the rate expected in the SM. At Run 2, this channel benefited largely from the increased production cross sections at 13 TeV and the much larger dataset. In this case as well, it is with the addition of the Run 2 data that both experiments were able to establish a measurement in this channel (as discussed in Section 11.3.2).

These are major milestones of the LHC physics program.

11.4.3 *Main production modes*

Most analysis channels are divided into exclusive categories allowing for an increased overall sensitivity and permitting to access the various Higgs boson production modes. The cross sections of the main production modes can be measured assuming that the branching fractions are those of the SM, i.e., for all f indices $\mu_f = 1$. These assumptions lead to a 5 parameter combination. The results are reported in terms of significances of observation of the production modes in Table 11.10.

The gluon fusion production process is the dominant production mode. Although no numerical estimate of combined significance of observation for this process has been given by the experiments, it is considered as established due to the overwhelming evidence from the three main discovery channels. None of the other production modes have been firmly established by the experiments individually. However, the table shows that, for the VBF production mode, the combination had a large sensitivity and produced a combined observation of 5.4σ, therefore establishing this process with a rate compatible with that expected in the SM.

The VH production mode has only very recently been unambiguously observed by ATLAS and CMS independently (as discussed in Section 11.3.2) through the $V(H \to b\bar{b})$ channel. This is illustrated in the relative contributions of all channels to the VH process shown in Figure 11.8.

With the Run 2 data, all production processes have been established, and in particular the $pp \to t\bar{t}H$ process, which provides direct evidence of the coupling of the Higgs boson to top quarks. This is another milestone in the LHC physics program.

11.5 Main quantum numbers and width of the Higgs boson

11.5.1 *Main quantum numbers* J^{PC}

Probing the Higgs boson quantum numbers is essential to further unveiling its coupling properties. The measurements of the signal event yields in all the channels discussed in Sections 11.3 and 11.4, and their compatibility with the SM Higgs boson predictions, give a qualitative but, nonetheless, compelling indication of its nature. This qualitative picture is further complemented by the implications of the observation of the particle in the diphoton channel. According to the Landau–Yang theorem [217], the observation made in the diphoton channel excludes the spin-1 hypothesis and restricts possibilities for the spin to 0 or 2.

The Landau–Yang theorem does not apply if the observed state is not decaying to a pair of photons but to a pair of scalars subsequently decaying to two very collimated pairs of photons (as for example in the case of $H \to a_1 a_1 \to 4\gamma$). This possibility has not been rigorously excluded but is not experimentally favoured since tight selection criteria are applied on the electromagnetic shower shapes of the reconstructed photons. A more systematic analysis of shower shapes and the fraction of conversions could be performed to further discriminate between the single prompt photon and the two overlapping photons hypotheses. There are also potential theoretical loopholes concerning the applicability of the Landau–Yang theorem, such as off-shell vector boson decays. However, for the observed particle not to be of spin 0 and +1 parity would require an improbable conspiracy of effects. It is nevertheless important to test this hypothesis independently, in particular since the measurements of coupling properties of the Higgs boson assume that it is a CP-even state.

11.5.1.1 *Charge conjugation*

The charge conjugation quantum number is multiplicative, therefore given that the Higgs-like particle is observed in the $H \to \gamma\gamma$ channel, and given that photons are C-odd eigenstates, assuming C conservation, the observed neutral particle should be C-even.

11.5.1.2 *Spin and parity*

To probe the spin and parity quantum numbers of the discovered particle, a systematic analysis of its production and decay processes is performed in several analyses. These analyses are designed to be independent of the measured event yields and they rely instead on the production and the decay angles, and on the threshold distributions as long as a significant signal is observed, i.e., in situations when an excess over the expected background can be used to further discriminate between signal hypotheses. These analyses are based on probing various alternative models of spin and parity [218]. These models can be expressed in terms of an effective Lagrangian [219] or in terms of helicity amplitudes [220]. The two approaches are equivalent. In the following, the effective Lagrangian formalism is chosen to describe the models considered and a restricted number of models are discussed [219]. In the analysis performed by CMS [220], a larger number of models have been investigated, however, the main channels studied by both experiments are essentially the same and the main conclusions are similar and fully consistent.

i. *Spin-0 model*

The interaction Lagrangian relevant for the analysis of spin-0 particle interaction with a pair of W or Z bosons with either fixed or mixed SM and BSM CP-even couplings or CP-odd couplings, is the following [221]:

$$\begin{aligned}\mathcal{L}_0^{W,Z} \supset \Big\{ & \cos(\alpha)\kappa_{\mathrm{SM}}\left[\frac{1}{2}g_{HZZ}Z_\mu Z^\mu + g_{HWW}W^+_\mu W^{-\mu}\right] \\ & - \frac{1}{4\Lambda}\left[\cos(\alpha)\kappa_{HZZ}Z_{\mu\nu}Z^{\mu\nu} + \sin(\alpha)\kappa_{AZZ}Z_{\mu\nu}\tilde{Z}^{\mu\nu}\right] \\ & - \frac{1}{2\Lambda}\left[\cos(\alpha)\kappa_{HWW}W^+_{\mu\nu}W^{-\mu\nu} + \sin(\alpha)\kappa_{AWW}W^+_{\mu\nu}\tilde{W}^{-\mu\nu}\right]\Big\} H, \end{aligned} \tag{11.20}$$

where $V^\mu = Z^\mu, W^{+\,\mu}$ are the vector boson fields, $V^{\pm\mu\nu}$ are the reduced field tensors and $\tilde{V}^{\pm\mu\nu} = 1/2\,\varepsilon^{\mu\nu\rho\sigma}V_{\rho\sigma}$ are the dual tensor fields. And Λ defines an effective theory energy scale. The factors $\kappa_{\mathrm{SM}}, \kappa_{HZZ}, \kappa_{HWW}, \kappa_{AZZ}, \kappa_{AWW}$ denote the coupling constants corresponding of the coupling of the SM and BSM CP-even and CP-odd components of the Higgs boson to the W and Z fields. The mixing angle α allows for the production of a CP-mixed state and the CP-symmetry is broken when $\alpha \neq 0, \pi$.

This formalism can be used to probe both CP-mixing for a spin-0 state, as discussed in Section 11.5.1.4 or specific alternative hypotheses, as discussed below in Section 11.5.1.3, such as a pure CP-odd state ($J^P = 0^-$) corresponding to $\alpha = \pi/2$, $\kappa_{\mathrm{SM}} = \kappa_{HVV} = 0$ and $\kappa_{AVV} = 1$. A BSM CP-even state $J^P = 0^+$ corresponds to $\alpha = 0$, $\kappa_{AVV} = 0$, $\kappa_{HVV} = 1$ and κ_{SM} arbitrary. These hypotheses are compared to the SM Higgs boson hypothesis corresponding to $\alpha = 0$ and $\kappa_{HVV} = \kappa_{AVV} = 0$ and $\kappa_{\mathrm{SM}} = 1$. This formalism has been adopted by the ATLAS experiment. The analysis of these benchmarks are illustrated in Fig. 11.9.

A different parametrisation of anomalous couplings of a spin-zero boson with two gauge bosons VV can also expressed in the general form of the scattering amplitude A:

$$\begin{aligned} A \sim & \left[a_1^{VV} - \frac{\kappa_1^{VV}q_1^2 + \kappa_2^{VV}q_2^2}{(\Lambda_1^{VV})^2} - \frac{\kappa_3^{VV}(q_1+q_2)^2}{(\Lambda_Q^{VV})^2}\right] m_{V_1}^2 \varepsilon^*_{V_1}\varepsilon^*_{V_2} \\ & + a_2^{VV} f^{*(1)}_{\mu\nu} f^{*(2)\mu\nu} + a_3^{VV} f^{*(1)}_{\mu\nu}\tilde{f}^{*(2)\mu\nu} \end{aligned} \tag{11.21}$$

where ε_i is the polarization vector of the boson V_i, $f^{*(i)}_{\mu\nu} = \varepsilon_i^\mu q^\nu - \varepsilon_i^\nu q^\mu$ is a scalar tensor constructed from the vector boson V_i polarization and four momentum, $\tilde{f}^{*(i)}_{\mu\nu} = \frac{1}{2}\varepsilon_{\mu\nu\rho\sigma}f^{*(i)\rho\sigma}$ is the corresponding pseudo-scalar tensor. Λ_1 and Λ_Q are new physics scales, $a_{1,2,3}$ are coupling strength modifiers and $|\kappa^{VV}_{(1,2,3)}| = 0$ or 1. The custodial symmetry would require that $a^{WW} = a^{ZZ}$ and, at tree-level, the only non-zero contributions would come from the a_1 term. This parametrisation is used by CMS. It is fully equivalent to the interaction Lagrangian approach described above.

ii. *Spin-2 model*

The graviton-inspired interaction Lagrangian for a spin-2 boson $X^{\mu\nu}$ that does not carry any color, weak and electromagnetic charge and that uniquely interacts with the energy momentum tensor $\mathcal{T}^{V,f}$ of vector bosons V or fermions f, can be written as follows [221]:

$$\mathcal{L}_2 \supset \frac{1}{\Lambda}\left[\sum_V \xi_V \mathcal{T}^V_{\mu\nu}X^{\mu\nu} + \sum_f \xi_f \mathcal{T}^f_{\mu\nu}X^{\mu\nu}\right], \tag{11.22}$$

where the strength of the interaction is determined by the couplings ξ_V and ξ_f. The simplest scenarios, referred to as universal couplings (UC), correspond to $\xi_V = \xi_f$. They predict a large branching ratio to photons (of approximately 5%) and negligible couplings to massive gauge bosons (W and Z). They are therefore disfavoured, and other models are investigated where the couplings of the W, Z and γ are assumed to be independent. Universality of the couplings refers to $\xi_g = \xi_q$. Two other scenarios are considered: $\xi_q = 0$ and $\xi_q = 2\xi_g$. In these scenarios, a large enhancement of the tail of the transverse momentum of the spin-2 state is expected and requires a further selection requirement in order to probe the models within the range of validity of the effective field theory. Two requirements are considered, $p_T^X < 300\,\mathrm{GeV}$ and $p_T^X < 125\,\mathrm{GeV}$ [219]. The analysss of these benchmarks are discussed below and results are illustrated in Fig. 11.9.

11.5.1.3 *Probing fixed J^P scenarios*

At the LHC, the determination of the spin and CP properties of the Higgs boson is done independently from the total rates measurement, it uses a global angular helicity analysis and, when applicable, the study of threshold effects. The channels used for this analysis, $H \to \gamma\gamma$, $H \to WW^{(*)} \to \ell\nu\ell\nu$ and $H \to ZZ^{(*)} \to 4\ell$, are those where the observation of a signal is unambiguous.

At the Tevatron, an analysis using the threshold distribution in the associated production mode VH with subsequent decay to a pair of b quarks was performed by the D0 collaboration.

i. *The VH production at D0*

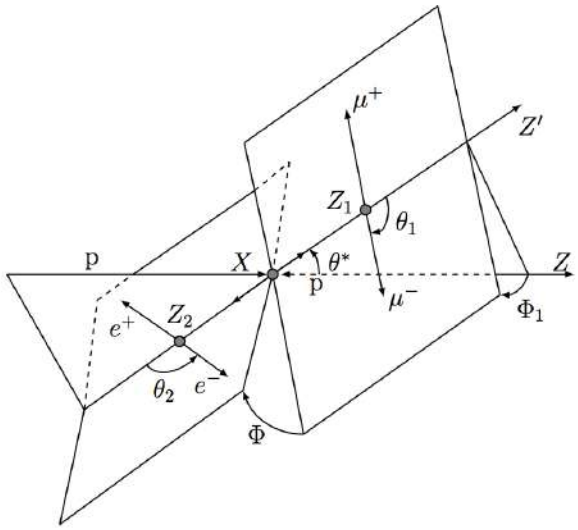
The mass of the VH system is a powerful discriminant to distinguish a $J^P = 0^+$, with a threshold behaviour in $d\sigma/dM^2 \sim \beta, \beta^3, \beta^5$ from a 0^+, 0^- and 2^+ state, respectively [222]. The VH mass observable not only discriminates signal hypotheses, but also has an increased separation between the 0^- and 2^+ hypotheses with respect to the backgrounds, thus allowing, with a small and not yet significant signal yield, to exclude that the observed state is 0^- at 98% CL [223] and 2^+ at the 99.9% CL [224], assuming a signal produced with their best fit signal strength (which was $\mu = 1.23$).

ii. *The $\gamma\gamma$ channel at the LHC*

In the $H \to \gamma\gamma$ channel, the analysis is performed inclusively using the production angle $\cos\theta^*_{CS}$ and the transverse momentum of the diphoton pair [219]. The polar angle in the rest frame is defined with respect to the bisector axis of the momenta of the incoming protons and is referred to as the polar angle in the Collins–Soper frame [225]. The SM Higgs boson signal distribution is expected to be uniform with a cutoff due to the selection requirements on the photons transverse momentum. The $H \to \gamma\gamma$ channel is mostly sensitive to the gluon-initiated spin-2 production scenarios, which yield a $\cos\theta^*_{CS}$ distribution peaking at values close to 1. The ATLAS limits are derived from a fit of the signal in bins of $\cos\theta^*_{CS}$ and diphoton transverse momentum and are summarised in Fig. 11.9 (right) (only combined results are shown). The data shows a good compatibility with the SM 0^+ hypothesis and contributes strongly to the exclusion of several spin-2 scenarios. The conclusions are the same from CMS results [220].

iii. *The $H \to WW^{(*)} \to \ell\nu\ell\nu$ channel at the LHC*

In the $H \to WW^{(*)} \to \ell\nu\ell\nu$ channel, the production and decay angles cannot be easily reconstructed due to the presence of neu-



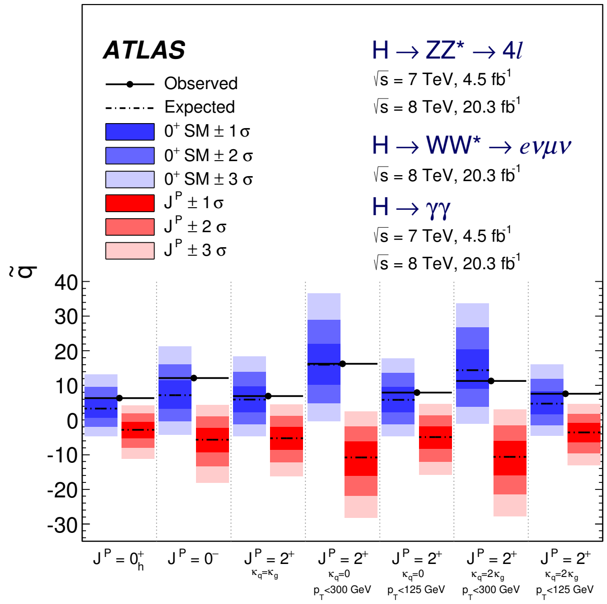


Figure 11.9: (Left) Definition of the production and decay angles defined for the $H \to ZZ^{(*)} \to 4\ell$ final state [220]. (Right) Expected distributions of the test statistic for the SM hypothesis (in blue) and several alternative spin and parity hypotheses (in red).

trinos in the final state, however, sensitivity arises from the $V-A$ structure of the decay of the W bosons. A scalar state thus yields a clear spin correlation pattern that implies that the charged leptons e or μ from the decays of the W bosons are produced close to one another in the transverse plane. This feature impacts observables such as the azimuthal angle between the two leptons $\Delta\Phi_{\ell\ell}$ or their invariant mass $m_{\ell\ell}$ in addition to the threshold behaviour of the decay. It can be used to discriminate between various spin and parity hypotheses. The approach adopted by ATLAS uses a multivariate discriminant, whereas CMS uses a 2D-fit of the dilepton mass and the transverse mass. Figure 11.9 (right) summarises the ATLAS results of the $H \to WW^{(*)} \to \ell\nu\ell\nu$ analyses alone and in combination with other channels. Spin-1 hypotheses (1^+ and 1^-) have also been tested in this channel by ATLAS and CMS. ATLAS and CMS exclude the 1^+ and 1^- hypotheses at more than 95% CL.

iv. *The $H \to ZZ^{(*)} \to 4\ell$ channel at the LHC*

The $H \to ZZ^{(*)} \to 4\ell$ coupling analysis, as described in Section 11.3, also uses a discriminant based on the 0^+ nature of the Higgs boson to further separate signal and background. In this analysis, this feature is used to discriminate between signal hypotheses. The observables sensitive to the spin and parity are [226] the masses of the two Z bosons (due to the threshold dependence of the mass of the off-shell Z boson), two production angle θ^* and Φ_1, and three decay angles, Φ, θ_1 and θ_2. The production and decay angles are defined as:

– θ_1 and θ_2, the angles between the negative final state lepton and the direction of flight of Z_1 and Z_2 in the rest frame.

– Φ, the angle between the decay planes of the four final state leptons expressed in the four lepton rest frame.

– Φ_1, the angle defined between the decay plane of the leading lepton pair and a plane defined by the vector of the Z_1 in the four lepton rest frame and the positive direction of the proton axis.

– θ^*, the production angle of the Z_1 defined in the four lepton rest frame with respect to the proton axis.

These angles are illustrated in Fig. 11.9 (left). There are two approaches to this analysis. The first, used by CMS, is a matrix element likelihood approach where a kinematic discriminant is defined based on the ratio of the signal and background probabilities. These probabilities are defined using the leading-order matrix elements. A similar approach is also performed by ATLAS as a cross check of their main result. The main approach adopted by ATLAS is the combination of sensitive observables with a Boosted Decision Tree. These analyses are sensitive to various J^P hypotheses and in particular discriminate the 0^+ hypothesis from the 0^-. In all scenarios investigated, and for both ATLAS and CMS, the data is compatible with the 0^+ hypothesis. ATLAS and CMS exclude a pure pseudo-scalar nature of the observed boson at CL_S levels of 98% and 99.8% [220].

11.5.1.4 *Probing CP-mixing and anomalous HVV couplings*

The careful study of the kinematic properties of the events observed in the $H \to ZZ^{(*)} \to 4\ell$ and $H \to WW^{(*)} \to \ell\nu\ell\nu$ channel, and in particular the angular distributions described above, allows one to further probe the HVV coupling beyond testing fixed hypotheses. Assuming that the observed particle is a spin-0 state, and using several discriminating observables in the $H \to ZZ^{(*)} \to 4\ell$ and $H \to WW^{(*)} \to \ell\nu\ell\nu$ channels, the anomalous terms in the formalism of Eq. (11.20) can be probed. In the approach of helicity amplitudes used by CMS [220], all terms are essentially equivalent, except for one additional phase which is neglected in Eq. (11.20).

Results are derived in terms of the parameters $\tilde{\kappa}_{HVV} = v\,\kappa_{HVV}/\Lambda$ and $\tilde{\kappa}_{AVV} = v\,\kappa_{AVV}/\Lambda$, and, more precisely, as measurements of $\tilde{\kappa}_{HVV}/\kappa_{\mathrm{SM}}$ and $\tan\alpha \cdot \tilde{\kappa}_{AVV}/\kappa_{\mathrm{SM}}$, as shown in Fig. 11.10. These parameters can be interpreted as mixing parameters of a tensor anomalous CP-even coupling and a CP-odd component. The measurements are made in the $H \to ZZ^{(*)} \to 4\ell$ and $H \to WW^{(*)} \to \ell\nu\ell\nu$ channels independently and then combined assuming that the $\tilde{\kappa}_{HVV}/\kappa_{\mathrm{SM}}$ and $\tan\alpha \cdot \tilde{\kappa}_{AVV}/\kappa_{\mathrm{SM}}$ are the same for the W and Z vector bosons. Only the combination of the WW and ZZ channels is shown in Fig. 11.10. The asymmetric shape of the likelihood as a function of $\tilde{\kappa}_{HWW,\,HZZ}/\kappa_{\mathrm{SM}}$ is mainly due to the interference between the BSM and the SM contributions that gives a maximal deviation from the SM predictions for negative relative values of the BSM couplings. In Fig. 11.10, the expected likelihood profiles for a SM Higgs boson are also displayed. While no significant deviation from the SM expectation is observed, the precision of the measurements of the mixing parameters is fairly low. The results and conclusions from the CMS measurements [220] are very similar.

An individual ZZ^* channel measurement has also been carried out with a partial Run 2 dataset by ATLAS [227]. CMS has performed a CP-mixing analysis of a partial Run 2 dataset of $36\,\mathrm{pb}^{-1}$ combined with the full Run 1 data using the ZZ^* channel [228]. In this analysis the CMS experiment sets constraints on the following parameters defined in the scattering amplitude

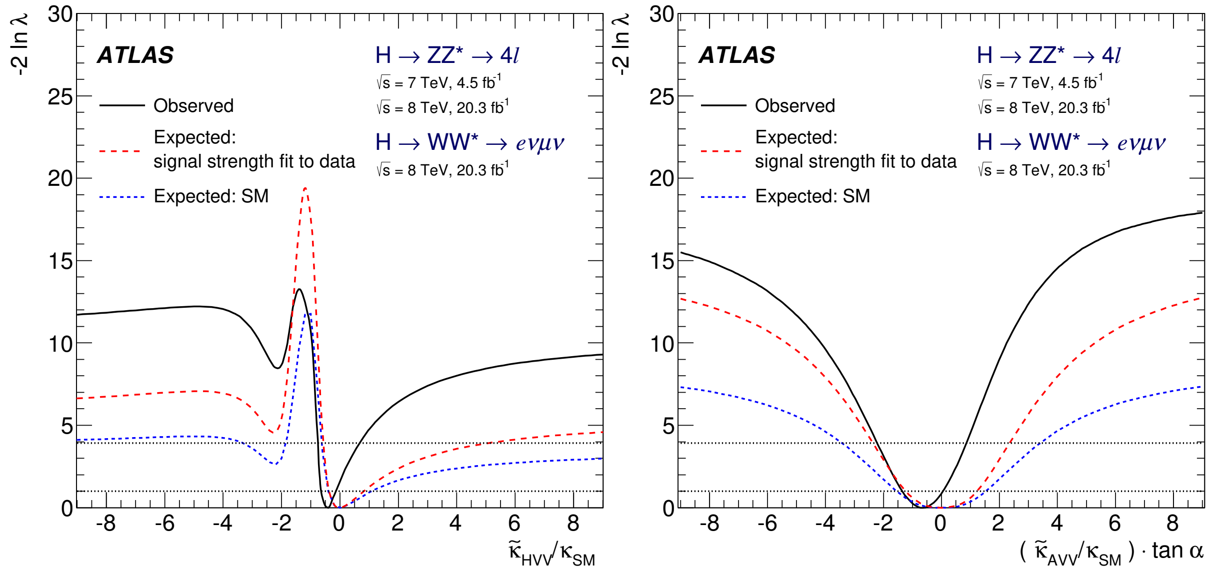

Figure 11.10: Likelihood profiles for the $\tilde{\kappa}_{HVV}$ and $\tilde{\kappa}_{AVV} \cdot \tan\alpha$ parameters, representing respectively CP-even and CP-odd anomalous couplings of the Higgs boson.

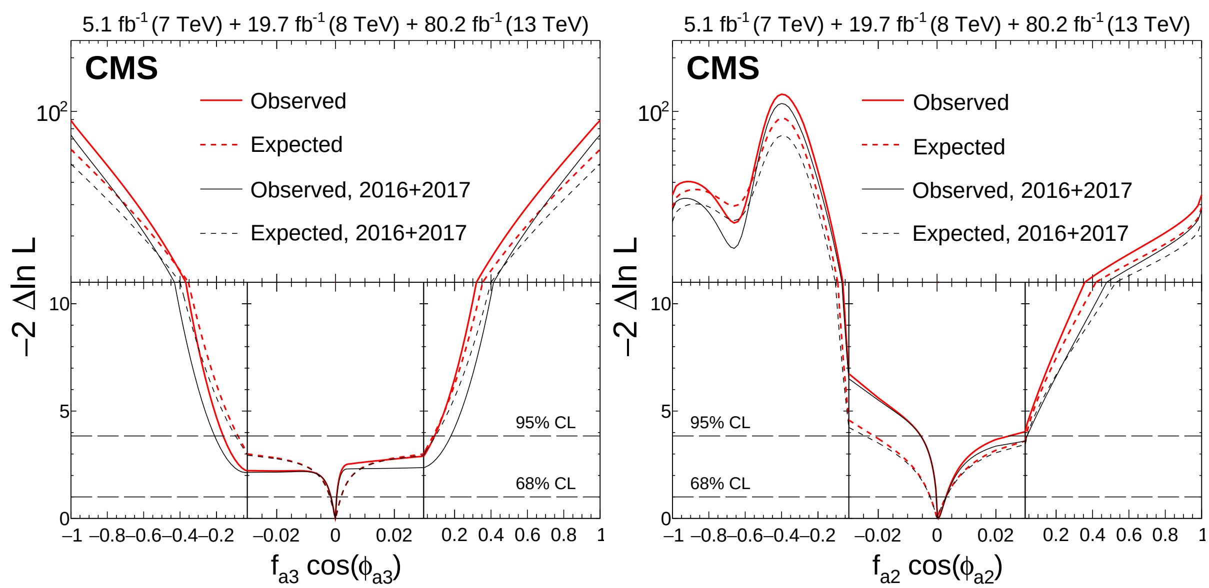

Figure 11.11: Observed (solid) and expected (dashed) likelihoods as a function of $f_{a3}\cos(\phi_{a3})$ (left), $f_{a2}\cos(\phi_{a2})$ (right) for the Run 1 and Run 2 datasets separately and combined.

parametrisation (11.21):

$$f_{a_i} = \frac{|a_i|^2\sigma_i}{\sum_{j=1,2,3}|a_j|^2\sigma_j}, \quad \phi_{a_i} = \arg\left(\frac{a_i}{a_1}\right), \tag{11.23}$$

where σ_i is the cross section for process with $a_i = 1$ and $a_{j\neq i} = 0$. The constraints on these parameters are shown in Fig. 11.11.

CP invariance in the HVV coupling can also be probed with the VBF production process in the $H \to \tau^+\tau^-$ channel. CMS has performed an analysis in this channel and has combined its results with the aforementioned ZZ^* channel using the same dataset [229].

ATLAS has also performed an analysis using optimal observables [230], defined as the ratio of the interference between the CP-odd and the SM contributions normalised to the SM matrix element squared, using the Run 1 data. In this study, the CP-mixing contributions are described in the framework of an effective field theory governed by a single parameter $\tilde{d}$, found to be consistent with its SM value of $\tilde{d} = 0$ and constrained to the interval [-0.11,0.05] at the 68% CL.

11.5.2 *Off-shell couplings of the Higgs boson*

In the dominant ggF production mode with a subsequent decay of the Higgs boson into a pair of Z bosons, the production cross section of an off-shell Higgs boson is known to be sizeable. This follows as a consequence of the enhanced couplings of the Higgs boson to the longitudinal polarisation of the massive vector bosons at high energy.

The off-shell to on-shell cross section ratio is approximately 8% in the SM [231]. Still the Higgs contribution to VV production at large invariant mass remains small compared to the background. It is nevertheless interesting to probe Higgs production in this regime as it is sensitive to new physics beyond the SM.

The difficulty in the off-shell VV analysis, beyond the small signal-to-background ratio, is due to a large negative interference between the signal and the $gg \to VV$ background.

The resulting presence of a SM Higgs boson signal in the far off-shell domain results in a deficit of events with respect to the expectation from background only events. It is only when the off-shell couplings of the Higgs boson are larger than expected in the SM that the presence of a signal appears as an excess over the background expectation. One additional intricacy arises from the precision in the prediction of the rate for $gg \to VV$, a loop process at lowest order, and its interference with the signal. At the time of the publication of the original ATLAS and CMS results, a full NLO prediction had not been computed.

It is interesting to note that, in this regime, the Higgs boson is studied as a propagator and not as a particle. The measurement of its off-shell couplings is therefore absolute and does not rely on the knowledge of the total Higgs boson width. The off-shell coupling constraints can then be used to indirectly constrain the width of the Higgs boson, under specific assumptions detailed in Section 11.5.3.3.

This measurement has been carried out in the $H \to ZZ \to 4\ell$, $H \to ZZ \to \ell\ell\nu\nu$ and $H \to WW \to \ell\nu\ell\nu$ channels. To enhance the sensitivity of the analysis, the knowledge of the full kinematics of the events is important. In particular the signal and the background can be further distinguished by the invariant mass of the VV system, which is more accurately accessible in the $H \to ZZ \to 4\ell$ channel. Angular distributions also play an important role in this analysis. For these reasons, the $H \to ZZ^{(*)} \to 4\ell$ channel is significantly more sensitive than $H \to WW^{(*)} \to \ell\nu\ell\nu$. The CMS results in Refs. [232] include the VBF and VH processes through the selection of two additional jets in the final state. The ATLAS results do not have a specific selection for the VBF or VH production processes, but their contributions are taken into account.

Limits on the off-shell rates have been reported for the two channels by ATLAS [233] and CMS [232]. The combined results, assuming that the off-shell rates in the ZZ and WW channels scale equally, are given for two different hypotheses on the VBF production rate: fixing it to its SM value or scaling it as the gluon fusion rate. The observed (expected) limits on the off-shell rate fraction with respect to its SM expectation is 6.7 (9.1) for ATLAS [233] with the VBF rate fixed to its SM value and 2.4 (6.2) for CMS [232] where no assumption is made on the relative production rates of gluon-fusion and VBF. In both cases, the custodial symmetry is assumed and the ratio of the rates in the ZZ and WW decays are fixed to those of the SM. Results without this assumption have also been reported in Ref. [232].

Both ATLAS [234] and CMS [228] have performed off-shell Higgs boson analyses to constrain the off-shell Higgs boson production rates with partial Run 2 datasets, corresponding respectively to luminosities of $36.1\,\mathrm{fb}^{-1}$ and $80.2\,\mathrm{fb}^{-1}$. With the increase in centre-of-mass energy and luminosities, significantly better sensitivities are achieved. The ATLAS analysis is based on two decay channels, $H \to 4\ell$ and $H \to 2\ell 2\nu$, and the two main ggF and VBF production modes, while the CMS analysis is based on the $H \to 4\ell$ channel exclusively, but uses the exclusive VH categories. The results obtained have already reached an impressive sensitivity, with 95% CL upper limits on the off shell signal strength $\mu_{\mathrm{off-shell}}$:

$$\begin{aligned} &(\mathrm{ATLAS})\ \ \mu_{\mathrm{off-shell}} < 3.8\ (\mathrm{obs})\ \ [3.4\ (\mathrm{exp})], \\ &(\mathrm{CMS})\ \ \mu_{\mathrm{off-shell}} < 2.28\ (\mathrm{obs})\ \ [3.2\ (\mathrm{exp})]. \end{aligned} \tag{11.24}$$

11.5.3 *The Higgs boson width*

In the SM, the Higgs boson width is very precisely predicted once the Higgs boson mass is known. For a mass of 125 GeV, the Higgs boson has a very narrow width of 4.1 MeV [44]. It is dominated by the fermionic decays partial width at approximately 75%, while the vector boson modes are suppressed and contribute 25% only.

At the LHC or the Tevatron, in all production modes, only the cross sections times branching fractions can be measured. As a consequence, the total width of the Higgs boson cannot be inferred from measurements of Higgs boson rates. Direct constraints on the Higgs boson width are much larger than the expected width of the SM Higgs boson.

11.5.3.1 *Direct constraints*

Analyses of the reconstructed mass line-shape in the two channels with a good mass resolution, the $H \to \gamma\gamma$ and $H \to ZZ^{(*)} \to 4\ell$ channels, allow for a direct measurement of the width of the SM Higgs boson. The intrinsic mass resolution in these channels is about 1–2 GeV, much larger than the expected width of the SM Higgs boson. As a result, only upper limits on the Higgs boson width have been set by ATLAS [235] and CMS [236]. The two main challenges of direct constraints on the width through the measurement of the line-shape are: (i) the modelling of resolution uncertainties and (ii) the modelling of the interference between the signal and the continuum background which can be sizeable for large widths, in particular in the range where direct constraints are set. Given that these interference effects are small with respect to the individual channels sensitivity, they are neglected in deriving constraints on the total width. The combined constraints, however, being more precise, could be affected by the interference. ATLAS [235] has therefore not combined the constraints on the width from the two channels. The results are reported in Table 11.11. These constraints are still three orders of magnitude larger than the expected SM width and are fully compatible with the SM hypothesis.

Another direct constraint on the Higgs boson width can be obtained, in the $H \to ZZ^{(*)} \to 4\ell$ channel, from the measurement of the average lifetime of the Higgs boson calculated from the displacement of the four-lepton vertex from the beam spot. This analysis has been carried out by CMS (see references in Ref. [123]), using the measured decay length. The measured $c\tau_H$ is $2^{+25}_{-2}\,\mu$m, yielding an observed (and expected) limit at the 95% CL of $c\tau_H < 57(56)\,\mu$m. From this upper limit on the lifetime of the Higgs boson, the 95% CL lower limit on its width is $\Gamma_H > 3.5 \times 10^{-12}$ GeV.

11.5.3.2 *Indirect constraints from mass shift in the diphoton channel*

In the diphoton channel, it was noticed in Ref. [237], that the effect of the interference between the main signal $gg \to H \to \gamma\gamma$ and the continuum irreducible background $gg \to \gamma\gamma$, taking into account detector resolution effects, is responsible for a non negligible mass shift. The size of the mass shift depends on the total width of the Higgs boson and it was suggested that measuring this mass shift could provide a constraint on the width [237]. It was further noticed that the mass shift has a dependence also on the diphoton transverse momentum. The total width of the Higgs boson could therefore be constrained using the diphoton channel alone.

Further studies were performed by ATLAS to estimate the size of the expected mass shift [134]. The expected shift in mass in the diphoton channel is 35±9 MeV for the SM Higgs boson. Very preliminary studies of the sensitivity of this method to estimate the width of the Higgs boson in the High-Luminosity regime have been made by ATLAS [238] and yield an expected 95% CL upper limit on the total width of approximately 200 MeV from $3\,\mathrm{ab}^{-1}$ of 14 TeV data.

11.5.3.3 *Indirect constraints from on-shell rate in the diphoton channel*

In the diphoton channel, it was noticed in Ref. [239], that the interference between the main signal $gg \to H \to \gamma\gamma$ amplitude and the continuum irreducible background $gg \to \gamma\gamma$ amplitude generates non-negligible change in the on-shell cross sections, as a result of the existence of a relative phase between these amplitudes. The size of this on-shell interference effect depends on the total width of the Higgs boson and it was suggested that measuring this on-shell cross section precisely could provide a constraint on the Higgs total width. This interference effect yields around 2% reduction for the $gg \to H \to \gamma\gamma$ cross section measurement. The current evaluation of this interference effect is performed at NLO and has a $^{+50\%}_{-30\%}$ uncertainty, due to the fact that the large relative phase is driven by the two-loop $gg \to \gamma\gamma$ background amplitude [237, 239]. This on-shell interference effect has a dependence on the p_T of the diphoton system and the photon polar angle in the diphoton rest frame, which can be further exploited to improve the measurement to constrain the Higgs total width.

Taking the ratios of the on-shell cross section of Higgs boson to diphoton channel and the cross section of Higgs boson to four-leptons channel where the interference effect is negligible could put bound on the Higgs boson total width. This ratio is free

Table 11.11: Run 1 observed (expected) direct 95% CL constraints on the width of the 125 GeV resonance from fits to the $\gamma\gamma$ and ZZ mass spectra and to the 4ℓ vertex lifetime. *The CMS measurement from the 4ℓ mass line-shape was performed using Run 2 data.

Exp.	$M_{\gamma\gamma}$ mass spectrum	$M_{4\ell}$ spectrum	4ℓ vertex lifetime
ATLAS	$< 5.0\,(6.2)$ GeV	$< 2.6\,(6.2)$ GeV	—
CMS	$< 2.4\,(3.1)$ GeV	$< 1.1\,(1.6)$ GeV*	$> 3.5 \times 10^{-12}$ GeV

from many dominant sources of systematic uncertainties for cross section measurements, i.e., PDF uncertainty and luminosity uncertainty, and can be further improved by the accumulation of the LHC data. From this cross section ratio measurement alone, a preliminary estimation of the current limit from this interference effect with current 30% precision puts an upper bound of 800 MeV on the Higgs boson total width and the limit improves to 60 MeV with 3 ab^{-1} of 14 TeV data [239, 240].

11.5.3.4 *Indirect constraints from off-shell couplings*

Using simultaneously on-shell and off-shell measurements in the VV channels, it was noticed [231, 241] that the total width of the Higgs boson could be constrained. This can be illustrated from the parametrisation of the signal strength measurements both on-shell ($\mu_{\mathrm{on-shell}}$) and off-shell ($\mu_{\mathrm{off-shell}}$) as a function of the couplings modifiers κ_g and κ_V parameterising the main process $gg \to H \to VV$ (see Section 11.6.2 for the definition of these coupling modifiers). The on-shell and off-shell signal strengths can be written as:

$$\mu_{\mathrm{on-shell}} = \frac{\kappa^2_{g,\,\mathrm{on-shell}}\,\kappa^2_{V,\,\mathrm{on-shell}}}{\Gamma_H/\Gamma_{\mathrm{SM}}}, \qquad \mu_{\mathrm{off-shell}} = \kappa^2_{g,\,\mathrm{off-shell}}\,\kappa^2_{V,\,\mathrm{off-shell}}. \tag{11.25}$$

A bound on the Higgs boson width can then be obtained from the measurements of the on-shell and off-shell signal strengths. This assumes that no new physics alters the Higgs boson couplings in the off-shell regime, i.e., that the running of its couplings is negligible in the off-shell regime [242, 243]. Both ATLAS [233] and CMS [232] have used their off-shell production limits to constrain the width of the Higgs boson.

Both ATLAS and CMS analyses use the kinematic event characteristics to further gain in sensitivity to discriminate between the signal and background. The ATLAS analysis assumed that there are no anomalous couplings of the Higgs boson to vector bosons, and obtains 95% CL observed (expected) upper limit on the total width of $5.7\times\Gamma_{\mathrm{SM}}$ ($9.0\times\Gamma_{\mathrm{SM}}$) with the Run 1 dataset. In the CMS analysis, the observed (expected) limit on the total width is $6.2\times\Gamma_{\mathrm{SM}}$ ($9.8\times\Gamma_{\mathrm{SM}}$) for the ZZ channel only at Run 1.

In addition, in the CMS analysis, results are also derived allowing for anomalous couplings of the Higgs boson, therefore reducing the discriminating power of the kinematic variables used in the analysis but reducing the model dependence. The observed (expected) limit on the total width is $10.9\times\Gamma_{\mathrm{SM}}$ ($17.4\times\Gamma_{\mathrm{SM}}$).

CMS has also combined the ZZ and W^+W^- channels while keeping the gluon-fusion and VBF production processes separate. For the gluon fusion mode, the observed (expected) combined upper limit at the 95% CL on the total width of the Higgs boson is $2.4\times\Gamma_{\mathrm{SM}}$ ($6.2\times\Gamma_{\mathrm{SM}}$) [232], while for the VBF production mode the exclusion limits are $19.3\times\Gamma_{\mathrm{SM}}$ ($34.4\times\Gamma_{\mathrm{SM}}$) [232].

At Run 2, using the ATLAS [234] and CMS [228] analyses described in Section 11.5.2, the following bounds were obtained:

$$\text{(ATLAS)}\ \ \Gamma_H/\Gamma_H^{SM} < 3.5\ \ [3.7\ \text{(exp)}], \tag{11.26}$$

$$\text{(CMS)}\ \ \Gamma_H < 9.16\ \ [13.7\ \text{(exp)}]\ \text{MeV}$$
$$\text{or}\ \ \Gamma_H\Gamma_H^{SM} = 3.2^{+2.8}_{-2.2}\ \ [4.1^{+5.0}_{-4.0}\ \text{(exp)}]. \tag{11.27}$$

CMS has also performed this analysis considering possible anomalous HZZ couplings as discussed in Section 11.5.1.4. Neither the results nor the sensitivities are significantly affected by allowing specific anomalous coupling parameters to float in the fits.

ATLAS and CMS have also performed a study of the prospects for measuring the Higgs boson width mainly in the four lepton channel. Projecting to a luminosity of 3 ab^{-1}, it was concluded that, within assumptions similar to the ones mentioned above and assuming the SM central value, the observed (expected) combined upper limit at the 95% CL on the total width of the Higgs boson would be $3.8\times\Gamma_{\mathrm{SM}}$ ($3.4\times\Gamma_{\mathrm{SM}}$), i.e., the width of the Higgs boson could be constrained with the following precision [104]:

$$\Gamma_H = 4.1^{+0.7}_{-0.8}\ \text{MeV}. \tag{11.28}$$

11.6 Probing the coupling properties of the Higgs boson

As discussed in Section 11.2, within the SM, all the Higgs boson couplings are fixed unambiguously once all the particle masses are known. Any deviation in the measurement of the couplings of the Higgs boson could therefore signal BSM physics.

Measuring the Higgs boson couplings without relying on the SM assumption requires a general framework treating deviations from the SM coherently at the quantum level in order to provide theoretical predictions for relevant observables to be confronted with experimental data. An attempt in that direction has been formalised in the so-called κ-formalism [244], following earlier attempts [245] and initial phenomenological studies of the first hints of the existence of the Higgs boson [246]. In this LO-inspired approach, the SM Higgs boson couplings are rescaled by arbitrary factors, κ's, keeping the same Lorentz structure of the interactions. This formalism allows for simple interpretation of the signal strengths measured in the various Higgs channels. It it has been utilised to test various physics scenarios, like the existence of additional new particles contributing to the radiative Higgs boson production and decays, or to probe various symmetries of the SM itself, as for example the custodial symmetry. It only compares the experimental measurements to their best SM predictions and does not require any new BSM computations per se. And, from a more theoretical perspective, its relevance arises from the fact that it actually fully captures the leading effects in single Higgs processes of well motivated scenarios. Still, the κ-formalism has obvious limitations and certainly does not capture the most general deformations of the SM, even under the assumptions of heavy and decoupling new physics. A particularly acute shortcoming at the time Higgs physics is entering a precision era is the lack of proficiency to assert the richness of kinematical distributions beyond simple signal strength measurements. Several extensions and alternative approaches are being developed as part of the activities of the LHC Higgs Cross Section Working Group [45].

The Higgs Pseudo-Observable (HPO) approach [247] allows one to report the data in terms of a finite set of on-shell form factors parametrising amplitudes of physical processes subject to constraints from Lorentz invariance and other general requirements like analyticity, unitarity, and crossing symmetry. These form factors are expanded in powers of kinematical invariants of the process around the known poles of SM particles, assuming that poles from BSM particles are absent in the relevant energy regime. A set of HPOs have been proposed to characterise both the Higgs boson decays and the EW Higgs boson production channels, thus exploring different kinematical regimes. Prospective studies concluded that these HPOs can be measured/bounded at the percent level at the HL-LHC and could therefore be used to constrain some explicit models of new physics.

Another systematic approach to characterise the possible Higgs boson coupling deviations induced by BSM physics is the use of Effective Field Theories (EFT) [248, 249]. This approach assumes again that the new physics degrees of freedom are sufficiently heavy to be integrated out and they give rise to effective interactions among the light SM particles. By construction, the effective Lagrangians cannot account for deviations in Higgs physics induced by light degrees of freedom, unless they are added themselves as extra fields in the effective Lagrangians. In Section 11.7, several examples of models with light degrees of freedom affecting Higgs boson production and decay rates will be presented. The main advantage of EFTs is their prowess to relate different observables in different sectors and at different energies to constrain a finite set of effective interactions among the SM degrees of freedom. In an EFT, the SM Lagrangian is extended by a set of higher-dimensional operators, and it reproduces the low-energy limit of a more fundamental UV description. It will be assumed that the Higgs boson is part of a CP-even EW doublet, Φ, and that the Lagrangian is an analytic function of the gauge invariant $\Phi^\dagger\Phi$. This scenario is commonly refereed as SMEFT. Even though it is not fully established experimentally, this set-up is motivated by the measurements of the Higgs couplings to the different SM particles that show an alignement with their masses, such an alignement naturally follows under this assumption of a linear realisation of the $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ symmetry of the SM but would require an ad-hoc tuning otherwise. General Lagrangians bypassing this linear assumption have been explicitly written down, see for instance Ref. [250]. They rely on a chiral expansion with a specific power-counting, effectively resumming the expansion in powers of the Higgs field, usually referred as HEFT as opposed to SMEFT.

11.6.1 *Effective Lagrangian framework*

The SMEFT has the same field content and it respects the same linearly-realised $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ local symmetry as the SM. The difference is the presence of operators with canonical mass-dimension d larger than 4. These are organised in a systematic expansion in d, where each consecutive term is suppressed by a larger power of a high mass scale. Assuming baryon and lepton number conservation, the most general Lagrangian takes the form

$$\mathcal{L}_{\mathrm{eff}} = \mathcal{L}_{\mathrm{SM}} + \sum_i c_i^{(6)} \mathcal{O}_i^{(6)} + \sum_j c_j^{(8)} \mathcal{O}_j^{(8)} + \cdots . \tag{11.29}$$

The contribution of the higher order operators of dimension d to physical amplitudes is suppressed by $(E/\Lambda)^{d-4}$, where E is the relevant energy scale of the process and Λ is the energy scale suppressing the higher-dimensional operators. The Wilson coefficients $c_i^{(d)}$ encode the virtual effects of the heavy new physics in low-energy observables. Their precise forms in terms of masses and couplings of the new particles can be obtained via matching with the ultraviolet (UV) completion of the SM, see, e.g., Ref. [251], or inferred using specific power-counting rules [248, 252].

The list of dimension-6 operators was first classified in a systematic way in Ref. [253] after the works of Ref. [254]. Subsequent analyses pointed out the presence of redundant operators, and a minimal and complete list of operators was finally provided in Ref. [255][4]. For a single family of fermions, there are 76 real ways to deform the SM generated by 59 independent operators. With the 3 families of fermions of the SM, flavour indices can be added to these 59 operators, and furthermore, new operator structures, that have been dismissed by means of Fierz transformations in the single family case, have to be considered, for a total of 2499 real deformations [258]. When considering Higgs data, one can reasonably focus on a relatively small subset of the 2499 operators of dimension 6. In particular the vast subset of 4-fermion operators, whether flavour and CP preserving or not, can be more strongly constrained by other processes. Thus, it makes sense to neglect this whole class, with the exception of one particular four-fermion interaction that contributes to the muon decay and thus directly affects the Fermi constant. The dipole operators, instead do directly affect Higgs boson production, however, under very general and plausible assumptions on the flavour structure of new physics, the coefficients of these operators display the same structure and the same chiral suppression of the Yukawa couplings. The consequence is that, with the possible exception of processes involving the top quark, their effect in Higgs boson production is expected to be negligible. Furthermore, as far as Higgs boson decays are concerned, the dipole operators only contribute to three (or more)-body final states (for instance $H \to \bar{b}b\gamma$) and as such they can easily be neglected too. Eliminating these two classes, there remain three other classes: 1) purely bosonic operators, 2) generalised Yukawas, 3) Higgs-fermion current operators. Operators in class 2 and 3, per se, can still contain CP- or flavour-violating terms, on which experimental constraints are rather strong. Under the assumption of flavour universality (respectively diagonality), one is left with 12 (14) parameters affecting EW precision measurements, diboson processes and single- and double-Higgs data and 7 (17) other parameters modifying the EW gauge boson couplings to fermions, see Ref. [44] for further technical details. Working in the unitary gauge and performing suitable redefinition of fields and input parameters the effective Lagrangian can be conveniently expressed in the parameterisation of Ref. [259], the so-called *Higgs basis* that conveniently single out these special less constrained parameters. Such a classification reflects the current experimental situation and the hierarchy in the sensitivity of the experimental measurements in the various sectors of the SM. As the sensitivity of the measurements in the Higgs sector improves, another and more general parametrisation of the SM deformation will have to be retained, in particular a parametrisation more suited for a treatment at the quantum level. In other bases of operators, in particular the so-called Warsaw basis [255] used in some experimental EFT analyses [128, 260, 261], one finds strong correlations among the operators affecting the EW gauge couplings to fermions, leaving 12 (14) linear combinations of operators with weaker constraints.

Section 11.6.2 illustrates how the Higgs data accumulated at the LHC can (partially) constrain the SM deformations, i.e., the dimension-6 operators of the SEMFT Lagrangian. Automatic tools are being developed to analyse the experimental data within an EFT framework, see the report [262] and references therein.

11.6.2 *Probing coupling properties*

As described in Section 11.3, a framework was developed by ATLAS and CMS [141], individually and together, to combine the very large number of exclusive categories aimed at reconstructing the five main decay modes and the five main production modes of the Higgs boson. The general conclusion of this combination, illustrating the compatibility of the observation with the SM expectations, is given in Section 11.3. The same framework with its master formula, Eq. (11.16), can be used to further measure coupling properties of the Higgs boson under specific additional assumptions.

11.6.2.1 *Combined measurements of the Higgs boson coupling properties*

i. *From effective Lagrangians to Higgs observables*

The κ framework, described in detail in Ref. [43, 244], facilitates the characterisation of Higgs coupling properties in terms of a series of Higgs coupling strength modifier parameters κ_i, which are defined as the ratios of the couplings of the Higgs bosons to particles i to their corresponding SM values. The κ framework assumes a single narrow resonance so that the zero-width approximation can be used to decompose the cross section as a product of two factors characterising the production and the decay of the Higgs boson. The κ parameters are introduced by expressing each of the these factors as their SM expectation multiplied by the square of a coupling strength modifier for the corresponding process at leading order:

$$\begin{aligned} (\sigma \cdot \mathrm{BR})(i \to \mathrm{H} \to f) &= \frac{\sigma_i^{SM} \kappa_i^2 \cdot \Gamma_f^{SM} \kappa_f^2}{\Gamma_H^{SM} \kappa_H^2} \quad \to \\ \to \quad \mu_i^f &\equiv \frac{\sigma \cdot \mathrm{BR}}{\sigma_{\mathrm{SM}} \cdot \mathrm{BR}_{\mathrm{SM}}} = \frac{\kappa_i^2 \cdot \kappa_f^2}{\kappa_H^2}, \end{aligned} \tag{11.30}$$

where μ_i^f is the rate relative to the SM expectation and κ_H^2 is an expression that adjusts the SM Higgs width to take into account the modifications induced by the deformed Higgs boson couplings. When all κ_i are set to 1, the SM is reproduced. For loop-induced processes, e.g. $H \to \gamma\gamma$, there is a choice of either resolving the coupling strength modification in its SM expectation,

[4] Complete enumerations of d=8 operators have been obtained [256] and some preliminary constraints on peculiar subsets of these operators have been derived from experimental measurements [257]. Still, in this review, the EFT Lagrangians will be truncated at the level of dimension-6 operators.

i.e., $\kappa_\gamma(\kappa_t, \kappa_W)$ or keeping κ_γ as an effective coupling strength parameter.

The κ-framework is the simplest parametrisation directly related to experimental measurements of the Higgs boson production and decay modes. For this reason, it has been widely used by the community. It can also be connected to the SMEFT formalism as follows. Restricting to the EFT directions not probed outside Higgs physics [263], the Higgs boson couplings are written in the unitary gauge as:

$$\begin{aligned}\mathcal{L} = &\kappa_Z \frac{m_Z^2}{v} Z_\mu Z^\mu H + \kappa_W \frac{2m_W^2}{v} W_\mu^+ W^{-\mu} H \\ &+ \kappa_{VV} \frac{\alpha}{2\pi v}\left(\cos^2\theta_W Z_{\mu\nu}Z^{\mu\nu} + 2\, W_{\mu\nu}^+ W^{-\mu\nu}\right) H \\ &+ \kappa_g \frac{\alpha_s}{12\pi v} G_{\mu\nu}^a G^{a\mu\nu} H + \kappa_\gamma \frac{\alpha}{2\pi v} A_{\mu\nu}A^{\mu\nu} H + \kappa_{Z\gamma}\frac{\alpha}{\pi v} A_{\mu\nu} Z^{\mu\nu} H \\ &+ \kappa_3 \frac{m_H^2}{2v} H^3 \\ &- \left(\kappa_t \sum_{f=u,c,t} \frac{m_f}{v} + \kappa_b \sum_{f=d,s,b} \frac{m_f}{v} + \kappa_\tau \sum_{f=e,\mu,\tau} \frac{m_f}{v}\right) f\bar{f}H.\end{aligned} \tag{11.31}$$

The exact correspondence between the effective coefficients of the dimension-6 operators and the κ's can be found for instance in Ref. [44]. In the SM, the Higgs boson does not couple to massless gauge bosons at tree level, hence $\kappa_g = \kappa_\gamma = \kappa_{Z\gamma} = 0$. Nonetheless, the contact operators are generated radiatively by SM particles loops. In particular, the top quark gives a contribution to the 3 coefficients $\kappa_g, \kappa_\gamma, \kappa_{Z\gamma}$ that does not decouple in the infinite top mass limit. For instance, in that limit $\kappa_\gamma = \kappa_g = 1$ [23, 24, 264].

The coefficient for the contact interactions of the Higgs boson to the W and Z field strengths is not independent but obeys the relation

$$(1 - \cos^4\theta_W)\kappa_{VV} = \sin 2\theta_W \kappa_{Z\gamma} + \sin^2\theta_W \kappa_{\gamma\gamma}. \tag{11.32}$$

This relation is a general consequence of the custodial symmetry [265], which also imposes $\kappa_Z = \kappa_W$ at leading order ($\kappa_Z/\kappa_W - 1$ is a measure of custodial symmetry breaking and, as such, is already constrained by electroweak precision data and the bounds on anomalous gauge couplings). When the Higgs boson is part of a $\mathrm{SU}(2)_L$ doublet, the custodial symmetry in the bosonic sector could only be broken by the $\mathcal{O}_T = \frac{1}{2}\left(\Phi^\dagger \overleftrightarrow{D}^\mu \Phi\right)^2$ operator at the level of dimension-6 operators and it is accidentally realised among the interactions with four derivatives, like the contact interactions considered.

The coefficient κ_3 can be accessed directly only through double Higgs boson production processes, hence it will remain largely unconstrained at the LHC. Before the associated production of a Higgs boson with a pair of top quarks was observed, the Higgs boson coupling to the top quark was only probed indirectly via the one-loop gluon fusion production or the radiative decay into two photons. However, these two processes are only sensitive to the combinations of couplings $(\kappa_t + \kappa_g)$ and $(\kappa_t + \kappa_\gamma)$ and not to the individual couplings. Therefore a deviation in the Higgs boson coupling to the top quark can in principle always be masked by new contact interactions to photons and gluons (and this is precisely what is happening in minimal incarnations of composite Higgs models [266]). The current and still limited sensitivity, of the order of 20%, in the $t\bar{t}H$ channel leaves elongated ellipses in the direction $\kappa_g = \kappa_\gamma = 1 - \kappa_t$.

The operators already bounded by EW precision data and the limits on anomalous gauge couplings modify in general the Lorentz structure of the Higgs couplings and hence induce some modifications of the kinematical differential distributions [267]. A promising way to have a direct access to the effective coefficients of these operators in Higgs physics is to study the VH associated production with a W or a Z at large invariant mass of the VH system [268]. These differential distributions could also be a way to test the hypothesis that the Higgs boson belongs to a $\mathrm{SU}(2)_L$ doublet together with the longitudinal components of the massive electroweak gauge bosons.

ii. *Interpretations of the experimental data*

The measurements of the coupling properties of the Higgs boson are entirely based on the formalism of the effective Lagrangian described above. Measurements of coupling properties in this framework implies assessing the parameters of the model Eq. (11.31) or combinations of these parameters with different sets of assumptions.

These measurements are carried out with the combination framework described in Section 11.4, where the μ_i and μ_f signal strength parameters are further interpreted in terms of modifiers of the SM couplings κ_k where $k \in \{Z, W, f, g, \gamma, Z\gamma\}$ as in Eq. (11.31). The number of signal events per category for the various production modes are typically estimated at higher orders in the analyses but are scaled by these single LO-inspired factors, thus not taking into account possible intricacies and correlations of these parameters through the higher-order corrections. This approximation is valid within the level of precision of current results and their compatibility with the SM expectation.

In this formalism, further assumptions are explicitly made: (i) the signals observed in the different search channels originate from a single narrow resonance with a mass of 125 GeV; (ii) similarly to the combination described in Section 11.4, the narrow width approximation is assumed (to allow the decomposition of signal yields into products of production and decay signal strengths); (iii) the tensor structure of the couplings is assumed to be the same as that of a SM Higgs boson. This means in particular that the observed state is assumed to be a CP-even scalar as in the SM.

Loop-level couplings such as the $gg \to H$, $H \to \gamma\gamma$ and $H \to Z\gamma$ can either be treated effectively, with κ_g, κ_γ and $\kappa_{Z\gamma}$ as free parameters in the fit or these parameters can be expressed in terms of the know SM field content and as a function of the SM coupling modifiers, in the following way [269]:

$$\begin{aligned}\kappa_g^2(\kappa_t, \kappa_b, \kappa_c) &= 1.042\,\kappa_t^2 - 0.040\,\kappa_t\kappa_b + 0.002\,\kappa_b^2 \\ &\quad - 0.005\kappa_t\kappa_c + 0.0005\kappa_b\kappa_c + 0.00002\kappa_c^2, \\ \kappa_\gamma^2(\kappa_F, \kappa_V) &= 1.59\,\kappa_V^2 - 0.66\,\kappa_V\kappa_F + 0.07\,\kappa_F^2, \\ \kappa_{Z\gamma}^2(\kappa_F, \kappa_V) &= 1.12\,\kappa_V^2 - 0.15\,\kappa_V\kappa_F + 0.03\,\kappa_F^2.\end{aligned} \tag{11.33}$$

The $\kappa_{Z\gamma}$ parametrisation has been used only in the ATLAS Run 1 combined measurements of the coupling properties of the Higgs boson. The $\mu^+\mu^-$ channels is included neither in the CMS and ATLAS-CMS Run 1 combinations, nor in the ATLAS [213] Run 2 individual combination, while it is included in the CMS [214] Run 2 combination.

The parametrisations are given for a Higgs boson mass hypothesis of 125.09 GeV (and in the last two expressions, all the Higgs-fermion couplings are assumed to be rescaled by an universal multiplicative factor κ_F). It can be noted from the expression of κ_γ that the coupling of the Higgs boson to photons is dominated by the loop of W bosons, and it is affected by the top quark loop mostly through its interference with the W loop. The sensitivity of the current measurements to the relative sign of the fermion and vector boson couplings to the Higgs boson is due to this large negative interference term. The κ_g parameter is expressed in terms of the scaling of production cross sections and therefore also depends on the pp collisions centre-of-mass energy. The parametrisations of κ_γ and $\kappa_{Z\gamma}$ are obtained from the scaling of partial widths and are only dependent on the Higgs boson mass hypothesis. Experiments use a more complete parametrisation with the contributions from the b-quarks, τ-leptons in the loops [43, 244].

The global fit is then performed expressing the μ_i and μ_f parameters in terms of a limited number of κ_k parameters or their ratios, under various assumptions. The parametrisation for the main production modes are: (i) $\mu_{\mathrm{ggF}} = \kappa_g^2$ for the gluon fusion and an effective coupling of the Higgs boson to the gluons; (ii) $\mu_{\mathrm{VBF},VH} = \kappa_V^2$ for the VBF and VH processes when the W and Z couplings are assumed to scale equally, and $\mu_{\mathrm{VBF}}^2(\kappa_W, \kappa_Z) = (\kappa_W^2\sigma_{WWH} + \kappa_Z^2\sigma_{ZZH})/(\sigma_{WWH} + \sigma_{ZZH})$, when the couplings to the W and Z bosons are varied independently (σ_{WWH} and

σ_{ZZH} denote the VBF cross sections via the fusion of a W and a Z boson respectively, the small interference term is neglected); (iii) $\mu_{t\bar{t}H} = \kappa_t^2$ for the $t\bar{t}H$ production mode. Numerically the production modes signal strengths as a function of the coupling modifiers to the SM fields are:

$$\begin{aligned}\mu_{\text{ggF}} &= 1.06\kappa_t^2 + 0.01\kappa_b^2 - 0.07\kappa_t\kappa_b, \quad \text{and} \\ \mu_{\text{VBF}} &= 0.74\kappa_W^2 + 0.26\kappa_Z^2.\end{aligned} \tag{11.34}$$

The decay mode signal strengths are parametrised as $\mu_k = \kappa_k^2/\kappa_H^2$ where $k \in \{Z, W, f, g, \gamma, Z\gamma\}$ denotes the decay mode and κ_H, the overall modifier of the total width that affects all the signal yields. κ_H is a priori an independent parameter. However, when it is assumed that the Higgs boson cannot decay to new particles beyond those of the SM, κ_H can also be treated as an effective parameter and expressed in terms of the coupling modifiers to the SM field content. Its general expression is:

$$\begin{aligned}\kappa_H^2 =&0.57\kappa_b^2 + 0.06\kappa_\tau^2 + 0.03\kappa_c^2 + 0.22\kappa_W^2 + 0.03\kappa_Z^2 + 0.09\kappa_g^2 \\ &+ 0.0023\kappa_\gamma^2.\end{aligned} \tag{11.35}$$

The general expression of the total width of the Higgs boson can be written as follows:

$$\Gamma_H = \frac{\kappa_H^2 \Gamma_H^{\text{SM}}}{1 - \text{BR}_{\text{BSM}}} \tag{11.36}$$

where Γ_H^{SM} is the total width of the SM Higgs boson and BR_{BSM} is the branching fraction of the Higgs boson to new particles beyond the SM.

Specific parametrisations will be made in order to address the following aspects of the coupling properties of the Higgs boson under different assumptions: (i) the relative couplings of the Higgs boson to fermions and bosons; (ii) the potential impact of the presence of new particles beyond the SM either in the loops or both in the loops and the decay of the H; and (iii) also, more general models either of coupling modifiers or their ratios, under different assumptions.

iii. *Couplings to bosons and fermions*

As it will be discussed in Section 11.7.6.3, it is interesting to probe a model where no additional field content is considered in the decay width of the Higgs boson and where the relative couplings of the Higgs boson to W- and Z-bosons is fixed to its SM value, i.e., $\kappa_W = \kappa_Z$, and where all Yukawa couplings scale with one coupling modifier. In this model, only the SM particles are assumed to contribute to the gluon fusion and the diphoton loops, and all fermion couplings modifiers are required to scale simultaneously with a unique factor κ_F while all vector boson couplings modifiers also scale with a common factor κ_V. It is a two-parameter fit with κ_V and κ_F as free variables of interest. The ATLAS-CMS combined results for each channel independently, the combinations of all channels for the two experiments separately and the results of the overall combination are all shown in Fig. 11.12.

The global fit is only sensitive to the relative sign of κ_V and κ_F. By convention, either κ_F or κ_V can be considered positive and negative values of κ_V or κ_F respectively can be considered. Such values are not excluded a priori, but would imply the existence of new physics at a light scale and would also raise questions about the validity of the perturbative treatment of the SM deformations and also about the stability of the vacuum [271]. Among the five main Higgs boson decay channels, only the $\gamma\gamma$ is sensitive to the sign of κ_F (or κ_V) through the interference of the W and t loops as shown in Eq. (11.33). The current global fit disfavours a negative value of κ_F at more than five standard deviations. A specific analysis for the Higgs boson production in association with a single top quark has been proposed in order to more directly probe the sign of κ_F (see references in Ref. [123]). All available experimental data show a fair agreement of the SM prediction of the couplings of the Higgs boson to fermions and gauge bosons. The results shown in Fig. 11.12 assume that $\kappa_F \geq 0$, however, in Ref. [141], a similar combination is done without this assumption.

The observed exclusion is fully compatible with the SM expectation The ATLAS and CMS combined measurements with the Run 1 dataset lead to

$$\kappa_V = 1.04 \pm 0.05 \quad \text{and} \quad \kappa_F = 0.98^{+0.11}_{-0.10}, \tag{11.37}$$

and were already at an impressive 5% level of accuracy for the κ_V parameter. The ATLAS Run 2 combination yielded:

$$\kappa_V = 1.05 \pm 0.04 \quad \text{and} \quad \kappa_F = 1.05 \pm 0.09. \tag{11.38}$$

And the results for the CMS Run 2 are reported as likelihood contours shown in Fig. 11.12.

iv. *Probing new physics in the loops (and the decay)*

A more constrained model fully focussing on BSM scenarios with new heavy particles contributing to the loops and where all couplings to the SM particles are assumed to be the same as in the SM ($\kappa_W = \kappa_Z = \kappa_t = \kappa_b = \kappa_\tau = 1$) is also used to constrain the κ_g and κ_γ parameters only. In this model, it can be assumed that the new physics affecting the loops are either introducing new decay channels (i.e., BR_{BSM} allowed to vary in the fit) or not (i.e., $\text{BR}_{\text{BSM}} = 0$). In the two cases, the results on the couplings through loops (to gluons and photons) do not change significantly. The constraints on BR_{BSM} will be discussed in the next section, while here the focus will be on the effective couplings of the Higgs boson to gluons and photons. The contours of the combined likelihood in the $(\kappa_\gamma, \kappa_g)$ plane for the ATLAS and CMS experiments and their combination are shown in Fig. 11.13. The measured values of these parameters for the ATLAS and CMS Run 1 combination are:

$$\kappa_g = 0.78^{+0.13}_{-0.10} \quad \text{and} \quad \kappa_\gamma = 0.87^{+0.14}_{-0.09}. \tag{11.39}$$

At Run 2, the ATLAS combination yielded:

$$\kappa_g = 1.03^{+0.07}_{-0.06} \quad \text{and} \quad \kappa_\gamma = 1.00 \pm 0.06. \tag{11.40}$$

The CMS results are reported as likelihood contours in the $(\kappa_g, \kappa_\gamma)$ plane only, as shown in Fig. 11.13.

In this model as well, all results are fully compatible with the SM expectations.

v. *Coupling measurements and probing BSM physics in loops and in the decay*

In the models described above, it was either assumed that no new latent BSM degree of freedom distorts neither the loop-induced Higgs boson couplings to gluons and photons nor the total Higgs boson width, or that all tree level couplings to SM particles are SM-like. These assumptions can be relaxed.

In order to probe simultaneously the Higgs boson couplings to massive and massless particles, only the assumption $\text{BR}_{\text{BSM}} = 0$ is kept. The couplings to photons and gluons are then parametrised by independent effective couplings, κ_g and κ_γ, and κ_Z, κ_W, κ_t, $|\kappa_\tau|$, and $|\kappa_b|$ are measured simultaneously. The absolute values of certain coupling modifiers only indicate the degeneracy of combined likelihood for the two signs. It can be noted that when the coupling to gluons is not considered effective, there is some sensitivity to the sign of κ_b through the interference between the top- and bottom-quark loops in the gluon fusion process. In this analysis, the constraint on the top quark Yukawa coupling comes from the $t\bar{t}H$ direct search channels only. The complete set of results from this model is given in Table 11.12 for the ATLAS-CMS combination using the full Run 1 dataset [270] and for the ATLAS [213] and CMS [214] individual combinations using partial Run 2 datasets. Figure 11.14 also displays the results of the individual ATLAS and CMS combinations. A negative relative sign is allowed for the κ_W and κ_Z parameters without loss of generality. This convention is used in the ATLAS and CMS Run 1 combination and in the CMS Run 2 combination. Neglecting the very small interference between the W and Z exchanges in the VBF production and when treating the photon and gluon couplings as effective, the sensitivity to the negative signs of the

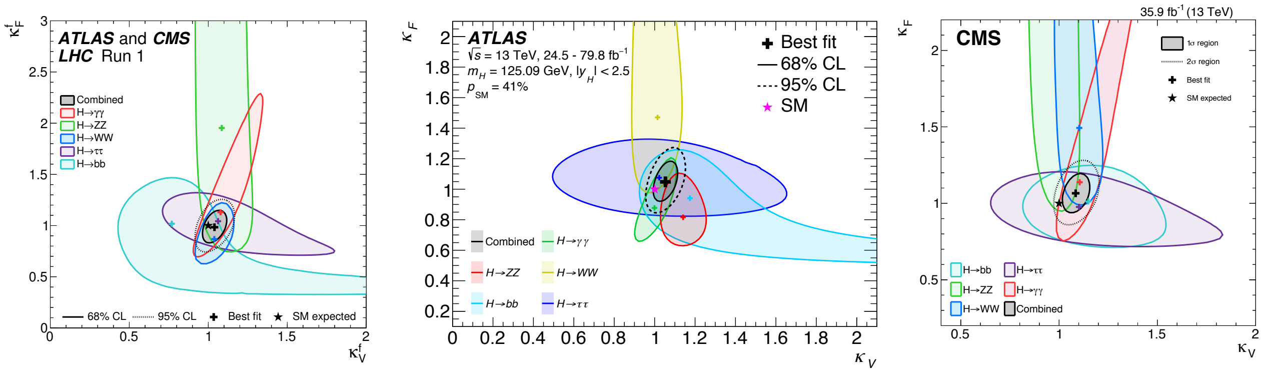

Figure 11.12: Likelihood contours in the (κ_F, κ_V) plane for the ATLAS-CMS Run 1 combination [270] (left) and the ATLAS [213] (center) and CMS [214] (right) individual Run 2 combinations.

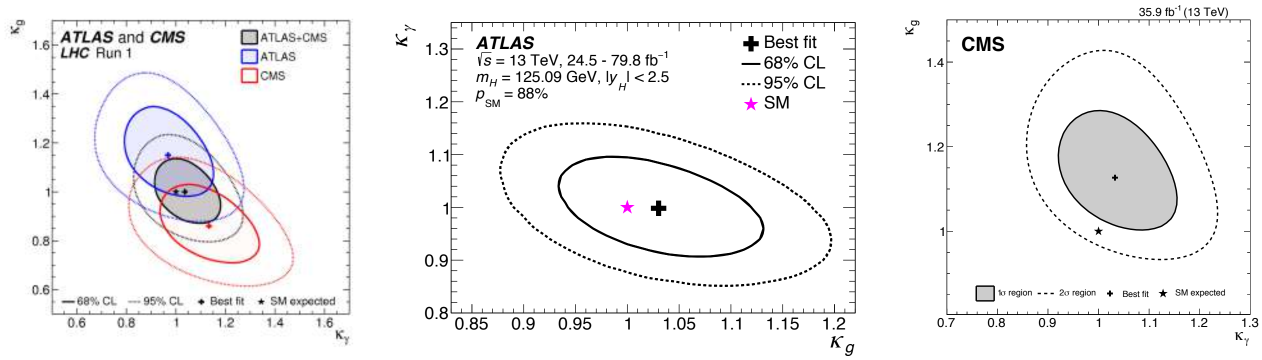

Figure 11.13: Likelihood contours in the $(\kappa_g, \kappa_\gamma)$ plane for the ATLAS-CMS [270] combination (left) and for the ATLAS [213] (center) and CMS [214] (right) individual Run 2 combinations.

couplings of the Higgs boson to the W and the top quark and that of the Z to the gluon come respectively from the tH and the $ggHZ$ production processes. In the case of the ATLAS Run 2 combination, only a relative negative sign of the coupling of the Higgs boson to the top quark is allowed. The cases reported in Table 11.12 of negative values of the couplings correspond to *quasi*-degenerate cases and the choice of sign is therefore not significant. For instance, the negative value of κ_W obtained by CMS in its Run 2 combination is due to tH contribution to the $t\bar{t}H$ channels as the specific tH analyses described in Section 11.3.3 are not included in the combination.

It is interesting to note that, with a partial Run 2 dataset, the sensitivity of individual experiments is already better than the one obtained at Run 1. This is in large part due to the improved systematic uncertainties related to the predictions of the Higgs boson production and decay that have been discussed in Section 11.2.

The results above are obtained under the assumption that the Higgs boson decays only to SM particles. This assumption is necessary since the signal rates cannot resolve separately κ_H and the absolute couplings of the Higgs boson to the SM particles. This degeneracy can, however, be resolved using an independent constraint on the Higgs boson width as the one derived from off-shell couplings measurements. This approach was used by the ATLAS experiment (see references in Ref. [123]), thus yielding a priori an absolute measurement of the couplings of the Higgs boson. The validity of the results obtained still relies on assumptions that have been discussed in Section 11.5.2. Another well-motivated assumption to resolve the aforementioned degeneracy preventing the determination of κ_H is inspired by unitarity conditions. Requiring that $\kappa_V \leq 1$ allows to free the $\mathrm{BR}_{\mathrm{BSM}}$ parameter and further probe new physics in the decay of the Higgs boson. An intuitive understanding of how this constraint works can be given by a simple example. In the VBF $H \to W^+W^-$ channel, the number of signal events compared to the SM prediction is rescaled by $(1 - \mathrm{BR}_{\mathrm{BSM}})\kappa_W^4/\kappa_H^2$, and, an observed signal close to the SM expectation cannot accommodate a large value of $\mathrm{BR}_{\mathrm{BSM}}$ since the depletion factor $(1 - \mathrm{BR}_{\mathrm{BSM}})$ cannot be compensated by an enhanced value $\kappa_W > 1$. Or, in other terms, if $\kappa_W \sim 1$ is preferred from other channels, a low signal in the VBF $H \to W^+W^-$ channel would be a sign of the presence of BSM physics in the Higgs boson decays. Within this framework, all the Higgs boson couplings to massive and massless SM particles can be measured in addition to $\mathrm{BR}_{\mathrm{BSM}}$. The results of this combination are shown in Fig. 11.14 (left). The results for all parameters do not change significantly with respect to the previous fit that assumed $\mathrm{BR}_{\mathrm{BSM}} = 0$. But a 95% CL bound on this parameter can now be obtained:

$$\mathrm{BR}_{\mathrm{BSM}} < 34\% \ \text{(ATLAS)}, \quad \mathrm{BR}_{\mathrm{BSM}} < 38\% \ \text{(CMS)}. \tag{11.41}$$

Both ATLAS and CMS in their Run 2 combinations have included the search for invisible decays of the Higgs boson [213,214], described in Section 11.3. This allows for a coherent interpretation of the constraints on invisible decays and the measurements in the visible channels as well as simultaneously constraining $\mathrm{BR}_{\mathrm{inv}}$ and the overall branching fraction to potentially "visible" particles but to which none of the considered measurements are sensitive, as for example Higgs boson decays to light quarks or BSM particles decaying subsequently mainly to light quarks ($\mathrm{BR}_{\mathrm{und}}$ referred to as branching fraction to undetected particles). The limits obtained on the invisible branching fractions are:

$$\mathrm{BR}_{\mathrm{inv}} < 30\% \ \text{(ATLAS)}, \quad \mathrm{BR}_{\mathrm{inv}} < 22\% \ \text{(CMS)}. \tag{11.42}$$

Models which are less sensitive to modelling systematic uncertainties and requiring no constraints on the natural width of the Higgs bosons have been considered, either through the ratio of cross section and branching ratios (see results in Ref. [123]) or through a more generic approach to avoid the degeneracy in the measurement of the coupling modifiers, probing the coupling properties of the Higgs boson through ratio of couplings. In the latter model, the cross section times branching fraction of the $gg \to H \to ZZ$ process is parametrised as a function of a single

Table 11.12: Coupling modifier combined measurements assuming the absence of perceptible new physics in the decay of the Higgs boson. No assumption is made for the loop level couplings of the Higgs boson to gluons and photons which are considered as effective.

	LHC Run 1	ATLAS Run 2	CMS Run 2	HL-LHC (expected)
κ_γ	$0.87^{+0.14}_{-0.09}$	1.05 ± 0.09	$1.07^{+0.10}_{-0.14}{}^{+0.09}_{-0.05}$	1.8%
κ_W	$0.87^{+0.13}_{-0.09}$	1.05 ± 0.09	$-1.13^{+0.15}_{-0.10}{}^{+0.06}_{-0.08}$	1.7%
κ_Z	-0.98 ± 0.10	1.11 ± 0.08	$1.00^{+0.09}_{-0.09}{}^{+0.06}_{-0.07}$	1.5%
κ_g	$0.78^{+0.13}_{-0.10}$	$0.99^{+0.11}_{-0.10}$	$1.18^{+0.10}_{-0.09}{}^{+0.12}_{-0.10}$	2.5%
κ_t	$1.40^{+0.24}_{-0.21}$	$1.09^{+0.15}_{-0.14}$	$0.98^{+0.08}_{-0.08}{}^{+0.12}_{-0.11}$	3.4%
κ_b	$0.49^{+0.27}_{-0.15}$	$1.03^{+0.19}_{-0.18}$	$1.17^{+0.18}_{-0.29}{}^{+0.20}_{-0.10}$	3.7%
κ_τ	$0.84^{+0.15}_{-0.11}$	$1.05^{+0.16}_{-0.15}$	$0.80^{+0.56}_{-0.81}{}^{+0.17}_{-0.00}$	1.9%

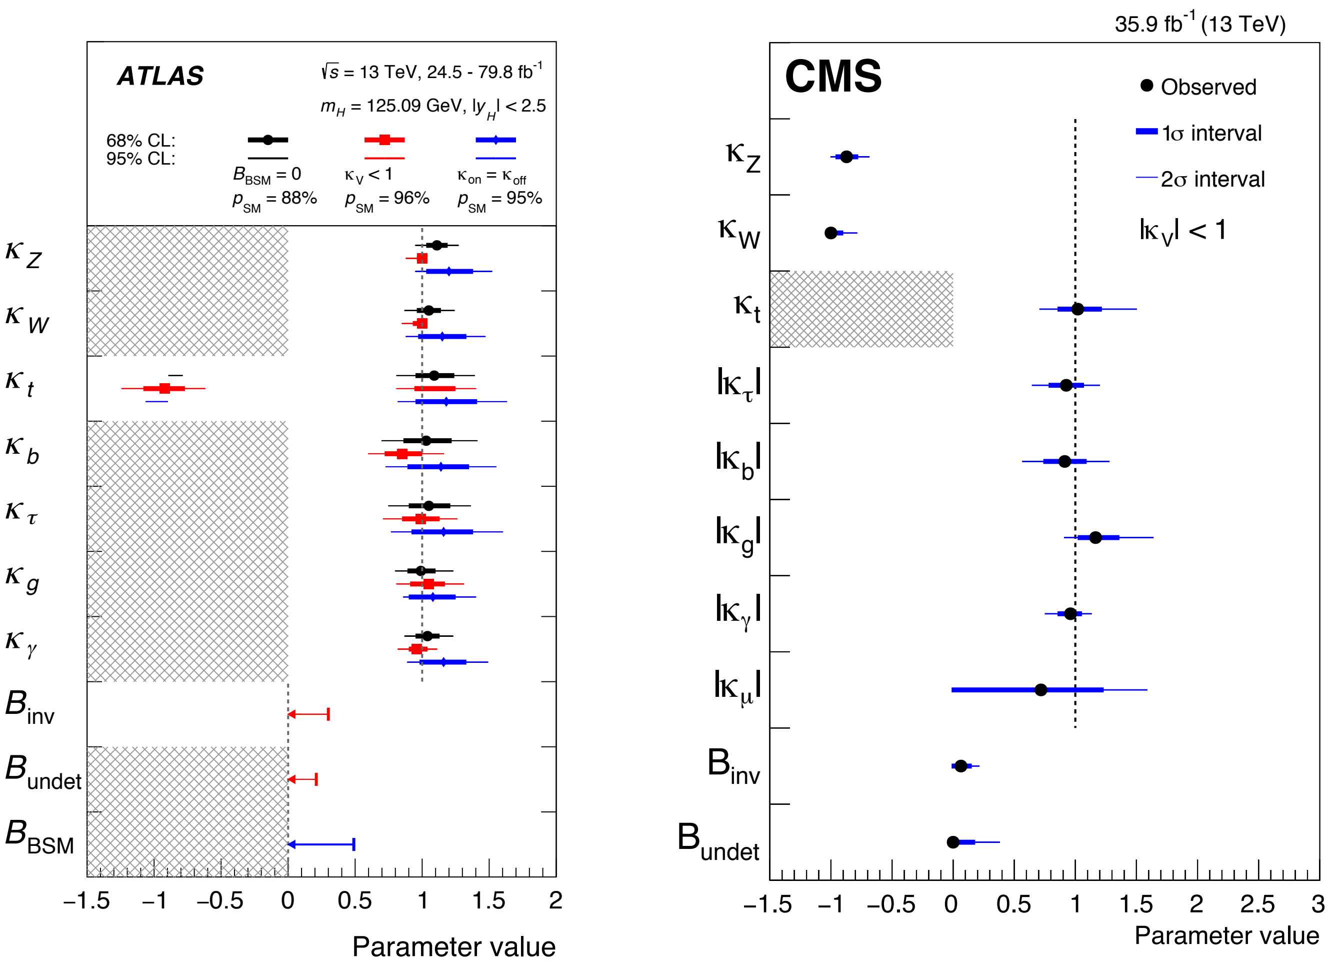

Figure 11.14: ATLAS [213] (left) and CMS [214] (right) combined measurements of coupling modifiers in the $\kappa_V < 1$ scenario, and in the case of the ATLAS measurements with the assumption $\mathrm{BR}_{\mathrm{BSM}} = 0$ and using the off-shell Higgs measurements.

coupling modifier:

$$\kappa_{gZ} = \kappa_g \times \frac{\kappa_Z}{\kappa_H} \tag{11.43}$$

Then all combination signals can be parametrised with the following ratios of coupling modifiers: (i) the $\lambda_{Zg} = \kappa_Z/\kappa_g$ ratio which is mainly probed by the measurements of the VBF and ZH production; (ii) the $\lambda_{tg} = \kappa_t/\kappa_g$ ratio constrained by the $t\bar{t}H$ production process; (iii) the $\lambda_{WZ} = \kappa_W/\kappa_Z$ ratio mainly probed by the WW and ZZ decay modes; (iv) the $\lambda_{\tau Z} = \kappa_\tau/\kappa_Z$ ratio constrained by the $\tau^+\tau^-$ channel; (v) the $\lambda_{bZ} = \kappa_b/\kappa_Z$ ratio probed mainly by the $VH(b\bar{b})$ channels; and (vi) the $\lambda_{\gamma Z} = \kappa_\gamma/\kappa_Z$ ratio constrained by the diphoton channel. In this parametrisation, the ZZ channel plays an important normalisation role (the results are discussed in detail in the previous edition of this review [123]).

11.6.2.2 *Differential cross sections*

To further characterise the production and decay properties of the Higgs boson, with the increase in size of the LHC datasets, measurements of fiducial and differential cross sections are being carried out by ATLAS and CMS both at Run 1 (the references can be found in the previous edition of this review [123]) and Run 2 [260, 272] and in several channels: (i) the diphoton, (ii) the four leptons, and (iii) the WW channels.

The definition of a fiducial volume as close as possible to the reconstruction level selection criteria is very important as it will minimise the model dependence from possible variations in the signal reconstruction efficiencies. Minimising model dependence of unfolded fiducial differential cross section measurements is also key to ensure their usefulness to further probe and tune more accurate models in the future.

As an example in the diphoton channel for the ATLAS Run 1 analysis (similar criteria are used at Run 2 and by CMS), the selection criteria defining the fiducial volume are the following: the two highest transverse momentum (E_T), isolated final state photons, within $|\eta| < 2.37$ and with $105\,\text{GeV} < M_{\gamma\gamma} < 160\,\text{GeV}$ are selected (the transition region between the barrel and end-cap calorimeters is not removed); after the pair is selected, the same cut on $E_T/M_{\gamma\gamma}$ as in the event selection, i.e., in excess of 0.35 (0.25) for the two photons is applied. The requirement of the isolation of the photon to define the fiducial volume is particularly important to avoid potentially large variations of the reconstruction efficiency within this volume for production processes as different as the gluon fusion and $t\bar{t}H$.

While strict fiducial requirements are key to minimise model dependence, these make combinations of decay channels impossible. To gain precision in the measurement of the production properties of the Higgs boson, the fiducial volume defined on the decay products of the Higgs boson can be removed and channels can be combined relying on the extrapolation from the reconstruction acceptance using Monte Carlo simulations. This has been used to combine differential cross section for instance in the transverse momentum of the Higgs boson. Such hybrid approaches are also discussed in Section 11.6.2.4.

A large number of observables have been studied aiming at probing the accuracy of the modelling of the Higgs boson production simulations. Some examples include (i) the transverse momentum and pseudo rapidity of the objects, such as jets or leptons, produced in association with the Higgs boson in several modes, the principal distributions of the Higgs boson decay products such for instance in the diphoton channel; (ii) the production angle in the Collins–Soper frame [225] in the diphoton channel; (iii) the overall distribution of the Higgs boson transverse momentum.

The measured differential cross section in the Higgs boson transverse momentum by ATLAS and CMS using the full Run 2 datasets are illustrated in Fig. 11.15.

11.6.2.3 *Constraints on non-SM Higgs boson interactions in an effective Lagrangian*

An example of the possible use of differential cross sections in constraining non-SM Higgs boson couplings in an EFT is given by ATLAS [273]. In this analysis, differential cross section measured in the diphoton channel are used to constrain an effective Lagrangian where the SM is supplemented by dimension six CP-even operators of the Strongly Interacting Light Higgs (SILH) formulation [248] and corresponding CP-odd operators. The diphoton differential cross sections are mainly sensitive to the operators that affect the Higgs boson interactions with gauge bosons. CMS has also recently analysed [260] the Higgs boson transverse momentum distribution to constrain the Higgs boson couplings to top, bottom, and charm quarks as well as the effective coupling to gluons. This analysis is, however, not performed in an EFT framework.

The differential distributions used in this combination are: (i) the transverse momentum of the Higgs boson, (ii) the number of reconstructed jets produced in association with the diphoton pair, (iii) the invariant mass of the diphoton system and (iv) the difference in azimuthal angle of the leading and sub-leading jets in events with two or more jets. This analysis shows how differential information significantly improves the sensitivity to dimension-6 operators.

11.6.2.4 *Simplified Template Cross Sections (STXS)*

An overarching subject of discussion between the theory and experimental communities in the field of Higgs physics has been how experimentalists could best communicate their results for them to be most efficiently used by others for further interpretation.

In the field of precision SM measurements, the commonly used practise is that results are given at particle level within a well defined fiducial volume of phase space. The fiducial volume is usually defined close enough to the experimental reconstruction to minimise the possible variations of the reconstruction efficiency within the particle level fiducial volume. In this way, results minimise their dependence on theoretical uncertainties.

ATLAS and CMS have produced fiducial and unfolded cross sections based on all objects reconstructed in the events. These measurements could be used for further interpretation. However, performing a proper combination of channels taking into account all experimental systematic uncertainties is non trivial. A proposal [44, 274] was made by the LHC Higgs Cross Section Working Group to produce results in each decay channel with a well defined fiducial phase space of the Higgs boson (and not its decay products) and for other associated objects pertaining to all channels, such as jets and missing transverse momentum (MET). The definition of the fiducial regions is motivated by maximising the experimental sensitivity, isolating possible BSM effects, and minimising the dependence on theoretical uncertainties. The number of regions is also minimised to avoid the loss of experimental sensitivity. The observables that are measured in this approach are still the standard production cross sections (the gluon fusion, the vector boson fusion, the VH and $t\bar{t}H$ associated production modes) within the defined fiducial volumes.

In summary, this approach is hybrid. It is fiducial on specific objects to reduce the theory dependence and inclusive in the Higgs kinematics in order to allow for a more straightforward combination. This approach also allows the use of multivariate techniques to enhance the sensitivity within given fiducial regions, at the expense of a greater extrapolation and therefore increased model dependence.

The currently used Simplified Template Cross Sections (STXS) scheme covers, with a limited number of bins, the ggF process in four categories in number of jets (0, 1, 2 and 2 VBF-like jets, where VBF-like means a selection of two high invariant mass jets with large pseudo rapidity difference) further subdivided in four transverse momentum categories covering the full spectrum with the last bin being inclusive for $p_T > 200$GeV. The VH process is subdivided two categories depending on the number of reconstructed charged leptons corresponding to the decays of either a W boson or a Z boson, and two bins in transverse momentum. VBF and hadronic VH categories are defined using jet cuts and two bins in transverse momentum.

Measurements in this framework have been made in various decay channels. The first measurements have been performed in the main Higgs boson discovery channels. ATLAS has produced measurements of the diphoton and the 4ℓ channels with Run 2 data [125, 227, 236, 275, 276]. And full Run 2 results are available for the $H \to 4\ell$ channel from ATLAS [131] and CMS [277].

CMS has carried out a measurement of the STXS in the $H \to \tau^+\tau^-$ decay channel targeting the high transverse momentum of the Higgs boson [145], in particular in the channel where the Higgs boson is produced with one jet of transverse energy in excess of 200 GeV.

ATLAS [149] has made a measurement of the STXS aiming at the VH production mode in the $H \to b\bar{b}$ decay mode at high transverse momentum of the vector boson above 250 GeV, where the discrimination of the background further increases.

A combination of STXS across decay channels has also been carried out by ATLAS with a dataset corresponding to an integrated luminosity of up to $80\,\text{fb}^{-1}$ [213].

11.6.2.5 *Indirect constraints on the Higgs boson couplings*

The direct measurements at the LHC provide direct probes of the Higgs boson couplings to the vector bosons (photons, W, Z and gluons) and to a limited number of Yukawa couplings to fermions. Currently these include essentially the third generation fermions – tau leptons, bottom and top quarks. For the High-Luminosity run, prospective studies [104] have shown that a good precision will be reached in the measurement of the coupling of the Higgs boson to muons and an evidence of the Higgs boson trilinear self-coupling with a precision of the order of 50% can be achieved. For the couplings of the Higgs boson to the other light SM fermions, direct evidences will be hard to reach at the LHC. However, from the measurements of the main observed Higgs final

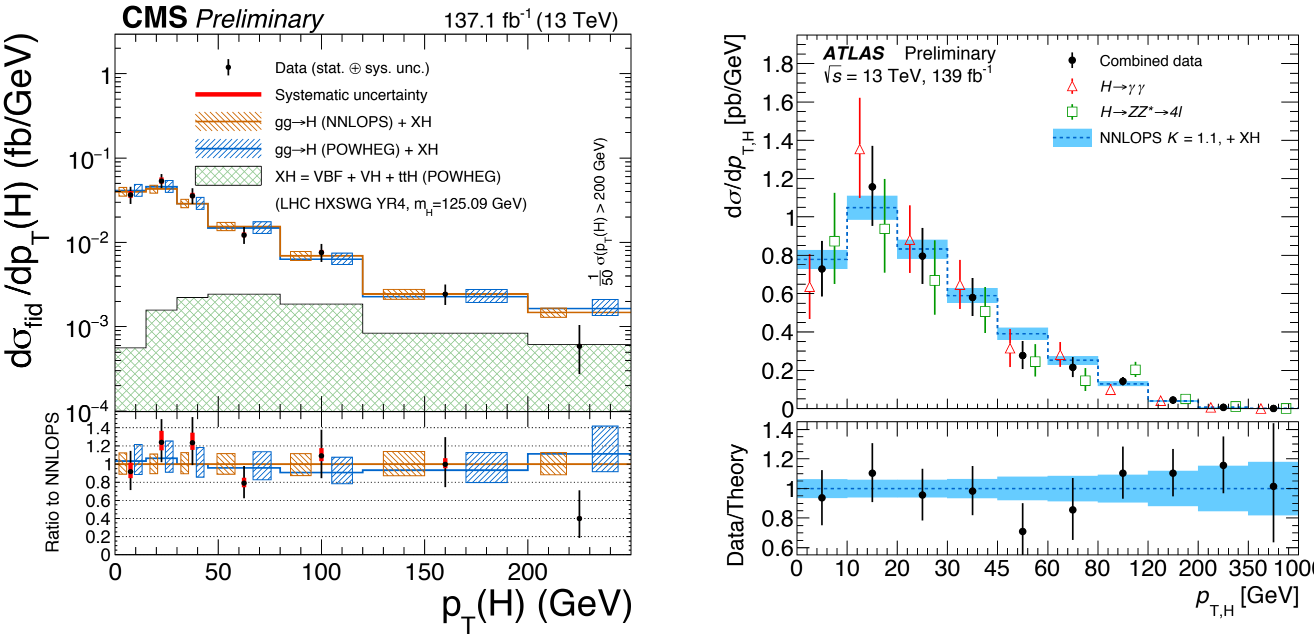

Figure 11.15: (Left) Fiducial differential, closely matching the reconstruction level selections, cross sections in Higgs boson transverse momentum in the $H \to 4\ell$ channel from the CMS experiment [126]. (Right) Partially fiducial combined cross sections using the $H \to \gamma\gamma$ and $H \to 4\ell$ channels from the ATLAS experiment [272].

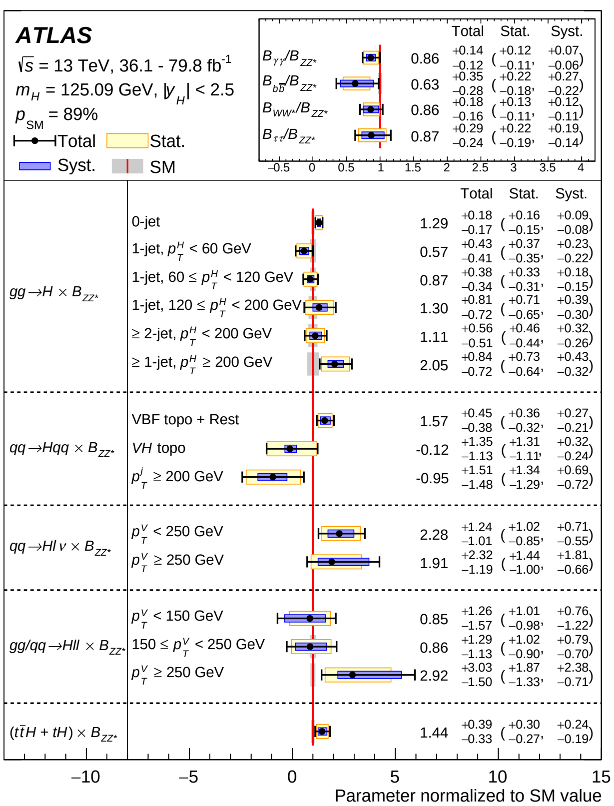

Figure 11.16: Simultaneous measurement of the simplified template cross sections times the branching fraction BR($H \to ZZ$) (normalised to their Standard Model expectations) and the ratios of branching fractions BR(f)/BR(ZZ) [213].

states, it is possible to constrain specific couplings through their radiative corrections to dominant processes. Two prime examples are: (i) the trilinear self-coupling can be constrained through loop corrections to the single Higgs boson production [278–280], see the interpretation carried out by ATLAS of the combination of the main decay channels [281]; (ii) the charm Yukawa coupling can be constrained from the differential cross section in Higgs boson transverse momentum [282], see the ATLAS [283] and CMS [260] analyses in the diphoton channel. These indirect constraints, however, require assumptions on the possible variations of all the other couplings.

ATLAS has also performed a preliminary combination of the single Higgs boson production measurements [284], using the approach and parametrisations of Ref. [279], which yield the following constraint:

$$-3.2 < \kappa_\lambda < 11.9. \tag{11.44}$$

When combined with results of the double Higgs boson production searches, the following combined constraint on the Higgs boson trilinear coupling yields:

$$-2.3 < \kappa_\lambda < 10.3\,(\text{obs}) \quad [-5.1 < \kappa_\lambda < 11.2.\,(\text{exp})]. \tag{11.45}$$

The *direct* and *indirect* constraints on the Higgs boson trilinear self-coupling are currently of similar strength. The double Higgs boson measurements are dominated by statistical uncertainties and are expected to improve much more rapidly than the precision on single Higgs boson measurements. Furthermore, it should be stressed that the constraints on the trilinear self-coupling obtained via the NLO fit of single Higgs boson data are less robust and more model-dependent since the NLO effects induced by a shift of the trilinear self-coupling compete with possible LO effects sourced by the deviations of the Higgs boson couplings to the other SM particles. The different effects can be disentangled by the measurements of various kinematical differential distributions in addition to the study of the inclusive rates [285], but the expected sensitivity in such global fits is not as promising as the one obtained when only the Higgs boson self-coupling is allowed to deviate from its SM value [286].

11.7 New physics models of EWSB in the light of the Higgs boson discovery

The discovery of a light scalar with couplings to gauge bosons and fermions that are consistent with SM predictions, together with the slow running of the Higgs boson self-coupling at high energies allow one to consider the SM as a valid perturbative description of nature all the way to the Planck scale. This picture is admittedly very attractive, but it posits that the Higgs boson is an elementary scalar field, whose mass has quantum sensitivity to possible new physics scales. This EW/Higgs naturalness problem [6] has become much more definite after the Higgs boson discovery.

There are two broad classes of models addressing the naturalness problem[5]. One is based on SUSY [7] (for recent reviews, see Refs. [8, 9]). This is a weakly coupled approach to EWSB, maintaining the perturbativity of the SM, and, the Higgs boson remains elementary and the corrections to its mass are screened at the scale at which SUSY is broken so the value of the weak scale remains insensitive to the details of the physics at higher scales. These theories predict at least three neutral Higgs particles and a pair of charged Higgs particles [25]. One of the neutral Higgs bosons, most often the lightest CP-even one, has properties that could resemble those of the SM Higgs boson (at least in some regions of the parameter space). It is referred to as a SM-like Higgs boson, meaning that its couplings are close to the ones predicted in the SM. The other approach invokes the existence of strong interactions at a scale of the order of one TeV or above and these new interactions induce the breaking of the electroweak symmetry [288]. In the original incarnation, dubbed technicolor, the strong interactions themselves trigger EWSB without the need of a Higgs boson. Another possibility, more compatible with the ATLAS and CMS discovery, is that the strong interactions produce four light resonances identified with the Higgs doublet and EWSB proceeds through vacuum misalignment [10] (see Refs. [11, 12] for recent reviews). In that case, the Higgs boson itself has a finite size and thus never feels the UV degrees of freedom that would otherwise have dragged its mass to much higher scales. The Higgs boson could also correspond to the Goldstone boson associated with the spontaneous breaking of scale invariance, see Ref. [289] and references therein. However, this dilaton/radion scenario now requires a jumbled model-building to be consistent with the constraints from the coupling measurements. All these BSM scenarios can have important effects on the phenomenology of the Higgs boson. Also, in each case, the role of the Higgs boson in the unitarisation of scattering amplitudes is shared by other particles which remain targets of experimental searches.

The realisation of SUSY at low energies has many good qualities that render it attractive as a model of new physics. First of all since, for every SM degree of freedom, there is a superpartner of different spin but of equal mass and effective coupling to the SM-like Higgs boson, in the case of exact SUSY, an automatic cancellation of quantum corrections to the Higgs mass parameter holds. In practice, it is known that SUSY must be broken since no superpartners of the SM particles have been observed so far. The mass difference between the precise value of the mass of any particle and that of its corresponding superpartner is proportional to the correlated soft SUSY breaking parameter, generically called M_{SUSY}. The quantum corrections to the Higgs boson mass parameter are proportional to M^2_{SUSY}, and provided M_{SUSY} is of order of a few TeV, the low energy mass parameters of the Higgs sector become insensitive to physics at the GUT or Planck scale. Another interesting feature of SUSY theories is related to the dynamical generation of EWSB [290]. In the SM, a negative Higgs mass parameter, m^2, needs to be inserted by hand to induce EWSB, see Eq. (11.1). In SUSY, instead, even if the relevant Higgs mass parameter is positive in the ultraviolet, it may become negative and induce EWSB radiatively through the strong effect of the top quark-Higgs boson coupling in its renormalisation group evolution [290].

In the following, the Higgs sector will be explored in specific SUSY models. In all of them, it is often possible to find regions of the parameter space that accommodate one neutral Higgs boson with properties that resemble those of the SM Higgs boson, whereas additional neutral and charged Higgs bosons are also predicted and are intensively being sought for at the LHC (see Section 11.7.7). In the simplest SUSY model, accommodating a SM-like Higgs boson mass of about 125 GeV results in constraints on the stop sector, with at least one stop mass in the few TeV mass range. In non-minimal SUSY extensions of the SM (details and related references can be found in the previous edition of this review [123]), a SM-like Higgs boson with mass of 125 GeV can be accomodated with less restrictions on the stop sector. While naturalness dictates relatively light stops and - at the two loop level - also gluinos, the first and second generation of squarks and sleptons couple weakly to the Higgs sector and may be heavy. Moreover, small values of the μ parameter and therefore light Higgsinos, the fermionic superpartners of the Higgs bosons, would be a signature of a natural realization of electroweak symmetry breaking [291]. Such SUSY spectra, consisting of TeV range stop masses and light Higgsinos, continue to be under intense scrutiny by the experimental collaborations [292] in order to understand if such natural SUSY scenarios endure and can explain why the Higgs boson remains light.

In the context of weakly coupled models of EWSB, one can also consider multiple Higgs $\mathrm{SU}(2)_L$ doublets as well as additional Higgs singlets, triplets or even more complicated multiplet structures, with or without low energy SUSY. In general, for such models, one needs to take into account experimental constraints from precision measurements and flavour changing neutral currents. The LHC signatures of such extended Higgs sectors are largely shaped by the role of the exotic scalar fields in EWSB.

The idea that the Higgs boson itself could be a composite bound state emerging from a new strongly-coupled sector has been reconsidered thanks to the insights gained from the AdS/CFT duality. The composite Higgs boson idea is an incarnation of EWSB via strong dynamics that smoothly interpolates between the standard technicolor approach and the true SM limit. To avoid the usual conflict with EW data, it is sufficient, if not necessary, that a mass gap separates the Higgs resonance from the other resonances of the strong sector. Such a mass gap can naturally follow from dynamics if the strongly-interacting sector exhibits a global symmetry, G, broken dynamically to a subgroup H at the scale f, such that, in addition to the three Nambu–Goldstone bosons of SO(4)/SO(3) that describe the longitudinal components of the massive W and Z, the coset G/H contains a fourth Nambu–Goldstone boson that can be identified with the physical Higgs boson. Simple examples of such a coset are SU(3)/SU(2) or SO(5)/SO(4), the latter being favoured since it is invariant under the custodial symmetry. It is also possible to have non-minimal custodial cosets with extra Goldstone bosons leading to additional Higgs bosons in the spectrum, see for instance Ref. [293]. Modern incarnations of composite Higgs models have been recently investigated in the framework of 5D warped models where, according to the principles of the AdS/CFT correspondence, the holographic composite Higgs boson then originates from a component of a gauge field along the 5th dimension with appropriate boundary conditions.

A last crucial ingredient in the construction of viable composite Higgs boson models is the concept of partial compositeness [294], i.e., the idea that there are only linear mass mixings between elementary fields and composite states. After diagonalisation of the mass matrices, the SM particles, fermions and gauge bosons, are admixtures of elementary and composite states and thus they interact with the strong sector, and in particular with the Higgs boson, through their composite component. This setup has important consequences on the flavour properties, chiefly the suppression of large flavour changing neutral currents involving light fermions. It also plays an important role in dynamically generating a potential for the would-be Goldstone bosons. Partial compositeness also links the properties of the Higgs boson to the spectrum of the fermionic resonances, i.e., the partners of the top quark. As in the MSSM, these top partners are really the agents that trigger the EWSB and also generate the mass of the Higgs boson that otherwise would remain an exact Goldstone boson and hence massless. The bounds from the direct searches for the top partners, in addition to the usual constraints from EW precision data, force the minimal composite Higgs models into some unnatural corners of their parameter spaces [295].

11.7.1 *Higgs bosons in the minimal supersymmetric standard model (MSSM)*

The particle masses and interactions in a SUSY theory are uniquely defined as a function of the superpotential and the Käh-

[5]Another solution to the naturalness problem is to lower the fundamental scale of quantum gravity, like for instance in models with large extra-dimensions, see Ref. [287].

ler potential [9]. A fundamental theory of SUSY breaking, however, is unknown at this time. Nevertheless, one can parametrise the low-energy theory in terms of the most general set of soft SUSY-breaking operators [9]. The simplest realistic model of low-energy SUSY is the minimal SUSY extension of the SM (MSSM) [9, 296], that associates a SUSY partner to each gauge boson and chiral fermion of the SM, and provides a realistic model of physics at the weak scale. However, even in this minimal model with the most general set of soft SUSY-breaking terms, more than 100 new parameters are introduced. Fortunately, only a subset of these parameters impact the Higgs boson phenomenology either directly at tree-level or through quantum effects.

The MSSM contains the particle spectrum of a two-Higgs-doublet model (2HDM) extension of the SM and the corresponding SUSY partners. Two Higgs doublets, Φ_1 and Φ_2, with hypercharge $Y = -1$ and $Y = 1$, respectively, are required to ensure an anomaly-free SUSY extension of the SM and to generate mass for down-type quarks/charged leptons (Φ_1) and up-type quarks (Φ_2) [25]. The Higgs potential reads

$$\begin{aligned} V =& m_1^2 \Phi_1^\dagger \Phi_1 + m_2^2 \Phi_2^\dagger \Phi_2 - m_3^2 (\Phi_1^T i\sigma_2 \Phi_2 + \text{h.c.}) \\ &+ \frac{1}{2}\lambda_1 (\Phi_1^\dagger \Phi_1)^2 + \frac{1}{2}\lambda_2 (\Phi_2^\dagger \Phi_2)^2 + \lambda_3 (\Phi_1^\dagger \Phi_1)(\Phi_2^\dagger \Phi_2) \\ &+ \lambda_4 |\Phi_1^T i\sigma_2 \Phi_2|^2 + \frac{1}{2}\lambda_5 \left[(\Phi_1^T i\sigma_2 \Phi_2)^2 + \text{h.c.}\right] \\ &+ \left[[\lambda_6 (\Phi_1^\dagger \Phi_1) + \lambda_7 (\Phi_2^\dagger \Phi_2)] \Phi_1^T i\sigma_2 \Phi_2 + \text{h.c.}\right], \end{aligned} \tag{11.46}$$

where $m_i^2 = \mu^2 + m_{H_i}^2$ $(i = 1, 2)$, with μ being the supersymmetric Higgsino mass parameter and m_i the soft supersymmetric breaking mass parameters of the two Higgs doublets; $m_3^2 \equiv B\mu$ is associated to the B-term soft SUSY breaking parameter; and λ_i, for $i = 1$ to 7, are all the Higgs quartic couplings.

After the spontaneous breaking of the electroweak symmetry, five physical Higgs particles are left in the MSSM spectrum: one charged Higgs pair, $H^\pm$, one CP-odd neutral scalar, A, and two CP-even neutral states, H and h, with h being the lightest.[6] The Higgs sector at tree level depends on the electroweak gauge coupling constants and the vacuum expectation value v – or equivalently the Z gauge boson mass – and is determined by only two free parameters: $\tan\beta$ - the ratio of the two Higgs doublets' vacuum expectation values v_2/v_1 - and one Higgs boson mass, conventionally chosen to be the CP-odd Higgs boson mass, m_A. The other tree-level Higgs boson masses are then given in terms of these parameters. The tree level value of m_h is maximised not only for $m_A \gg m_Z$ but also for $\tan\beta \gg 1$. For $m_A \gg m_Z$ it acquires a maximum value $m_h = m_Z \cos 2\beta$.

Radiative corrections have a significant impact on the values of Higgs boson masses and couplings in the MSSM. The dominant radiative effects to the SM-like Higgs boson mass arise from the incomplete cancellation between top and scalar-top (stop) loops and at large $\tan\beta$ also from sbottom and stau loops. The stop, sbottom and stau masses and mixing angles depend on the SUSY Higgsino mass parameter μ and on the soft-SUSY-breaking parameters [9, 296]: M_Q, M_U, M_D, M_L, M_E, and A_t, A_b A_τ. The first three of these are the left-chiral and the right-chiral top and bottom scalar quark mass parameters. The next two are the left-chiral stau/sneutrino and the right-chiral stau mass parameters, and the last three are the trilinear parameters that enter in the off-diagonal squark/slepton mixing elements: $X_t \equiv A_t - \mu\cot\beta$ and $X_{b,\tau} \equiv A_{b,\tau} - \mu\tan\beta$. At one-loop, the electroweak gauginos yield a small contribution to the Higgs boson mass, and at the two-loop level, the masses of the gluinos also enter in the calculations. Radiative corrections to the Higgs boson masses have been computed using a number of techniques, with a variety of approximations; for a discussion see for example Refs. [39, 297, 298] and the corresponding section of the previous edition of this review [123].

The discovered SM-like Higgs boson, if interpreted as the lightest MSSM Higgs boson with a mass of about 125 GeV, provides information on the possible MSSM parameter space, see Fig. 11.17.

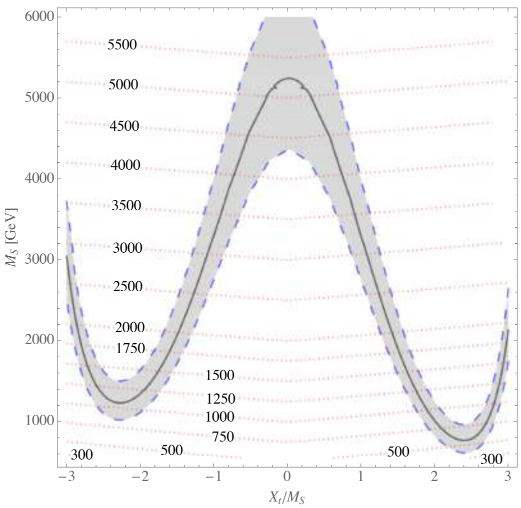

Figure 11.17: Values of the SUSY mass scale $M_{\text{SUSY}} = M_S$ versus the stop mixing parameter normalised by the SUSY mass scale X_t/M_{SUSY}, for fixed $\tan\beta = 20$, $\mu = 200$ GeV and $M_A = A_t = A_b = A_\tau = M_{\text{SUSY}}$. The solid black line corresponds to $m_h = 125$ GeV while in the grey band m_h varies by ± 1 GeV. The red dotted lines are iso-values of the stop mass. This figure is based on Ref. [299].

The phenomenology of the Higgs sector depends on the couplings of the Higgs bosons to gauge bosons and fermions. At tree-level, the couplings of the two CP-even Higgs bosons to W and Z bosons are given in terms of the angles α, that diagonalises the CP-even Higgs boson squared-mass matrix, and β

$$g_{hVV} = g_V m_V \sin(\beta - \alpha), \quad g_{HVV} = g_V m_V \cos(\beta - \alpha), \tag{11.47}$$

where $g_V \equiv 2m_V/v$, for $V = W$ or Z ($g_V m_V$ is the SM hVV coupling). Observe that in the limit $\cos(\beta - \alpha) \to 0$, the lightest CP-even Higgs boson h behaves as the SM Higgs boson. This situation is called alignment and is achieved in specific regions of parameter space for $m_A \geq m_Z$ [300] or in the large $m_A \gg m_Z$ limit, in which alignment is achieved through decoupling [300, 301]. There are no tree-level couplings of A or $H^\pm$ to VV. The couplings of the Z boson to two neutral Higgs bosons are given by $g_{\phi AZ}(p_\phi - p_A)$, where $\phi = H$ or h, the momenta p_ϕ and p_A point into the vertex, and

$$g_{hAZ} = g_Z \cos(\beta - \alpha)/2, \quad g_{HAZ} = -g_Z \sin(\beta - \alpha)/2\,. \tag{11.48}$$

The expressions of the couplings between a charged Higgs boson, a neutral Higgs boson and the W boson as well as the expressions of the four-point couplings of vector bosons and Higgs bosons can be found in Ref. [25].

The tree-level Higgs boson couplings to fermions obey the following property: the neutral components of one Higgs doublet, Φ_1, couple exclusively to down-type fermion pairs while the neutral components of the other doublet, Φ_2, couple exclusively to up-type fermion pairs [25]. This Higgs-fermion coupling structure defines the Type-II 2HDM. In the MSSM, fermion masses are generated when both neutral Higgs components acquire a vacuum expectation value, and the relations between Yukawa couplings and fermion masses are (in third-generation notation)

$$h_{b,\tau} = \sqrt{2}\, m_{b,\tau}/(v\cos\beta), \qquad h_t = \sqrt{2}\, m_t/(v\sin\beta)\,. \tag{11.49}$$

The couplings of the neutral Higgs bosons to $f\bar{f}$, relative to their

[6] Observe that in the SM sections of this review, H denotes the SM Higgs boson, whereas in the sections about SUSY, or extensions of the SM with two Higgs doublets, H is used for the heaviest CP-even Higgs boson, since this is the standard notation in the literature, and the 125 GeV SM-like light Higgs boson will be denoted by h. Generically, in the MSSM, the lightest CP-even Higgs boson is indeed SM-like and thus it is naturally identified with the 125 GeV Higgs boson discovered by ATLAS and CMS, while in 2HDM extensions, with or without SUSY, there could still be lighter scalar states below 125 GeV.

SM values, $g\, m_f/(2m_W)$, are given by

$$\begin{aligned} h b\bar{b}:&\ -\sin\alpha/\cos\beta, & h t\bar{t}:&\ \cos\alpha/\sin\beta\,, \\ H b\bar{b}:&\ \cos\alpha/\cos\beta, & H t\bar{t}:&\ \sin\alpha/\sin\beta\,, \\ A b\bar{b}:&\ \gamma_5\tan\beta, & A t\bar{t}:&\ \gamma_5\cot\beta\,. \end{aligned} \tag{11.50}$$

In each relation above, the factor listed for $b\bar{b}$ also pertains to $\tau^+\tau^-$. The charged Higgs boson couplings to fermion pairs, normalised to $g/(\sqrt{2}m_W)$, are given by

$$\begin{aligned} g_{H^- t\bar{b}}&: m_t\cot\beta\frac{1+\gamma_5}{2} + m_b\tan\beta\frac{1-\gamma_5}{2}, \\ g_{H^-\tau^+\nu}&: m_\tau\tan\beta\frac{1-\gamma_5}{2}\,. \end{aligned} \tag{11.51}$$

The non-standard neutral Higgs bosons have significantly enhanced couplings to down-type fermions at sizeable $\tan\beta$. Radiative corrections can modify significantly the values of the Higgs boson couplings to fermion pairs and to vector boson pairs, through a radiatively-corrected value for $\cos(\beta-\alpha)$ as well as from the one-loop vertex corrections to tree-level Higgs-fermion Yukawa couplings, see Ref. [9] and references therein, for a detailed discussion.

11.7.1.1 *MSSM Higgs boson phenomenology*

The MSSM parameters have to be arranged such that the mass, the CP properties, the decay and production properties of one of the neutral Higgs bosons agree with the LHC Higgs data. Given that present data allows only for moderate departures from the SM predictions, it implies that some degree of alignment is necessary.

The SM-like branching ratios of h can be modified if decays into SUSY particles are kinematically allowed, and, in particular, decays into a pair of the lightest SUSY particles – i.e., the lightest neutralinos, $\tilde{\chi}_1^0$ – can become dominant and would be invisible if R-parity is conserved [302]. Moreover, if light superpartners exist and couple to photons and/or gluons, the h loop-induced coupling to gg and $\gamma\gamma$ could deviate sizeably from the corresponding SM predictions (see for instance the review [297]), and would be in conflict with present data (see Section 11.3). For the heavier Higgs states, there are two possibilities to be considered[7]:

i) Alignment triggered by decoupling, hence $m_A \geq$ several hundred GeV: The HWW and HZZ couplings are very small. The dominant H, A decay branching ratios strongly depend on $\tan\beta$. The decay modes $H, A \to b\bar{b}$, $\tau^+\tau^-$ dominate when $\tan\beta$ is large (this holds even away from decoupling). For small $\tan\beta$, the $t\bar{t}$ decay mode dominates above its kinematic threshold. For the charged Higgs boson, $H^+ \to t\bar{b}$ dominates.

ii) Some degree of alignment without decoupling, hence $m_A \leq$ a few hundred GeV: The main difference with the previous case is that, in the low $\tan\beta$ regime ($\tan\beta \leq 5$), additional decay channels may be allowed which involve decays into the lightest SM-like Higgs boson; $A \to Zh$, $H \to hh$ as well as $H \to WW/ZZ$ decay modes are available (they are suppressed in the strict alignment limit). When kinematically open, the decays $A/H \to t\bar{t}$ become relevant or even dominant for sufficiently small $\tan\beta$. For the charged Higgs boson, $H^+ \to \tau^+\nu_\tau$ dominates below the $t\bar{b}$ threshold, and also $H^\pm \to W^\pm h$ may be searched for.

In both cases i) and ii), the heavier Higgs states, H, A and $H^\pm$, are roughly mass degenerate (with masses $\pm$ 20 GeV or less apart). If kinematically allowed, the heavy Higgs boson decays into charginos, neutralinos and third-generation squarks and sleptons can be important [305].

At hadron colliders, the dominant neutral Higgs boson production mechanism at moderate values of $\tan\beta$ is gluon fusion, mediated by loops containing heavy top and bottom quarks and the corresponding SUSY partners. The effect of light stops that may contribute to the gluon fusion production can be partially cancelled by mixing effects. Higgs boson radiation off bottom quarks becomes important for large $\tan\beta$, where at least two of the three neutral Higgs bosons have enhanced couplings to bottom-type fermions [306, 307]. Detailed discussions of the impact of radiative corrections in these search modes are presented for instance in Ref. [308]. The vector boson fusion and Higgs-strahlung production of the CP-even Higgs bosons as well as the associated production of neutral Higgs bosons with top quark pairs have lower production cross sections by at least an order of magnitude with respect to the dominant ones, depending on the precise region of MSSM parameter space [41–44]. Higgs boson pair production of non-standard MSSM Higgs bosons has been studied in Ref. [309]. For a discussion of charged Higgs boson production at LHC, see Refs. [42, 43, 310].

Strong production of a heavy neutral Higgs boson followed by its decay into top-quark pairs is a challenging channel, only most recently being searched for by ATLAS and CMS. Interference effects between the signal and the SM $t\bar{t}$ background need to be carefully taken into account [311].

Summarising, the additional Higgs bosons are sought for mainly via the channels:

$$\begin{aligned} & pp \to A/H \to \tau^+\tau^- \text{ (inclusive)}, \\ & b\bar{b}A/H, A/H \to \tau^+\tau^- \text{ (with } b\text{-tag)}, \\ & b\bar{b}A/H, A/H \to b\bar{b} \text{ (with } b\text{-tag)}, \\ & pp \to t\bar{t} \to H^\pm W^\mp b\bar{b},\ H^\pm \to \tau\nu_\tau\ , \\ & gb \to H^- t \text{ or } g\bar{b} \to H^+\bar{t},\ H^\pm \to \tau\nu_\tau\ . \end{aligned} \tag{11.52}$$

After the Higgs boson discovery, updated MSSM benchmarks scenarios have been defined to highlight interesting conditions for the MSSM Higgs boson searches [43, 304, 312]. The latest benchmark scenarios update [304], partly based in MSSM parameter space discussions in Ref. [312], considers six benchmarks to illustrate different aspects of Higgs phenomenology in the MSSM. They include one case with complex parameters, but they all assume R-parity conservation and no flavour mixing. Each scenario contains one CP-even scalar with mass around 125 GeV and SM-like couplings. These scenarios include a M_h^{125} scenario with relatively heavy superparticles, so the Higgs phenomenology at the LHC resembles that of a 2HDM with MSSM-inspired Higgs boson couplings. Other two scenarios are characterised by some of the superparticles – staus or electroweakinos – being relatively light, that in turn is of relevance for heavy neutral Higgs boson searches. In particular, the traditional $A/H \to \tau^+\tau^-$ search channel varies depending on the values of μ and M_2, that may enable the A/H decays into electroweakinos. Another two scenarios are characterised by the phenomenon of alignment without decoupling, in which one of the two neutral CP-even scalars has SM-like couplings independently of the mass spectrum of the remaining Higgs bosons, hence allowing for all the Higgs bosons to have relatively low mass values (about few hundred GeV). Finally there is one scenario which incorporates CP violation in the Higgs sector and gives rise to a strong admixture of the two heavier neutral states. All the above scenarios assume all parameters in the mass range from 1 to a few TeV, hence they are not applicable for values of $\tan\beta$ of order a few, for which a Higgs boson mass value of 125 GeV is out of reach. An additional study, EFTMSSM [313], proposes two scenarios specifically designed for the low $\tan\beta$ region and ensures a 125 GeV Higgs boson mass in almost the entire parameter space by employing a flexible supersymmetric mass scale, reaching values of up to 10^{16} GeV.

An alternative approach to reduce the large number of parameters relevant to the Higgs sector is to consider that, in the Higgs basis, the only important radiative corrections are those affecting the Higgs boson mass [314]. This approximation is called hMSSM and works well in large regions of parameter space but it breaks down for sizeable values of μ and A_t, and moderate values of $\tan\beta$, for which the radiative corrections to the mixing between the two CP even eigenstates become relevant. The effect of such radiative corrections is to allow for alignment for small to intermediate values of $\tan\beta$, independent of the specific value of m_A [315]. In

[7] In very special regions of the parameter space, there is still the possibility that the heavier CP-even Higgs state is identified with the 125 GeV Higgs boson discovered by ATLAS and CMS, see for instance the discussion in Ref. [303] and the benchmark M_H^{125} defined in Ref. [304].

addition, the hMSSM assumption that the right value of the Higgs boson mass may be obtained for all values of m_A and $\tan\beta$ is in conflict with the MSSM predictions for the Higgs boson mass for small values of m_A and $\tan\beta \simeq \mathcal{O}(1)$. The recent M_h^{125} [304] and EFTMSSM benchmarks [313], are designed to address the limitations of the hMSSM, in particular the low $\tan\beta$ region for the EFTMSSM.

The M_h^{125} scenarios are aiming at treating more rigorously all radiative correction to the observed Higgs boson mass as well as specifically taking into possibly intermediate to light MSSM colorless states as electroweakinos or staus [304]. The main M_h^{125} benchmark, however, assumes that super partners are heavy, so that the phenomenology of the observed Higgs boson is not altered except in its couplings due to the existence of another doublet. Another important example scenario, referred to as $M_h^{125}(\tilde{\chi})$, considers light electroweakinos and therefore the heavy Higgs bosons H and A can have sizeable decay rates to charginos and neutralinos, consequently suppressing the $\tau^+\tau^-$ decay rate. It is interesting to note that in this scenario the branching fraction of the Higgs boson to photons is enhanced for small values of $\tan\beta$ due to the presence of electroweakinos in the loop. These two scenarios are illustrated in Fig. 11.18.

The compatibility between the predicted and measured Higgs boson mass is an important constraint in these scenarios. The predictions are illustrated in Fig. 11.18. To use the predicted Higgs boson mass as a constraint (exclusion at nearly constant $\tan\beta$ at high M_A in the (M_A,$\tan\beta$) plane), it is important to account for the theoretical uncertainty on the prediction which is in excess of an order of magnitude larger than the experimental uncertainty on the measured mass of the Higgs boson. The theoretical uncertainty depends itself on the specific SUSY spectrum for a given MSSM parameter set and should be estimated accordingly, however, a more generic estimate of ± 3 GeV is made and found to be a conservative choice.

Reviews of the properties and phenomenology of the Higgs bosons of the MSSM can be found for example in Refs. [9,39,297]. Future precision measurements of the Higgs boson couplings to fermions and gauge bosons together with information on heavy Higgs boson searches will provide powerful information on the SUSY parameter space [315,316].

Improvements in our understanding of B-physics observables put indirect constraints on additional Higgs bosons in mass ranges that would be accessible in direct LHC searches. In particular, $\mathrm{BR}(B_s \to \mu^+\mu^-)$, $\mathrm{BR}(b \to s\gamma)$, and $\mathrm{BR}(B_u \to \tau\nu)$ play an important role within minimal flavour-violating (MFV) models [317], in which flavor effects proportional to the CKM matrix elements are induced as in the SM.

11.7.2 *Supersymmetry with singlet extensions*

The Higgs mass parameter μ is a SUSY parameter, and as such, it should naturally be of order M_{GUT} or M_{Planck}. The fact that phenomenologically it is required that μ be at the electroweak/TeV scale is known as the μ problem [318]. SUSY models with additional singlets can provide a solution to the μ problem, by promoting the μ parameter to a dynamical singlet superfield S that only interacts with the MSSM Higgs doublets through a coupling λ_S at the level of the superpotential. An effective μ is generated when the real scalar component of S acquires a vacuum expectation value v_S, yielding $\mu_{eff} = \lambda_S\, v_S$. After the minimization of the Higgs potential, the vacuum state relates the vacuum expectation values of the three CP-even neutral scalars, v_1, v_2 and v_S, to the scalar doublet and singlet soft SUSY breaking masses, hence, one expects that these VEVs should all be of order M_{SUSY} and therefore the μ problem is solved.

The addition of a singlet superfield to the MSSM may come along with additional symmetries imposed to the theory. Depending on such symmetries, different models with singlet extensions of the MSSM (xMSSM) have been proposed, see Ref. [319] for a general review. Among the most studied examples are the NMSSM with an additional discrete Z_3 symmetry (first introduced in Ref. [320]), the Nearly-Minimal SUSY SM (nMSSM), with additional discrete Z_5^R, and Z_7^R symmetries [321], and the $\mathrm{U}(1)'$-extended MSSM (UMSSM) [322]. A Secluded $\mathrm{U}(1)'$-extended MSSM (sMSSM) [323] contains three singlets in addition to the standard UMSSM Higgs boson singlet; this model is equivalent to the nMSSM in the limit that the additional singlet VEV's are large, and the trilinear singlet coupling, λ_S, is small [324].

A singlet extended SUSY Higgs sector opens new avenues for discovery. Since the singlet pseudoscalar particle may be identified as the pseudo-Goldstone boson of a spontaneously broken Peccei–Quinn symmetry, it may become naturally light [325]. Generally, there is mixing of the singlet sector with the MSSM Higgs sector, and for a sufficiently light, singlet-dominated scalar or pseudoscalar, h_S or A_S, respectively, the SM-like Higgs boson h may decay to pairs of h_S or A_S. The light scalar and/or pseudoscalar may subsequently decay to $\tau\tau$ or $b\bar{b}$ pairs. Such cascade decays are more difficult to detect than in standard searches due to the potentially soft decay products. There is also a rich phenomenology for the decays of the heavy CP-even and CP-odd doublets, H and A into two lighter Higgs bosons such as $H \to hh_S$, hh, $h_S h_S$ or $A \to A_S h_S$, $A_S h$ as well as into a light Higgs boson and a gauge boson: $H \to A_S Z$; $A \to h_S Z$, hZ. If kinematically allowed, the heavy Higgs bosons decay into $t\bar{t}$. If the singlet-dominated scalar or pseudoscalar are somewhat heavier, the decays $h_S \to WW$ or $A_S \to h_S Z$ will be allowed.

In addition, the light singlet scenario in the NMSSM or nMSSM is typically associated with a light singlino-dominated neutralino. The recently discovered SM-like Higgs boson can then decay to pairs of this neutralino [326], opening an invisible decay mode that is not excluded by present data. All of the Higgs bosons can decay into electroweakinos depending on kinematics and on the singlino or Higgsino composition of the electroweakinos.

In models with extended singlets, at low $\tan\beta$, it is possible to trade the requirement of a large stop mixing by a sizeable trilinear Higgs-singlet Higgs coupling λ_S, rendering more freedom on the requirements for gluon fusion production. As in the MSSM, mixing in the Higgs sector – additionally triggered by the extra new parameter λ_S – can produce variations in the Higgs–$b\bar{b}$ and Higgs–$\tau^-\tau^+$ couplings that can alter the Higgs to ZZ/WW and to diphoton rates. Light charginos at low $\tan\beta$ can independently contribute to enhance the di-photon rate, without altering any other of the Higgs boson decay rates, see for instance Ref. [327].

There is much activity in exploring the NMSSM phenomenology in the light of the 125 GeV Higgs boson as well as in defining benchmark scenarios with new topologies including Higgs decay chains, see Refs. [44, 328] and references therein. An analytic understanding of the alignment condition in the NMSSM is presented in Ref. [329]. The NMSSM with a Higgs boson of mass 125 GeV can be compatible with stop masses of order of the electroweak/TeV scale, thereby reducing the degree of fine tuning necessary to achieve electroweak symmetry breaking. Interestingly, the alignment conditions point toward a more natural region of parameter space for electroweak symmetry breaking, while allowing for perturbativity of the theory up to the Planck scale and yielding a rich and interesting Higgs boson phenomenology at the LHC.

11.7.3 *Supersymmetry with extended gauge sectors*

In the MSSM, the tree-level value of the lightest CP-even Higgs boson mass originates from the D-term dependence of the scalar potential that comes from the SUSY kinetic terms in the Kähler potential. The D-terms lead to tree-level quartic couplings which are governed by the squares of the gauge couplings of the weak interactions, under which the Higgs boson has non-trivial charges. Hence, the lightest Higgs mass is bounded to be smaller than M_Z. In the presence of new gauge interactions at the TeV scale, and if the Higgs fields had non-trivial charges under them, new D-term contributions would lead to an enhancement of the tree-level Higgs boson mass value. Since the low energy gauge interactions reduce to the known $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ ones, in order for this mechanism to work, the extended gauge and Higgs sectors should be integrated out in a non-SUSY way. This means that there must be SUSY breaking terms that are of the order of, or larger than, the new gauge boson masses. The tree-level quartic couplings would then be enhanced through their dependence on the square of the gauge couplings of the extended Higgs sector. This effect will be suppressed when the heavy gauge boson masses are larger than the SUSY breaking scale and will acquire its full

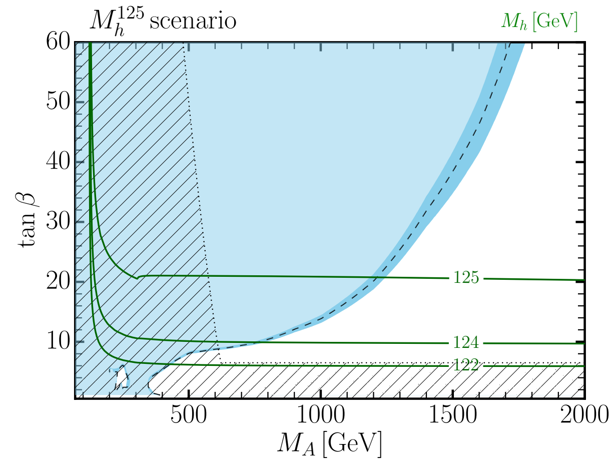

Figure 11.18: The 95% CL exclusion contours in the $(M_A, \tan\beta)$ parameter space for the M_h^{125} (right) and $M_h^{125}(\tilde{\chi})$(left) benchmark scenarios. The nearly vertical dotted line illustrated the lower limit on the mass of the A boson and the close-to horizontal dotted line represents the limit on $\tan\beta$ from the compatibility of the measured mass of the observed Higgs boson and the prediction using radiative corrections (mostly from the stop sector).

potential only for large values of this scale.

One of the simplest possibilities is to extend the weak interactions to a $SU(2)_1 \times SU(2)_2$ sector, such that the known weak interactions are obtained after the spontaneous breaking of these groups to $SU(2)_L$ [330]. This example is briefly summarized in the previous editions of this review [123]. Assuming SUSY breaking terms of the order of the new gauge boson masses, enhancements of order 50% of the MSSM D-term contribution to the Higgs boson mass may be obtained. Such enhancements are sufficient to obtain the measured Higgs mass value without the need for very heavy stops or large stop mixing parameters. This gauge extension leads to new, heavy gauge and Higgs bosons, as well as new neutralinos and charginos, that depending on the region of parameter space can induce novel phenomenology at the LHC. Gauge extensions including new abelian gauge groups have also been considered.

Gauge extensions of the MSSM can also lead to an enhancement of the Higgs boson mass value by modifying the renormalisation group evolution of the Higgs quartic coupling to low energies. In the MSSM, the evolution of the quartic coupling is governed by the top-quark Yukawa interactions and depends on the fourth power of the top-quark Yukawa coupling. The neutralino and chargino contributions, which depend on the fourth power of the weak gauge couplings, are small due to the smallness of these couplings. Depending on the values of the soft SUSY breaking parameters in the gaugino and Higgsino sectors, the $SU(2)_1$ gauginos may become light, with masses of the order of the weak scale. Since the $SU(2)_1$ coupling may be significantly larger than the $SU(2)_L$ one, for small values of the Higgsino mass parameter μ, the associated charginos and neutralinos may modify the evolution of the quartic coupling in a significant way [331]. This may lead to a significant increase of the lightest CP-even Higgs boson mass, even for small values of $\tan\beta \simeq 1$ for which the D-term contributions become small. Radiative corrections should be properly taken into account in this scenario as they might modify the tree-level result.

11.7.4 *Effects of CP violation*

SUSY scenarios with CP-violation (CPV) phases are theoretically appealing, since additional CPV beyond that observed in the K, D, and B meson systems is required to explain the observed cosmic matter-antimatter asymmetry. In the MSSM, CP-violation effects in the Higgs sector appear at the quantum level, while in singlet extensions of the MSSM CP-violation effects can already be effective at tree level. In general, CP-violation effects in the Higgs sector have significant constraints from electric dipole moments data [332].

In the MSSM, the gaugino mass parameters ($M_{1,2,3}$), the Higgsino mass parameter, μ, the bilinear Higgs squared-mass parameter, m_{12}^2, and the trilinear couplings of the squark and slepton fields to the Higgs fields, A_f, may carry non-trivial phases. The two parameter combinations $\arg[\mu A_f (m_{12}^2)^*]$ and $\arg[\mu M_i (m_{12}^2)^*]$ are invariant under phase redefinitions of the MSSM fields [333, 334]. Therefore, if one of these quantities is non-zero, there would be new sources of CP-violation affecting the Higgs sector through radiative corrections, see Ref. [335] and references therein. The mixing of the neutral CP-odd and CP-even Higgs boson states is no longer forbidden. Hence, m_A is no longer a physical parameter. However, the charged Higgs boson mass $m_{H^\pm}$ is still physical and can be used as an input for the computation of the neutral Higgs boson spectrum of the theory. For large values of $m_{H^\pm}$, corresponding to the decoupling limit, the properties of the lightest neutral Higgs boson state approach those of the SM Higgs boson. In particular, the upper bound on the lightest neutral Higgs boson mass takes the same value as in the CP-conserving case [334]. Nevertheless, there still can be significant mixing between the two heavier neutral mass eigenstates. For a detailed study of the Higgs boson mass spectrum and parametric dependence of the associated radiative corrections, see Ref. [335] and references therein.

Major variations to the Higgs boson phenomenology occur in the presence of explicit CPV phases. In the CPV case, vector boson pairs couple to all three neutral Higgs boson mass eigenstates, H_i $(i = 1, 2, 3)$, with couplings

$$
\begin{aligned}
g_{H_iVV} &= \cos\beta\,\mathcal{O}_{1i} + \sin\beta\,\mathcal{O}_{2i}\,, \\
g_{H_iH_jZ} &= \mathcal{O}_{3i}\,\left(\cos\beta\,\mathcal{O}_{2j} - \sin\beta\,\mathcal{O}_{1j}\right) \\
&\quad - \mathcal{O}_{3j}\left(\cos\beta\,\mathcal{O}_{2i} - \sin\beta\,\mathcal{O}_{1i}\right)\,,
\end{aligned}
\tag{11.53}
$$

where the g_{H_iVV} couplings are normalised to the analogous SM coupling and the $g_{H_iH_jZ}$ have been normalised to $g_Z^{\rm SM}/2$. The orthogonal matrix $\mathcal{O}_{ij}$, only defined in the $p^2 \to 0$ limit, is relating the weak eigenstates to the mass eigenstates. It has non-zero off-diagonal entries mixing the CP-even and CP-odd components of the weak eigenstates. Moreover, CPV phases imply that all neutral Higgs bosons can couple to both scalar and pseudoscalar fermion bilinear densities. The couplings of the mass eigenstates H_i to fermions depend on the loop-corrected fermion Yukawa couplings (similarly to the CP conserving (CPC) case), on $\tan\beta$ and on $\mathcal{O}_{ji}$ [336].

The production processes of neutral MSSM Higgs bosons in the CPV scenario are similar to those in the CPC scenario. Regarding the decay properties, the lightest mass eigenstate, H_1, predominantly decays to $b\bar{b}$ if kinematically allowed, with a smaller fraction decaying to $\tau^+\tau^-$. If kinematically allowed, a SM-like neutral Higgs boson, H_2 or H_3 can decay predominantly to H_1H_1 leading to many new interesting signals both at lepton and hadron colliders; otherwise it will decay preferentially to $b\bar{b}$.

The discovery of a 125 GeV Higgs boson has put strong constraints on the realisation of the CPV scenario within the MSSM. This is partly due to the fact that the observed Higgs boson rates are close to the SM values, and a large CP-violating component would necessarily induce a large variation in the rate of the SM-like Higgs boson decays into the weak gauge bosons $W^{\pm}$ and Z. The measured Higgs mass imposes additional constraints on the realisation of this scenario. Once all effects are considered, the CP-odd Higgs boson A component of the lightest Higgs boson tends to be smaller than about 10% [337]. This restriction can be alleviated in the NMSSM or more general two Higgs doublet models. CP-violating effects can still be significant in the heavy Higgs sector. For instance, the Higgs bosons H_2 and H_3 may be admixtures of CP-even and CP-odd scalars, and therefore both may be able to decay into pairs of weak gauge bosons. The observation of such decays would be a clear signal of CP-violation. In the MSSM, the proximity of the masses of H_2 and H_3 makes the measurement of such effect quite challenging, but in generic two Higgs doublet models, the mass splitting between the two heavy mass eigenstates may become larger, facilitating the detection of CP-violating effects at collider experiments [338].

11.7.5 *Non-supersymmetric extensions of the Higgs sector*

There are many ways to extend the minimal Higgs sector of the SM. In the preceding sections the phenomenology of SUSY Higgs sectors is considered, which at tree level implies a constrained type-II 2HDM (with restrictions on the Higgs boson masses and couplings). In the following discussion, more generic 2HDM's are presented (for some comprehensive reviews, see Ref. [339]). These models are theoretically less compelling since they do not provide an explanation for the SM Higgs naturalness problem, but can lead to different patterns of Higgs-fermion couplings, hence, to different phenomenology. It is also possible to consider models with a SM Higgs boson and one or more additional scalar SU(2) doublets that acquire no VEV and hence play no role in the EWSB mechanism. Such models are dubbed Inert Higgs Doublet Models (IHD) [340]. Without a VEV associated to it, a Higgs boson from an inert doublet has no tree-level coupling to gauge bosons and hence cannot decay into a pair of them. Moreover, imposing a Z_2 symmetry that prevents them from coupling to the fermions, it follows that, if the lightest inert Higgs boson is neutral, it becomes a good DM candidate with interesting associated collider signals. Various studies of IHD models in the light of a 125 GeV Higgs boson have been performed, see for instance Ref. [341], showing an interesting interplay between collider and direct DM detection signals.

An interesting type of 2HDMs are those in which an abelian flavour symmetry broken at the electroweak scales creates the fermion mass hierarchies and mixing angles [17]. This idea is based on the Froggatt–Nielsen model [342], where a flavon field couples differently to the SM fermions of different flavour charges. Such flavon acquires a vacuum expectation value, breaking the flavour symmetry but leaving both the flavour breaking and the new physics scales undetermined. In Refs. [343], it was proposed to relate the flavour breaking scale to the electroweak scale by identifying the flavon with the modulus square of the Higgs field. A 2HDM, however, provides a more compelling realisation of the electroweak scale flavour breaking idea. In the most ambitious constructions of two Higgs doublet flavour models (2HDFM), the textures of the Yukawa couplings are a result of an abelian flavour symmetry that only allows renormalisable Yukawa couplings of the top quark to the Higgs bosons. All other Yukawa couplings are generated by higher dimensional operators that produce hierarchical entries of the Yukawa matrices, explaining the observed quark masses and mixing angles. Flavour observables, LHC Higgs signal strength measurements, electroweak precision measurements, unitarity and perturbativity bounds, as well as collider searches for new scalar resonances result in precise predictions for the parameters of these 2HDFMs. In particular, correlated departures from SM Higgs boson couplings, as well as additional Higgs bosons with masses < 700 GeV must be observed at the LHC. Other incarnations of 2HDFMs can aim at only partially explaining the fermion mass hierarchies but are therefore less restrictive.

Other extensions of the Higgs sector can include multiple copies of $SU(2)_L$ doublets [344], additional Higgs singlets [345], triplets or more complicated combinations of Higgs multiplets. It is also possible to enlarge the gauge symmetry beyond $SU(2)_L \times U(1)_Y$ along with the necessary Higgs field structure to generate gauge boson and fermion masses. There are two main experimental constraints on these extensions: (i) precision measurements which constrain $\rho = m_W^2/(m_Z^2 \cos^2\theta_W)$ to be very close to 1 and (ii) flavour changing neutral current (FCNC) effects. In electroweak models based on the SM gauge group, the tree-level value of ρ is determined by the Higgs multiplet structure. By suitable choices for the hypercharges, and in some cases the mass splitting between the charged and neutral Higgs sector or the vacuum expectation values of the Higgs fields, it is possible to obtain a richer combination of singlets, doublets, triplets and higher multiplets compatible with precision measurements. Concerning the constraints coming from FCNC effects, the Glashow–Weinberg (GW) criterion [346] states that, in the presence of multiple Higgs doublets, the tree-level FCNC's mediated by neutral Higgs bosons will be absent if all fermions of a given electric charge couple to no more than one Higgs doublet. An alternative way of suppressing FCNC in a two Higgs doublet model has been considered in Ref. [347], where it is shown that it is possible to have tree level FCNC completely fixed by the CKM matrix, as a result of an abelian symmetry.

11.7.5.1 *Two-Higgs-doublet models*

General two Higgs doublet models [339] can have a more diverse Higgs-fermion coupling structure than in SUSY, and can be viewed as a simple extension of the SM to realise the spontaneous breakdown of $SU(2)_L \times U(1)_Y$ to $U(1)_{\rm em}$. Quite generally, if the two Higgs doublets contain opposite hypercharges, the scalar potential will contain mixing mass parameters of the kind $m_{12}^2 \Phi_1^T i\sigma_2 \Phi_2 + h.c.$. In the presence of such terms, both Higgs doublets will acquire vacuum expectation values, $v_1/\sqrt{2}$ and $v_2/\sqrt{2}$, respectively, and the gauge boson masses will keep their SM expressions with the Higgs VEV v replaced by $\sqrt{v_1^2 + v_2^2}$. Apart from the mass terms, the most generic renormalisable and gauge invariant scalar potential for two Higgs doublets with opposite hypercharges contains seven quartic couplings, as presented in Eq. (11.46).

Just as in the MSSM case, after electroweak symmetry breaking and in the absence of CP-violation, the physical spectrum contains a pair of charged Higgs bosons $H^{\pm}$, a CP-odd Higgs boson A and two neutral CP-even Higgs bosons, h and H. The angles α and β diagonalise the CP-even, and the CP-odd and charged Higgs sectors, respectively. The complete 2HDM is defined only after considering the interactions of the Higgs fields to fermions. Yukawa couplings of the generic form

$$- h_{ij}^a \bar{\Psi}_L^i H_a \Psi_R^j + h.c. \tag{11.54}$$

may be added to the renormalisable Lagrangian of the theory. Contrary to the SM, the two Higgs doublet structure does not ensure the alignment of the fermion mass terms $m_{ij} = h_{ij}^a v_a/\sqrt{2}$ with the Yukawa couplings h_{ij}^a. This implies that quite generally the neutral Higgs boson will mediate flavour changing interactions between the different mass eigenstates of the fermion fields. Such flavour changing interactions should be suppressed in order to describe properly the Kaon, D and B meson phenomenology. Based on the Glashow–Weinberg criterion, it is clear that the simplest way of avoiding such transitions is to assume the existence of a symmetry that ensures the couplings of the fermions of each given quantum number (up-type and down-type quarks, charged and neutral leptons) to only one of the two Higgs doublets. Different models may be defined depending on which of these fermion fields couple to a given Higgs boson, see Table 11.13. Models of type-I are those in which all SM fermions couple to a single Higgs field. In type-II models, down-type quarks and charged leptons couple to a common Higgs field, while the up-type quarks and neutral leptons couple to the other. In models of type-III (lepton-specific), quarks couple to one of the Higgs bosons, while leptons couple to the other. Finally, in models of type-IV (flipped), up-type quarks and charged leptons couple to one of the Higgs fields while down-quarks and neutral leptons couple to the other.

Table 11.13: Higgs boson couplings to up, down and charged lepton-type $SU(2)_L$ singlet fermions in the four discrete types of 2HDM models that satisfy the Glashow–Weinberg criterion.

Model	2HDM I	2HDM II	2HDM III	2HDM IV
u	Φ_2	Φ_2	Φ_2	Φ_2
d	Φ_2	Φ_1	Φ_2	Φ_1
e	Φ_2	Φ_1	Φ_1	Φ_2

The two Higgs doublet model phenomenology depends strongly on the size of the mixing angle α and therefore on the quartic couplings. For large values of m_A, $\sin\alpha \to -\cos\beta$, $\cos\alpha \to \sin\beta$, $\cos(\beta-\alpha) \to 0$, and the lightest CP-even Higgs boson h behaves as the SM Higgs boson. The same behaviour is obtained if the quartic couplings are such that $\mathcal{M}_{12}^2 \sin\beta = -(\mathcal{M}_{11}^2 - m_h^2)\cos\beta$. The latter condition represents a situation in which the couplings of h to fermions and weak gauge bosons become the same as in the SM, without decoupling the rest of the non-standard scalars and it is of particular interest due to the fact that the discovered Higgs boson has SM-like properties. This situation will be referred to as alignment, as in the MSSM case.

In analogy to the effects of CP violation in the SUSY 2HDM, some parameters of the Higgs potential can be complex and one has a model that is explicitly CP violating. The three neutral mass eigenstates mixed with each other and the Higgs phenomenology is analogous to the one described for the SUSY case above, with the caveat that when considering the neutral Higgs boson couplings to the scalar and pseudoscalar fermion bilinear densities, the proper weight should be considered for the respective 2HDM's.

In type-II Higgs doublet models, at large values of $\tan\beta$ and moderate values of m_A, the non-standard Higgs bosons H, A and $H^\pm$ couple strongly to bottom quarks and τ leptons. Hence the decay modes of the non-standard Higgs bosons tend to be dominated by the b-quark and τ-lepton modes, including top quarks or neutrinos in the case of the charged Higgs boson. However, for large and negative values of λ_4, the charged Higgs boson mass may be sufficiently heavy to allow on-shell decays $H^\pm \to W^\pm + (H, A)$, via a trilinear coupling

$$g_{H^\pm W^\mp H,A} \simeq \frac{M_W}{v}\sin(\beta-\alpha)(p_{H^+} - p_{H,A})\,, \quad (11.55)$$

where p_{H^+} and $p_{H,A}$ are the charged and neutral scalar Higgs boson momenta pointing into the vertex. On the other hand, for large and positive values of λ_5, the above charged Higgs boson decay into a $W^\pm$ and the CP-odd Higgs boson may be allowed, but the heavy Higgs boson H may be sufficiently heavy to decay into a CP-odd Higgs boson and an on-shell Z, $H \to Z + A$, via

$$g_{HZA} \simeq \frac{M_Z}{v}\sin(\beta-\alpha)(p_H - p_A). \quad (11.56)$$

The decay $H^\pm \to W^\pm + H$, on the other hand may be allowed only if $\lambda_4 < -\lambda_5$. The couplings controlling all the above decay modes are proportional to $\sin(\beta-\alpha)$ and therefore they are unsuppressed in the alignment limit. Moreover, these could still be the dominant decay modes at moderate values of $\tan\beta$, offering a way to evade the current bounds obtained assuming a dominant decay into b-quarks or τ-leptons.

The quartic couplings are restricted by the condition of stability of the effective potential as well as by the restriction of obtaining the proper value of the lightest CP-even Higgs boson mass. Close to the alignment limit, the lightest CP-even Higgs boson mass becomes approximately independent of m_A and is given by

$$\begin{aligned} m_h^2 \simeq v^2(&\lambda_1\cos^4\beta + \lambda_2\sin^4\beta + 2\tilde{\lambda}_3 v^2\cos^2\beta\sin^2\beta \\ &+ 4\lambda_6\cos^3\beta\sin\beta + 4\lambda_7\sin^3\beta\cos\beta)\,, \end{aligned} \quad (11.57)$$

where $\tilde{\lambda}_3 = \lambda_3 + \lambda_4 + \lambda_5$.

The stability conditions imply the positiveness of all masses, as well as the avoidance of run-away solutions to large negative values of the fields in the scalar potential. These conditions imply

$$\begin{aligned} &\lambda_1 \geq 0, \quad \lambda_2 \geq 0, \quad \lambda_3 + \lambda_4 - |\lambda_5| \geq -\sqrt{\lambda_1\lambda_2}, \quad \lambda_3 \geq -\sqrt{\lambda_1\lambda_2}, \\ &2|\lambda_6 + \lambda_7| < \frac{\lambda_1 + \lambda_2}{2} + \tilde{\lambda}_3, \end{aligned} \quad (11.58)$$

where the first four conditions are necessary and sufficient conditions in the case of $\lambda_6 = \lambda_7 = 0$, while the last one is a necessary condition in the case all couplings are non-zero. Therefore, to obtain the conditions that allow the decays $H^\pm \to W^\pm H, A$ and $H \to ZA$, λ_3 should take large positive values in order to compensate for the effects of λ_4 and λ_5. For more detailed discussions about 2HDM phenomenology, see for example Refs. [44, 339].

11.7.5.2 *Higgs triplets*

Electroweak triplet scalars are the simplest non-doublet extension of the SM that can participate in the spontaneous breakdown of $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ to $\mathrm{U}(1)_{\mathrm{em}}$. Two types of model have been developed in enough detail to make a meaningful comparison to LHC data: the Higgs triplet model (HTM) [348] and the Georgi–Machacek model (GM) [349].

The Higgs triplet model extends the SM by the addition of a complex $\mathrm{SU}(2)_L$ triplet scalar field Δ with hypercharge $Y = 2$, and a general gauge-invariant renormalisable potential $V(\Phi, \Delta)$ for Δ and the SM Higgs doublet Φ. The components of the triplet field can be parameterised as

$$\Delta = \frac{1}{\sqrt{2}}\begin{pmatrix} \Delta^+ & \sqrt{2}\Delta^{++} \\ v_\Delta + \delta + i\xi & -\Delta^+ \end{pmatrix}. \quad (11.59)$$

where Δ^+ is a singly-charged field, Δ^{++} is a doubly-charged field, δ is a neutral CP-even scalar, ξ is a neutral CP-odd scalar, and v_Δ is the triplet VEV. The general scalar potential mixes the doublet and triplet components. After electroweak symmetry breaking there are seven physical mass eigenstates, denoted $H^{\pm\pm}$, $H^\pm$, A, H, and h.

A distinguishing feature of the HTM is that it violates the custodial symmetry of the SM; thus the ρ parameter deviates from 1 even at tree level. Letting x denote the ratio of triplet and doublet VEVs, the tree level expression is

$$\rho = \frac{1 + 2x^2}{1 + 4x^2}\,. \quad (11.60)$$

The measured value of the ρ parameter then limits the triplet VEV to be quite small, $x \lesssim 0.03$, or $v_\Delta < 8\,\mathrm{GeV}$. This constraint severely limits the role of the triplet scalar in the EWSB mechanism.

The small VEV of the Higgs triplet in the HTM is a virtue from the point of view of generating neutrino masses without the necessity for introducing right-handed neutrino fields. The gauge invariant dimension four interaction

$$h_{\nu_{ij}}\,\ell_i^T C^{-1} i\sigma_2\,\Delta\,\ell_j\,, \quad (11.61)$$

where ℓ_i are the lepton doublets, C is the charge conjugation matrix, and $h_{\nu_{ij}}$ is a complex symmetric coupling matrix, generates a Majorana mass matrix for the neutrinos:

$$m_{\nu_{ij}} = \sqrt{2} h_{\nu_{ij}} v_\Delta\,. \quad (11.62)$$

This can be combined with the usual neutrino seesaw to produce what is known as the type-II seesaw [350].

The HTM suggests the exciting possibility of measuring parameters of the neutrino mass matrix at the LHC. If the doubly-charged Higgs boson is light enough and/or its couplings to W^+W^+ are sufficiently suppressed, then its primary decay is into same-sign lepton pairs: $H^{++} \to \ell_i^+\ell_j^+$; from Eq. (11.61) and Eq. (11.62), it is apparent that these decays are in general lepton-flavor violating with branchings proportional to elements of the neutrino mass matrix [351].

Precision electroweak data constrain the mass spectrum as well as the triplet VEV of the HTM [352]. These constraints favour a spectrum where H^{++} is the lightest of the exotic bosons, and where the mass difference between H^+ and H^{++} is a few hundred GeV. The favoured triplet VEV is a few GeV, which also favours H^{++} decays into W^+W^+ over same-sign dileptons.

The GM model addresses the ρ parameter constraint directly by building in custodial symmetry. Writing the complex scalar doublet of the SM as a $(2,2)$ under $\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R$, it is obvious that the next simplest construction respecting custodial symmetry is a scalar transforming like a $(3,3)$ [353]. These nine real degrees of freedom correspond to a complex electroweak triplet combined with a real triplet, with the scalar potential required to be invariant under $\mathrm{SU}(2)_R$. Under the custodial $\mathrm{SU}(2)_{L+R}$, they transform as $1 \oplus 3 \oplus 5$, with a CP-even neutral scalar as the custodial singlet (thus matching the SM Higgs boson), a CP-odd neutral scalar in the custodial triplet, and another CP-even neutral scalar in the custodial 5-plet.

The scalar components can be decomposed as

$$\Xi = \begin{pmatrix} \chi_3^* & \xi_1 & \chi_1 \\ -\chi_2^* & \xi_2 & \chi_2 \\ \chi_1^* & -\xi_1^* & \chi_3 \end{pmatrix}, \tag{11.63}$$

where ξ_2 is a real scalar and the others are complex scalars. Linear combinations of these scalars account for the neutral custodial singlet, a neutral and singly-charged field making up the custodial triplet, and neutral, singly-charged, and doubly-charged fields making up the custodial 5-plet.

When combined with the usual SM doublet field Φ, the electroweak scale v is now related to the doublet and triplet VEVs by

$$v^2 = v_\Phi^2 + 8v_\Xi^2 \,. \tag{11.64}$$

Note that the GM triplets by themselves are sufficient to explain electroweak symmetry breaking and the existence of a 125 GeV neutral boson along with a custodial triplet of Goldstone bosons; the complex doublet field in the GM model is required to generate fermion masses via the usual dimension four Yukawa couplings. This raises the question of whether one can rule out the possibility that the 125 GeV boson is the neutral member of a custodial 5-plet rather than a custodial singlet, without invoking decays to fermions. A conclusive answer is given by observing that the ratio of the branching fractions to W versus Z bosons is completely determined by the custodial symmetry properties of the boson. For a custodial 5-plet, the ratio of the signal strength to WW over that to ZZ is predicted to be 1/4 that of a SM Higgs boson [353], and thus already ruled out by the experimental results presented in Section 11.6.

Another interesting general feature of Higgs triplet models is that, after mixing, the SM-like neutral boson can have stronger couplings to WW and ZZ than predicted by the SM [354]; this is in contrast to mixing with additional doublets and singlet, which can only reduce the WW and ZZ couplings versus the SM. This emphasises that LHC Higgs data cannot extract model independent coupling strengths for the Higgs boson [244].

Because of the built-in custodial symmetry, the triplet VEV in the GM model can be large compared to the doublet VEV. The custodial singlet neutral boson from the triplets mixes with the neutral boson from the doublet. Two interesting special cases are (i) the triplet VEV is small and the 125 GeV boson is SM-like except for small deviations, and (ii) the 125 GeV boson is mostly the custodial singlet neutral boson from the electroweak triplets. The phenomenology of the doubly-charged and singly-charged bosons is similar to that of the HTM. The constraints on the GM model from precision electroweak data, LEP data, and current LHC data are summarised in Ref. [44].

11.7.6 *Composite Higgs models*

Within the SM, EWSB is posited but has no dynamical origin. Furthermore, the Higgs boson appears to be unnaturally light. A scenario that remedies these two catches is to consider the Higgs boson as a bound state of new dynamics becoming strong around the weak scale. The Higgs boson can be made significantly lighter than the other resonances of the strong sector if it appears as a pseudo-Nambu–Goldstone boson, see Refs. [11] for reviews.

11.7.6.1 *Little Higgs models*

The idea behind the Little Higgs boson models [355] is to identify the Higgs doublet as a (pseudo) Nambu–Goldstone boson while keeping some sizeable non-derivative interactions, in particular a largish Higgs quartic interaction. By analogy with QCD where the pions $\pi^{\pm,0}$ appear as Nambu–Goldstone bosons associated to the breaking of the chiral symmetry $\mathrm{SU}(2)_\mathrm{L} \times \mathrm{SU}(2)_\mathrm{R}/\mathrm{SU}(2)$, switching on some interactions that break explicitly the global symmetry will generate masses for the would-be massless Nambu–Goldstone bosons of the order of $g\Lambda_{G/H}/(4\pi)$, where g is the coupling of the symmetry breaking interaction and $\Lambda_{G/H} = 4\pi f_{G/H}$ is the dynamical scale of the global symmetry breaking G/H. In the case of the Higgs boson, the top Yukawa interaction or the gauge interactions themselves will certainly break explicitly (part of) the global symmetry since they act non-linearly on the Higgs boson. Therefore, obtaining a Higgs boson mass around 125 GeV would demand a dynamical scale $\Lambda_{G/H}$ of the order of 1 TeV, which is known to lead to too large oblique corrections. Raising the strong dynamical scale by at least one order of magnitude requires an additional selection rule to ensure that a Higgs boson mass is generated at the 2-loop level only

$$m_H^2 = \frac{g^2}{16\pi^2}\Lambda_{G/H}^2 \to m_H^2 = \frac{g_1^2 g_2^2}{(16\pi^2)^2}\Lambda_{G/H}^2. \tag{11.65}$$

The way to enforce this selection rule is through a "collective breaking" of the global symmetry:

$$\mathcal{L} = \mathcal{L}_{G/H} + g_1\mathcal{L}_1 + g_2\mathcal{L}_2. \tag{11.66}$$

Each interaction $\mathcal{L}_1$ or $\mathcal{L}_2$ individually preserves a subset of the global symmetry such that the Higgs boson remains an exact Nambu–Goldstone boson whenever either g_1 or g_2 is vanishing. A mass term for the Higgs boson can be generated only by diagrams involving simultaneously both interactions. At one-loop, such diagrams are not quadratically divergent, so the Higgs boson mass is not UV sensitive. Explicitly, the cancellation of the SM quadratic divergences is achieved by a set of new particles around the Fermi scale: gauge bosons, vector-like quarks, and extra massive scalars, which are related, by the original global symmetry, to the SM particles with the same spin. Contrary to SUSY, the cancellation of the quadratic divergences is achieved by same-spin particles. These new particles, with definite couplings to SM particles as dictated by the global symmetries of the theory, are perfect goals for the LHC.

The simplest incarnation of the collective breaking idea, the so-called littlest Higgs boson model, is based on a non-linear σ-model describing the spontaneous breaking SU(5) down to SO(5). A subgroup $\mathrm{SU}(2)_1 \times \mathrm{U}(1)_1 \times \mathrm{SU}(2)_2 \times \mathrm{U}(1)_2$ is weakly gauged. This model contains a weak doublet, that is identified with the Higgs doublet, and a complex weak triplet whose mass is not protected by collective breaking. Other popular little Higgs models are based on different coset spaces: minimal moose $(\mathrm{SU}(3)^2/\mathrm{SU}(3))$, the simplest little Higgs $(\mathrm{SU}(3)^2/\mathrm{SU}(2)^2)$, the bestest little Higgs $(\mathrm{SO}(6)^2/\mathrm{SO}(6))$. For comprehensive reviews, see Ref. [356].

Generically, oblique corrections in Little Higgs models are reduced either by increasing the coupling of one of the gauge groups (in the case of product group models) or by increasing the masses of the W and Z partners, leading ultimately to a fine-tuning of the order of a few percents (see for instance Ref. [357] and references therein). The compatibility of Little Higgs models with experimental data is significantly improved when the global symmetry involves a custodial symmetry as well as a T-parity [358] under which, in analogy with R-parity in SUSY models, the SM particles are even and their partners are odd. Such Little Higgs models would therefore appear in colliders as jet(s) with missing transverse energy [359] and the ATLAS and CMS searches for squarks and gluinos (see "Supersymmetry, Part II" in this review) can be recast to obtain limits on the masses of the heavy vector-like quarks. The T-even top partner, with an expected mass below 1 TeV to cancel the top loop quadratic divergence without too much fine-tuning, would decay dominantly into a $t + Z$ pair or into a $b + W$ pair or even into $t + H$. The latest CMS and ATLAS direct searches [360] for vector-like top partners put a lower bound around 1.1–1.3 TeV (for various branching fraction combinations), excluding the most natural region of the parameter space of these models, i.e., imposing a fine-tuning below the percent level.

The motivation for Little Higgs models is to solve the little hierarchy problem, i.e., to push the need for new physics (responsible for the stability of the weak scale) up to around 10 TeV. Per se, Little Higgs models are effective theories valid up to their cut-off scale $\Lambda_{G/H}$. Their UV completions could either be weakly or strongly coupled.

11.7.6.2 *Models of partial compositeness*

Even in composite models, the Higgs boson cannot appear as a regular resonance of the strong sector without endangering the viability of the setup when confronted to data. The way out is that the Higgs boson appears as a pseudo Nambu–Goldstone boson: the new strongly coupled sector is supposed to be invariant under a global symmetry G spontaneously broken to a subgroup H at the scale f (the typical mass scale of the resonances of the strong sector is $m_\rho \sim g_\rho f$ with g_ρ the characteristic coupling of the strong sector). To avoid conflict with EW precision measurements, the strong interactions themselves should better not break the EW symmetry. Hence the SM gauge symmetry itself should be contained in H. See Table 11.14 for a few examples of coset spaces.

Table 11.14: Global symmetry breaking patterns and the corresponding Goldstone boson contents of the SM, the minimal composite Higgs model, the next to minimal composite Higgs model, and the minimal composite two Higgs doublet model. Note that the SU(3) model does not have a custodial invariance. a denotes a CP-odd scalar while h and H are CP-even scalars.

Model	Symmetry Pattern	Goldstones
SM	SO(4)/SO(3)	W_L, Z_L
–	SU(3)/SU(2)×U(1)	W_L, Z_L, H
MCHM	SO(5)/SO(4)	W_L, Z_L, H
NMCHM	SO(6)/SO(5)	W_L, Z_L, H, a
MC2HM	SO(6)/SO(4)×SO(2)	$W_L, Z_L, h, H, H^\pm, a$

The SM (light) fermions and gauge bosons cannot be part of the strong sector itself since LEP data have already put stringent bounds on the compositeness scale of these particles far above the TeV scale. The gauge bosons couple to the strong sector by a weak gauging of a SU(2)×U(1) subgroup of the global symmetry G. Inspiration for the construction of such models comes from the AdS/CFT correspondence: the components of a gauge field along an extra warped space dimension can be interpreted as the Goldstone bosons resulting from the breaking of global symmetry of the strong sector. The couplings of the SM fermions to the strong sector could a priori take two different forms:

(i) a bilinear coupling of two SM fermions to a composite scalar operator, $\mathcal{O}$, of the form $\mathcal{L} = y\,\bar{q}_L u_R \mathcal{O} + h.c.$, in simple analogy with the SM Yukawa interactions. This is the way fermion masses were introduced in technicolor theories and it generically comes with severe flavour problems and calls for extended model-building gymnastics [12] to circumvent them;

(ii) a linear mass mixing with fermionic vector-like operators: $\mathcal{L} = \lambda_L\,\bar{q}_L \mathcal{Q}_R + \lambda_R \bar{\mathcal{U}}_L u_R$. $\mathcal{Q}$ and $\mathcal{U}$ are two fermionic composite operators of mass M_Q and M_U.

Being part of the composite sector, the composite fermionic operators can have a direct coupling of generic order Y_* to the Higgs boson. In analogy with the photon-ρ mixing in QCD, once the linear mixings are diagonalised, the physical states are a linear combination of elementary and composite fields. Effective Yukawa couplings are generated and read for instance for the up-type quark

$$y = Y_* \sin\theta_L \sin\theta_R \tag{11.67}$$

where $\sin\theta_i = \lambda_i / \sqrt{M_{Q,U}^2 + \lambda_i^2}$, $i = L, R$, measure the amount of compositeness of the SM left- and right-handed up-type quark. If the strong sector is flavour-anarchic, i.e., if the couplings of the Higgs boson to the composite fermions does not exhibit any particular flavour structure, the relation Eq. (11.67) implies that the light fermions are mostly elementary states ($\sin\theta_i \ll 1$), while the third generation quarks need to have a sizable degree of compositeness. The partial compositeness paradigm offers an appealing dynamical explanation of the hierarchies in the fermion masses. In fact, assuming the strong sector to be almost conformal above the confinement scale, the low-energy values of the mass-mixing parameters $\lambda_{L,R}$ are determined by the (constant) anomalous dimension of the composite operator they mix with. If the UV scale at which the linear mixings are generated is large, then $\mathcal{O}(1)$ differences in the anomalous dimensions can generate naturally large hierarchies in the fermion masses via renormalisation group running [361]. While the introduction of partial compositeness greatly ameliorated the flavor problem of the original composite Higgs models, nevertheless, it did not solve the issue completely, at least in the case where the strong sector is assumed to be flavour-anarchic [362]. While the partial compositeness set-up naturally emerges in models built in space-times with extra dimensions, no fully realistic microscopic realisation of partial compositeness has been proposed in the literature.

Another nice aspect of the partial compositeness structure is the dynamical generation of the Higgs potential that is not arbitrary like in the SM. The Higgs boson being a pseudo-Nambu–Goldstone boson, its mass does not receive any contribution from the strong sector itself but it is generated at the one-loop level via the couplings of the SM particles to the strong sector since these interactions are breaking the global symmetries under which the Higgs doublet transforms non-linearly. Obtaining $v \ll f$, as required phenomenologically, requires some degree of tuning, which scales like $\xi \equiv v^2/f^2$. A mild tuning of the order of 10% ($\xi \approx 0.1$) is typically enough to comply with electroweak precision constraints. This is an important point: in partial compositeness models, the entire Higgs potential is generated at one loop, therefore the separation between v and f can only be obtained at a price of a tuning. This marks a difference with respect to the Little Higgs models which realise a parametric hierarchy between the quartic and mass terms through the collective symmetry breaking mechanism. In fact in Little Higgs models, the quartic coupling is a tree-level effect, leading to a potential

$$V(H) \approx \frac{g_{\mathrm{SM}}^2}{16\pi^2} m_\rho^2 H^2 + g_{\mathrm{SM}}^2 H^4, \tag{11.68}$$

where g_{SM} generically denotes the SM couplings. The minimisation condition reads $v^2/f^2 \sim g_\rho^2/(16\pi^2)$, therefore v is formally loop suppressed with respect to f. This is the major achievement of the Little Higgs constructions, which however comes at the price of the presence of sub-TeV vectors carrying EW quantum numbers and therefore giving rise generically to large oblique corrections to the propagators of the W and the Z gauge bosons.

After minimisation, the dynamically generated potential leads to an estimate of the Higgs boson mass as

$$m_H^2 \approx g_\rho^3\, y_t 2\pi^2 v^2. \tag{11.69}$$

It follows that the limit $f \to \infty$, i.e., $\xi \to 0$, is a true decoupling limit: all the resonances of the strong sector become heavy but the Higgs boson whose mass is protected by the symmetries of the coset G/H. When compared to the experimentally measured Higgs boson mass, this estimate puts an upper bound on the strength of the strong interactions: $g_\rho \lesssim 2$. In this limit of not so large coupling, the Higgs potential receives additional contributions. In particular, the fermionic resonances in the top sector which follow from the global symmetry structure of the new physics sector can help raising the Higgs boson mass. Using some dispersion relation techniques, the mass of the Higgs is connected to the resonance masses. In the minimal SO(5)/SO(4) model, it was shown [363] that a 125 GeV mass can be obtained if at least one of the fermionic resonances is lighter than $\sim 1.4\,f$. As in SUSY scenarios, the top sector is playing a crucial role in the dynamics of EWSB and can provide the first direct signs of new physics. The direct searches for these top partners, in particular the ones with exotic electric charges 5/3, are already exploring the natural parameter spaces of these models [364].

The main physics properties of a pseudo Nambu–Goldstone Higgs boson can be captured in a model-independent way by a small number of higher-dimensional operators. Indeed, the strong dynamics at the origin of the composite Higgs boson singles out a few operators among the complete list discussed earlier in Section 11.6: these are the operators that involve extra powers of the Higgs doublets and they are therefore generically suppressed by a factor $1/f^2$ as opposed to the operators that involve extra derivatives or gauge bosons that are suppressed by a factor $1/(g_\rho^2 f^2)$. The relevant effective Lagrangian describing a strongly interacting light Higgs boson is:

$$\begin{aligned}\mathcal{L}_{\mathrm{SILH}} =& \frac{c_H}{2f^2}\left(\partial_\mu\left(\Phi^\dagger\Phi\right)\right)^2 + \frac{c_T}{2f^2}\left(\Phi^\dagger \overleftrightarrow{D}^\mu \Phi\right)^2 - \frac{c_6\lambda}{f^2}\left(\Phi^\dagger\Phi\right)^3 \\ &+ \left(\sum_f \frac{c_f\, y_f}{f^2}\Phi^\dagger\Phi \bar{f}_L \Phi f_R + \text{h.c.}\right).\end{aligned} \tag{11.70}$$

Typically, these new interactions induce deviations in the Higgs boson couplings that scale like $\mathcal{O}(v^2/f^2)$. Hence the measurements of the Higgs boson couplings can be translated into some constraints on the compositeness scale, $4\pi f$, of the Higgs boson. The peculiarity of these composite models is that, due to the Goldstone nature of the Higgs boson, the direct couplings to photons and gluons are further suppressed and generically the coupling modifiers scale like

$$\begin{aligned}&\kappa_{W,Z,f} \sim 1 + \mathcal{O}\left(\frac{v^2}{f^2}\right), \quad \kappa_{Z\gamma} \sim \mathcal{O}\left(\frac{v^2}{f^2}\right), \\ &\kappa_{\gamma,g} \sim \mathcal{O}\left(\frac{v^2}{f^2} \times \frac{y_t^2}{g_\rho^2}\right),\end{aligned} \tag{11.71}$$

where g_ρ denotes the typical coupling strength among the states of the strongly coupled sector and y_t is the top Yukawa coupling, the largest interaction that breaks the Goldstone symmetry. The $\kappa_{Z\gamma,\gamma,g}$ coupling modifiers are not generated by the strong coupling operators of Eq. (11.70) but by some subleading form-factor operator generated by loops of heavy resonances of the strong sector. The coupling modifiers also receive additional contributions from the other resonances of the strong sector, in particular the fermionic resonances of the top sector that are required to be light to generate a 125 GeV Higgs boson mass. Some indirect information on the resonance spectrum could thus be inferred by a precise measurement of the Higgs boson coupling deviations. However, it was realised, see in particular Ref. [266], that the task is actually complicated by the fact that, in the minimal models, these top partners give a contribution to both κ_t (resulting from a modification of the top Yukawa coupling) and κ_γ and κ_g (resulting from new heavy particles running into the loops) and the structure of interactions is such that the net effect vanishes for inclusive quantities like $\sigma(gg \to H)$ or $\Gamma(H \to \gamma\gamma)$ as a consequence of the Higgs low energy theorem [23, 24, 264]. So, one would need to rely on differential distribution, like the Higgs boson p_T distribution discussed in Section 11.2.4.1, to *see* the top partner effects in Higgs data [365]. The off-shell channel $gg \to H^* \to 4\ell$ [243] and the double Higgs boson production $gg \to HH$ [366] can also help to resolve the gluon loop and separate the top and top-partner contributions.

11.7.6.3 *Minimal composite Higgs models*

The minimal composite Higgs models (MCHM) are concrete examples of the partial compositeness paradigm. The Higgs doublet is described by the coset space SO(5)/SO(4) where a subgroup $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ is weakly gauged and under which the four Goldstone bosons transform as a doublet of hypercharge 1. There is some freedom on how the global symmetry is acting on the SM fermions: in MCHM4 the quarks and leptons are embedded into spinorial representations of SO(5), while in MHCM5 they are part of fundamental representations (it might also be interesting phenomenologically to consider larger representations like MCHM14 [367] with the SM fermions inside a representation of dimension 14). It is also possible to consider that fermions of different chirality and flavour are in different representations of SO(5), leading to a more varied phenomenology [368]. The non-linearly realised symmetry acting on the Goldstone bosons leads to general predictions of the coupling of the Higgs boson to the EW gauge bosons. For instance, it can be shown that the quadratic terms in the W and Z bosons read

$$m_W^2(H)\left(W_\mu W^\mu + \frac{1}{2\cos^2\theta_W} Z_\mu Z^\mu\right), \tag{11.72}$$

with $m_W(H) = \frac{gf}{2}\sin\frac{H}{f}$. Expanding around the EW vacuum, the expression of the weak scale is $v = f\sin(\langle H\rangle/f)$. And the values of the modified Higgs boson couplings to the W and Z become:

$$g_{HVV} = \frac{2m_V^2}{v}\sqrt{1 - v^2/f^2}\,, \quad g_{HHVV} = \frac{2m_V^2}{v^2}(1 - 2v^2/f^2)\,. \tag{11.73}$$

Note that the Higgs boson couplings to gauge bosons is always suppressed compared to the SM prediction. This is a general result [369] that holds as long as the coset space is compact.

The Higgs boson couplings to the fermions depend on the representation which the SM fermions are embedded into. The most commonly used embeddings consider all fermion doublets and singlets in the same representations. While, in MCHM4 and MCHM5, the modifications of the couplings depend only on the Higgs boson compositeness scale, in MCHM14 the leading corrections depend also on the mass spectrum of the resonances [367]. This is due to the fact that more than one SO(5) invariant gives rise to SM fermion masses. The (κ_V, κ_f) experimental fit of the Higgs boson couplings can be used to derive a lower bound on the Higgs boson compositeness scale $4\pi f \gtrsim 9\,\mathrm{TeV}$, which is less stringent than the indirect bound obtained from EW precision data, $4\pi f \gtrsim 15\,\mathrm{TeV}$ [370] but more robust and less subject on assumptions [371].

11.7.6.4 *Twin Higgs models*

In all composite models presented above, the particles responsible for canceling the quadratic divergences in the Higgs boson mass are charged under the SM gauge symmetries. In particular, the top partner carries color charge, implying a reasonably large minimal production cross section at the LHC. An alternative scenario, which is experimentally quite challenging and might explain the null result in various new physics searches, is the case nowadays referred to as "neutral naturalness" [13, 14], where the particles canceling the 1-loop quadratic divergences are neutral under the SM. The canonical example for such theories is the Twin Higgs model of Ref. [13]. This is an example of a pseudo-Goldstone boson model with an approximate global SU(4) symmetry broken to SU(3). The Twin Higgs model is obtained by gauging the $\mathrm{SU}(2)_A \times \mathrm{SU}(2)_B$ subgroup of SU(4), where $\mathrm{SU}(2)_A$ is identified with the SM $\mathrm{SU}(2)_L$, while $\mathrm{SU}(2)_B$ is the twin SU(2) group. Gauging this subgroup breaks the SU(4) symmetry explicitly, but quadratically divergent corrections do not involve the Higgs boson when the gauge couplings of the two SU(2) subgroups are equal, $g_A = g_B$. The SU(4)→ SU(3) breaking will also result in the breaking of the twin $\mathrm{SU}(2)_B$ group and, as a result, three of the seven Goldstone bosons will be eaten, leaving 4 Goldstone bosons corresponding to the SM Higgs doublet. In fact, imposing the Z_2 symmetry on the full model will ensure the cancellation of all 1-loop quadratic divergences to the Higgs boson mass. Logarithmically divergent terms can, however, arise for example from gauge loops, leading to a Higgs boson mass of order $g^2 f/4\pi$, which is of the order of the physical Higgs boson mass for $f \sim 1\,\mathrm{TeV}$. The quadratic divergences from the top sector can be eliminated if the Z_2 protecting the Higgs boson mass remains unbroken by the couplings that result in the top Yukawa coupling. This can be achieved by introducing top partners charged under a twin $\mathrm{SU}(3)_C$. In this case, the quadratic divergences are cancelled by top partners that are neutral under the SM gauge symmetries.

Twin Higgs models are low-energy effective theories valid up to a cutoff scale of order $\Lambda \sim 4\pi f \sim 5$–$10\,\mathrm{TeV}$, beyond which a UV completion has to be specified. The simplest such possibility is to also make the Higgs boson composite, and to UV complete the twin Higgs model via gauge and top partners at masses of the order of a few TeV. A concrete implementation is the holographic twin Higgs model [372], which also incorporates a custodial symmetry to protect the T-parameter from large corrections. It is based on a warped extra dimensional theory with a bulk SO(8) gauge group, which incorporates the SU(4) global symmetry discussed above enlarged to contain the $\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R$ custodial symmetry. In addition the bulk contains either a full SU(7) group or an $\mathrm{SU}(3) \times \mathrm{SU}(3) \times \mathrm{U}(1) \times \mathrm{U}(1) \times Z_2$ subgroup of it to incorporate the QCD, its twin, and the hypercharge local symmetries. The breaking on the UV brane is to the SM symmetries and their twin symmetries, while on the IR brane $\mathrm{SO}(8) \to \mathrm{SO}(7)$, giving rise to the 7 Goldstone bosons, three of which will be again eaten by the twin W, Z. The main difference compared to ordinary composite Higgs models is that, in composite twin Higgs models, the cancellation of the one-loop quadratic divergences is achieved by the twin partners. They have a mass of order 700 GeV–1 TeV and they are uncharged under the SM gauge group. This allows the IR scale of the warped extra dimension to be raised to the multi-TeV range without reintroducing the hierarchy problem. The role of the composite partners is to UV complete the theory, rather than to cancel the one-loop quadratic divergences. For more details about the composite twin Higgs models, see Refs. [373].

11.7.7 *Searches for signatures of extended Higgs sectors*

The measurements described in Sections 11.3 to 11.6 have established the existence of one state of the electroweak symmetry breaking sector, compatible with a SM Higgs boson, but not that it is the only one. As was discussed above, several classes of models beyond the SM require extended Higgs sectors. The searches are typically designed to be as model-independent as possible[8] and can be categorised in the classes summarised as follows:

- **(i)** the search for an additional CP-even state mostly in the high mass domain decaying to vector bosons, which would correspond either to the heavy CP-even state in a generic 2HDM where the light state would be the discovered Higgs boson at 125 GeV or to a generic additional singlet;
- **(ii)** the search for a state in the high mass domain decaying to pairs of fermions, which would correspond to the CP-odd A or the heavy CP-even state H in a generic 2HDM;
- **(iii)** the search for charged Higgs bosons, which also appear in generic 2HDMs;
- **(iv)** the search for a CP-odd state a in the low mass region which appears in the NMSSM in a variety of final states, e.g., with one or two a bosons decaying to pairs of photons, muons, taus, and b-quarks;
- **(v)** the search for doubly charged Higgs bosons which are expected in extensions of the Higgs sector with triplets.

Below is a concise description of the most recent searches performed at the LHC and elsewhere. A summary of these searches in terms of final states is given in Table 11.15 where the corresponding references are given for more details.

11.7.7.1 *Searches for an additional CP-even state*

(a) Exclusion limits from LEP

The searches for the SM Higgs boson at LEP provided an absolute lower limit of 114 GeV on its mass. These searches are also relevant for non-SM Higgs bosons. These searches were interpreted as 95% CL upper bounds on the ratio of the coupling g_{HZZ} to its SM prediction as a function of the Higgs boson mass [122, 436]. These results have an impact on MSSM benchmarks such as the low-m_H scenario, which is also nearly ruled out by current direct constraints and charged Higgs boson limits from LHC. These results also impact scenarios of light CP-even Higgs boson of the NMSSM which are constrained to project predominantly onto the EW singlet component. Additional interest for these scenarios is due to the slight excess observed at LEP [122] at a Higgs boson mass hypothesis of approximately 98 GeV.

(b) Searches at the LHC

At the LHC, the searches for the SM Higgs boson before the 2012 discovery covered a wide range of mass hypotheses up to approximately 1 TeV. After the discovery, the SM Higgs boson searches have been reappraised to search for a heavy CP-even state, extending progressively the search mass range beyond 1 TeV. This state could be the heavy CP-even Higgs boson of a 2HDM, or a generic additional singlet. In both cases, the natural width of the additional H state can be very different from that of the SM Higgs boson. To preserve unitarity of the longitudinal vector boson scattering and the longitudinal vector boson scattering into fermion pairs, the couplings of the additional CP-even Higgs boson to gauge bosons and fermions should not be too large and should constrain the natural width to be smaller than that of a unique Higgs boson at high mass with couplings to fermions and gauge bosons as predicted by the SM (and provided that trilinear and quartic couplings are not too large and that no new state affects the heavy state total width). It is therefore reasonable to consider total widths for the high mass CP-even state smaller than the equivalent SM width. Two specific cases have been considered: (i) the SM width using the complex pole scheme (CPS), and (ii) the narrow width approximation. For the sake of generality, these searches are now done as a function of the Higgs boson mass and total width.

Searches for the Higgs boson in the channels $H \to \gamma\gamma$, $H \to Z\gamma$, $H \to WW^{(*)}$ leptonic and semi-leptonic, and in the $H \to ZZ^{(*)}$ searches in the 4ℓ, $\ell\ell q\bar{q}$ and $\ell\ell\nu\nu$ channels have also been done, but some of them are simple reinterpretations of the SM Higgs boson search in the CPS scheme. References for these searches are summarised in Table 11.15.

(c) Searches for an additional resonance decaying to a pair of Higgs bosons

In addition to the rare and expected Higgs boson pair production mode, high mass CP-even Higgs bosons can be searched for in the resonant double Higgs boson mode. Searches for such processes, where the Higgs boson is used as a tool for searches for BSM phenomena, have been carried out in a variety of distinct modes depending on the subsequent decays of each Higgs bosons. ATLAS and CMS have searched for the $H \to hh \to b\bar{b}\tau\tau$, $b\bar{b}\gamma\gamma$, $H \to hh \to 4b$, $H \to hh \to \gamma\gamma WW^*$, $H \to hh \to bbWW^*$, $H \to hh \to WW^*WW^*$ and $H \to hh \to bbZZ^*$ final states. For mass hypotheses of an additional Higgs boson below 500 GeV, the two dominant search channels are the $b\bar{b}\gamma\gamma$ and the $b\bar{b}\tau\tau$ channels. For masses above 500 GeV, the most powerful search is with the $4b$ final state. As illustrated in Figure 11.19, these searches provide useful limits in the low $\tan\beta$ and high mass domain. The list of references for these searches is given in Table 11.15.

(d) Searches for an additional state with the presence of the Higgs boson

In the post-discovery era, analyses searching for additional Higgs bosons need to take into account the presence of the 125 GeV Higgs boson. For searches with sufficiently high mass resolution to disentangle the additional states which are not degenerate in mass, the strength of the observed state and limits on the signal strength of a potential additional state can be set independently, as discussed in the next section. However, in some cases where channels do not have a sufficiently fine mass resolution to resolve states nearly degenerate in mass, specific analyses need to be designed. There are two examples of such analyses: (i) the search for an additional state in the $H \to WW^{(*)} \to \ell\nu\ell\nu$ channel in ATLAS, and (ii) the search for nearly degenerate states in the $H \to \gamma\gamma$ channel with the CMS detector.

In the $H \to WW^{(*)} \to \ell\nu\ell\nu$ channel, the search for an additional state is done using a boosted decision tree combining several discriminating kinematic characteristics to separate both the signal from the background and a high mass signal H from the lower mass state h [437]. A simultaneous fit of the two states h

[8] Still, most non-SUSY models are likely to include further states and dynamics above the weak scale to stabilise the scalar sector and this new and unknown physics may influence the searches described in this section in a way difficult to estimate.

Table 11.15: Summary of references to the searches for additional states from extended Higgs sectors. (BBr) denotes the BaBar experiment and (TeV), the Tevatron experiments. Results using the full Run 2 dataset are indicated by (*). V denotes either the W or the Z boson. Only Run 2 searches references are indicated except when searches have been carried out using Run 1 data only. References for Run 1 searches are available in Ref. [123].

and H is then made to test the presence of an additional state. In this case, the usual null hypothesis of background includes the SM signal.

The CMS search for nearly degenerate mass states decaying to a pair of photons [438] is more generic and could for instance apply to CP-odd Higgs bosons as well. It consists of a fit to the diphoton mass spectrum using two nearly degenerate mass templates.

(e) Type I 2HDM and fermiophobia

The measurements of coupling properties of the 125 GeV Higgs boson directly establish its couplings to fermions. However, the presence of an additional fermiophobic state, as predicted by Type I 2HDMs, is not excluded. Prior to the discovery, ATLAS and CMS have performed searches for a fermiophobic Higgs boson, i.e., produced through couplings with vector bosons only (VBF and VH) and decaying in two photons. CMS has further combined these results with searches in the W^+W^- and ZZ channels, assuming fermiophobic production and decay. This way, CMS excluded a fermiophobic Higgs boson in the range 110 GeV $< m_H <$ 188 GeV at the 95% CL. References for these Run 1 measurements can be found in Ref. [123]

11.7.7.2 *Searches for additional neutral states ($\phi \equiv h$, H, A) decaying to fermions*

(a) Exclusion limits from LEP

In e^+e^- collisions, around the centre-of-mass energies reached by LEP, the main production mechanisms of the neutral MSSM Higgs bosons were the Higgs-strahlung processes $e^+e^- \to hZ$, HZ and the pair production processes $e^+e^- \to hA$, HA, while the vector boson fusion processes played a marginal role. Higgs boson decays to $b\bar{b}$ and $\tau^+\tau^-$ were used in these searches.

The searches and limits from the four LEP experiments are described in Refs. [439]. The combined LEP data did not contain any excess of events which would imply the production of a Higgs boson. Combined limits were derived [436]. For $m_A \gg M_Z$, the limit on m_h is nearly that of the SM searches, as $\sin^2(\beta-\alpha) \approx 1$. For high values of $\tan\beta$ and low m_A ($m_A \leq m_h^{max}$), the $e^+e^- \to hA$ searches become the most important, and the lightest Higgs boson h is non SM-like. In this region, the 95% CL mass bounds are $m_h >$ 92.8 GeV and $m_A >$ 93.4 GeV. In the m_h^{max} scenario [440], values of $\tan\beta$ from 0.7 to 2.0 are excluded taking $m_t = 174.3$ GeV, while a much larger $\tan\beta$ region is excluded for other benchmark scenarios such as the no-mixing one.

A flavour-independent limit for Higgs bosons in the Higgs-strahlung process at LEP has also been set at 112 GeV [441].

Neutral Higgs bosons may also be produced by Yukawa processes $e^+e^- \to f\bar{f}\phi$, where the Higgs particle $\phi \equiv h$, H, A, is radiated off a massive fermion ($f \equiv b$ or $\tau^\pm$). These processes can be dominant at low masses, and whenever the $e^+e^- \to hZ$ and hA processes are suppressed. The corresponding ratios of the $f\bar{f}h$ and $f\bar{f}A$ couplings to the SM coupling are $-\sin\alpha/\cos\beta$ and $\tan\beta$, respectively. The LEP data have been used to search for $b\bar{b}\,b\bar{b}$, $b\bar{b}\tau^+\tau^-$, and $\tau^+\tau^-\,\tau^+\tau^-$ final states [442]. Regions of low mass and high enhancement factors are excluded by these searches.

The searches for the Higgs boson at LEP also included the case where it does not predominantly decay to a pair of b quarks. All four collaborations conducted dedicated searches for the Higgs boson with reduced model dependence, assuming it is produced via the Higgs-strahlung process, and not addressing its flavour of decay, a lower limit on the Higgs boson mass of 112.9 GeV is set by combining the data of all four experiments [441].

Using an effective Lagrangian approach and combining results sensitive to the $h\gamma\gamma$, $hZ\gamma$ and hZZ couplings, an interpretation of several searches for the Higgs boson was made and set a lower limit of 106.7 GeV on the mass of a Higgs boson that can couple anomalously to photons [441].

(b) Searches at the Tevatron and the LHC

The best sensitivity is in the regime with low to moderate m_A and with large $\tan\beta$ which enhances the couplings of the Higgs bosons to down-type fermions. The corresponding limits on the Higgs boson production cross section times the branching ratio of the Higgs boson into down-type fermions can be interpreted in MSSM benchmark scenarios [443]. If $\phi = A, H$ for $m_A > m_h^{\max}$, and $\phi = A, h$ for $m_A < m_h^{\max}$, the most promising channels at the Tevatron are the inclusive $p\bar{p} \to \phi \to \tau^+\tau^-$ process, with contributions from both $gg \to \phi$ and $b\bar{b}\phi$ production, and $b\bar{b}\phi, \phi \to \tau^+\tau^-$ or $\phi \to b\bar{b}$, with $b\tau\tau$ or three tagged b-jets in the final state, respectively. Although the Higgs boson production via gluon fusion has a higher cross section in general than via associated production, it cannot be used to study the $\phi \to b\bar{b}$ decay mode since the signal is overwhelmed by the QCD background.

CDF and D0 have searched for neutral Higgs bosons produced in association with bottom quarks and which decay into $b\bar{b}$ [409, 410], or into $\tau^+\tau^-$ [396,397]. The most recent searches in the $b\bar{b}\phi$ channel with $\phi \to b\bar{b}$ analyse approximately 2.6 fb^{-1} (CDF) and 5.2 fb^{-1} (D0) of data, seeking events with at least three b-tagged jets. The cross section is defined such that at least one b quark not from ϕ decay is required to have $p_T > 20$ GeV and $|\eta| < 5$. The invariant mass of the two leading jets as well as b-tagging variables are used to discriminate the signal from the backgrounds. The QCD background rates and shapes are inferred from data control samples, in particular, the sample with two b-tagged jets and a third, untagged jet. Separate-signal hypotheses are tested and limits are placed on $\sigma(p\bar{p} \to b\bar{b}\phi) \times \mathrm{BR}(\phi \to b\bar{b})$. A local excess of approximately 2.5σ significance has been observed in the mass range of 130–160 GeV, but D0's search is more sensitive and sets stronger limits. The D0 result had a $\mathcal{O}(2\sigma)$ local upward fluctuation in the 110 to 125 GeV mass range. These results have been superseded by the LHC searches and the excess seen by D0 has not been confirmed elsewhere.

A substantially larger sensitivity in the search for the $\phi \to \tau^+\tau^-$ is obtained with the ATLAS and CMS analyses. The higher centre-of-mass energy reached at the Run 2 brings a substantial, though not excessively large, increase in sensitivity due to the intermediate masses probed. Both ATLAS and CMS have reported the result of their searches in this important channel with the full 2016 dataset. The searches are performed in categories of the decays of the two tau leptons: $e\tau_{\text{had}}$, $\mu\tau_{\text{had}}$, $e\mu$, and $\mu\mu$, where τ_{had} denotes a tau lepton which decays to one or more hadrons plus a tau neutrino, e denotes $\tau \to e\nu\nu$, and μ denotes $\tau \to \mu\nu\nu$. The dominant background comes from $Z \to \tau^+\tau^-$ decays, although $t\bar{t}$, W+jets and Z+jets events contribute as well. Separating events into categories based on the number of b-tagged jets improves the sensitivity in the MSSM. The $b\bar{b}$ annihilation process and radiation of a Higgs boson from a b quark gives rise to events in which the Higgs boson is accompanied by a $b\bar{b}$ pair in the final state. Requiring the presence of one or more b-jets reduces the background from Z+jets. Data control samples are used to constrain background rates. The rates for jets to be identified as a hadronically decaying tau lepton are measured in dijet samples, and W+jets samples provide a measurement of the rate of events that, with a fake hadronic tau, can pass the signal selection requirements. Lepton fake rates are measured using samples of isolated lepton candidates and same-sign lepton candidates. Constraints from the ATLAS searches are shown in Fig. 11.19 (left) in the hMSSM approximation defined in Ref. [314]. The neutral Higgs boson searches consider the contributions of both the CP-odd and CP-even neutral Higgs bosons with enhanced couplings to bottom quarks, similarly to was done for the Tevatron results. In Fig. 11.19, decays of the charged Higgs boson into $\tau\nu$ and decays of the heavy Higgs boson into a pair of SM-like Higgs bosons or gauge bosons, or decays of A into hZ are also being constrained. In addition, decays of the neutral Higgs bosons into muon pairs are also being explored. In the m_h-mod+ scenario the region of $\tan\beta$ lower than 5 does not allow for a Higgs boson mass m_h close to 125 GeV. For the hMSSM scenario, instead, the SM-like Higgs boson mass is fixed as an input and hence the requirement that it is close to 125 GeV is always fulfilled, although this may imply other limitations as discussed in Section 11.7.1.1.

A search for $\phi \to \mu^+\mu^-$ has also been performed by ATLAS [400] and CMS [401].

Finally searches for a resonance decaying to a top quark pair were done by ATLAS [405, 444] and CMS [406, 445]. These searches were interpreted as searches for scalar resonances by ATLAS [405], however, an important component of these searches is an accurate treatment of the interference effects between the signal and the continuum background. These effects can yield a dip and peak structure instead of a simple peak [311]. ATLAS has performed a search for a high mass state decaying to a pair of top quarks taking into account the deformation in mass shape of the signal in the presence of the continuum background [446].

The LHC has the potential to explore a broad range of SUSY parameter space through the search for non-SM-like Higgs bosons. As illustrated in Fig. 11.19, the parameter space corresponding to large $\tan\beta$ values and large masses of the A boson are covered mostly by the searches in the $A, H \to \tau^+\tau^-$ channel. A projection of the combined sensitivity of ATLAS and CMS at the HL-LHC has been performed in Ref. [104], showing that, compared to the current sensitivity, the full HL-LHC luminosity can expand the exclusion domain by nearly 1 TeV. In the low $\tan\beta$ limit, the parameter space spanning large A boson masses is best excluded indirectly from the observed Higgs boson measurements. This is illustrated in the Mh125 scenario by the nearly horizontal exclusion which is due to the compatibility of the Higgs boson mass measurement with its prediction from radiative corrections (mostly from the stop sector). Nevertheless, Fig. 11.19 (right) shows a broad region with intermediate $\tan\beta$ and large values of m_A that is not accessed by current searches, and in which the most promising channel is the very difficult search for $t\bar{t}$ decays with its aforementioned intricacies. In this region of parameter space, it is possible that only the SM-like Higgs boson can be within the LHC's reach. If no other state of the EWSB sector than the 125 GeV state is discovered, it may be challenging to determine only from the Higgs sector whether there is a SUSY extension of the SM in nature.

11.7.7.3 *Searches for a CP-odd state decaying to hZ*

Similarly to the search for a CP-even high mass Higgs boson decaying to a pair of Higgs bosons, the search for a CP-odd states decaying to hZ was carried out at the LHC by ATLAS and CMS in various channels:

(i) $(Z \to \ell\ell)(h \to b\bar{b})$,
(ii) $(Z \to \nu\nu)(h \to b\bar{b})$,
(iii) $(Z \to \ell\ell)(h \to \tau\tau)$,
(iv) and $(Z \to \ell\ell)(h \to \tau\tau)$.

The searches where the A boson decays to a pair of b quarks have been performed both in the regime where both b-jets are resolved and in the boosted regime where the two b-jets are merged in a single larger radius jet. These searches have been used to constrain the parameter space of 2HDMs. In the MSSM, these searches place limits on small values of $\tan\beta$ for masses of A between 220 GeV and 360 GeV.

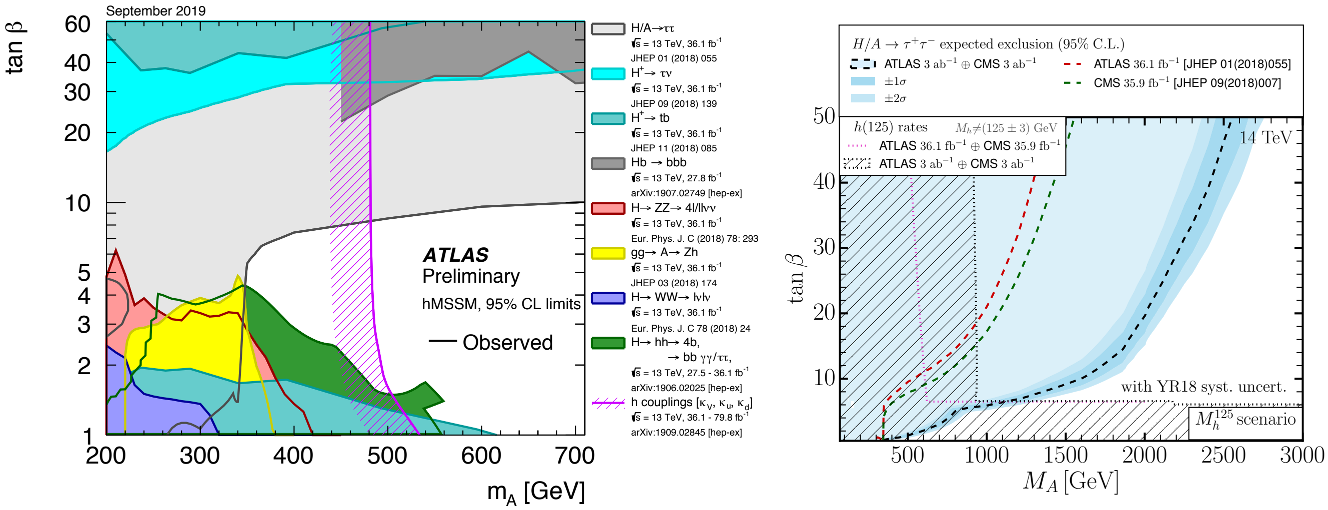

Figure 11.19: The 95% CL exclusion contours in the $(M_A, \tan\beta)$ parameter space for: (left) a summary of ATLAS Run 2 searches in the hMSSM and (right) the projected sensitivity for the combination of ATLAS and CMS searches in the $A, H \to \tau^+\tau^-$ channel at HL-LHC and the interpretation of the constraints from the measurements of the Higgs boson couplings in the Mh125 benchmark (the projected ATLAS sensitivity in the $A, H \to \tau^+\tau^-$ channel used for this projection was not optimised for high masses, when re-optimised similar sensitivities are obtained between ATLAS and CMS).

11.7.7.4 *Searches for low mass states*

Searches for pseudo-scalar Higgs boson at intermediate to low masses, below the Z mass (in the 25 GeV to 80 GeV mass range) have been performed by CMS both in the $\tau^+\tau^-$ [447] and the $\mu^+\mu^-$ [448] decay channels. A light pseudo-scalar in this mass range is excluded by current direct constraints in the MSSM but not in general 2HDMs [449]. These searches are done in the decay channels where the pseudo-scalar Higgs boson is produced in association with a pair of b-quarks and decays into a pair of taus or muons.

CMS has also reported an anomaly observed in the search for $\mu^+\mu^-$ resonances produced with one jet tagged as containing a b-hadron and a forward jet in the Run 1 data. A mild excess appeared in the di-muon mass distribution at approximately 28 GeV. Another very mild excess was then also found in the 2016 Run 2 data [404]. ATLAS then performed a similar analysis with the full Run 2 dataset corresponding to an integrated luminosity of approximately 139 fb^{-1}, and no significant excess was found [403].

Searches for low mass Higgs bosons were also performed in the diphoton channel by both ATLAS and CMS [450, 451] at Run 1. CMS has updated the results of this search with the full 2016 dataset [452]. A modest excess has been observed by CMS at a mass of 95.3 GeV with a local significance of 2.8σ (the corresponding global significance is 1.3σ). A slight excess was also seen by CMS in the 8 TeV data at a slightly higher mass of 97.6 GeV with a local significance of 2.0σ (1.47σ global). No significant excess has been observed in this region by ATLAS neither in the Run 1 nor Run 2 [374] data. It should, however, be noted that the ATLAS search does not reach the level of sensitivity to exclude at the 95% CL the excess seen in CMS. This mildly significant excess also coincides in mass with the excess observed at LEP and discussed in Section 11.7.7.1. It has therefore raised interest and speculations on its possible nature, see for instance Ref. [453] and references therein.

11.7.7.5 *Searches for charged Higgs bosons $H^\pm$*

At e^+e^- colliders, charged Higgs bosons can be pair produced in the s-channel via γ or Z boson exchange. This process is dominant in the LEP centre-of-mass energies range, i.e., up to 209 GeV. At higher centre-of-mass energies, other processes can play an important role such as the production in top quark decays via $t \to b + H^+$ if $m_{H^\pm} < m_t - m_b$ or via the one-loop process $e^+e^- \to W^\pm H^\mp$ [454, 455], which allows the production of a charged Higgs boson with $m_{H^\pm} > \sqrt{s}/2$, even when H^+H^- production is kinematically forbidden. Other single charged Higgs boson production mechanisms include $t\bar{b}H^- / \bar{t}bH^+$ production [108], $\tau^+\nu H^- / \tau^-\bar{\nu}H^+$ production [456], and a variety of processes in which $H^\pm$ is produced in association with a one or two other gauge and/or Higgs bosons [457].

At hadron colliders, charged Higgs bosons can be produced in several different modes depending on the value of its mass with respect to the top-quark mass. For light values of the charged Higgs boson mass, defined by Higgs boson masses smaller than the mass of the top quark (with experimental analyses typically considering masses up to $m_{H^\pm} \leq 160$ GeV), the top-quark decay $t \to Hb$ is allowed and the charged Higgs boson is light enough so that top-quark off-shell effects can be neglected. The cross section for the production of a light charged Higgs boson is simply given by the product of the top-pair production cross section and the branching ratio of a top quark into a charged Higgs boson. The top-pair production cross section is known up to NNLO in perturbative QCD [458], and relevant QCD and SUSY-QCD including NLO corrections to the branching ratio for $t \to H^+b$ have been computed in the literature, see Refs. [459–461] and references therein. At present, the theoretical accuracy for the production of a light charged Higgs boson is at the few percent level. For the intermediate mass range, values of $m_{H^\pm}$ near m_t, the finite top-width effects as well as the interplay between top-quark resonant and non-resonant diagrams cannot be neglected. Hence, the full process $pp \to H^\pm W^\mp b\bar{b}$ (with massive b-quarks) must be considered to perform a reliable perturbative calculation of the charged Higgs boson production cross section [461]. For heavy charged Higgs boson scenarios, with charged Higgs boson masses larger than the top-quark mass (typically above 180 GeV), the dominant charged Higgs boson production channel is the associated production with a top quark/antiquark and a (possibly low transverse momentum) bottom antiquark/quark. Theoretical calculation at NLO have been computed both at the inclusive and fully-differential level in the five-flavour scheme and in the four-flavour scheme, see Ref. [44] and references therein. Charged Higgs bosons can also be produced via associated production with $W^\pm$ bosons through $b\bar{b}$ annihilation and gg-fusion annihilation [462].

For charged Higgs boson production cross section predictions for the Tevatron and the LHC, see Refs. [42, 43, 310].

(a) Exclusion limits from LEP

Charged Higgs bosons have been searched for at LEP, where the combined data of the four experiments, ALEPH, DELPHI, L3, and OPAL, were sensitive to masses of up to about 90 GeV [436] in two decay channels, $\tau\nu$ and $c\bar{s}$. The combined LEP data exclude, at 95% CL, charged Higgs bosons with mass below 80 GeV (Type II scenario) or 72.5 GeV (Type I scenario) [463].

(b) Exclusion limits from Tevatron

Compared to the mass domain covered by LEP searches, the Tevatron covered a complementary range of charged Higgs boson masses. CDF and D0 have also searched for charged Higgs bosons in top quark decays with subsequent decays to $\tau\nu$ or to $c\bar{s}$ [464]. For the $H^+ \to c\bar{s}$ channel, the limits on $\mathrm{BR}(t \to H^+ b)$ from CDF and D0 are $\approx 20\%$ in the mass range $90\,\mathrm{GeV} < m_{H^+} < 160\,\mathrm{GeV}$ and assuming a branching fraction of 100% in this specific final state. $H^+ \to \tau^+\nu_\tau$ channel, D0's limits on $\mathrm{BR}(t \to H^+ b)$ are also $\approx 20\%$ in the same mass range and assuming a branching fraction of 100% in this final state. These limits are valid in general 2HDMs, and they have also been interpreted in terms of the MSSM [464].

(c) Exclusion limits from LHC

Similarly to the Tevatron, at the LHC, light charged Higgs bosons can be searched for in the decays of top quarks. The main initial production mode for light charged Higgs bosons ($m_{H^\pm} < m_t - m_b$) is top pair production. The subsequent decay modes of the charged Higgs boson for these searches are $\tau\nu$ and $c\bar{s}$. More recently, ATLAS and CMS have also searched for higher mass charged Higgs bosons ($m_{H^\pm} > m_t + m_b$) in $H^+ \to t\bar{b}$. The main production modes are the associated production of a charged Higgs boson in association with a top and a bottom quark or in association with a top quark only.

The decay $H^+ \to \tau^+\nu_\tau$ is searched typically in three final state topologies:

(i) lepton+jets: with $t\bar{t} \to \bar{b}WH^+ \to b\bar{b}(q\bar{q}')(\tau_{\mathrm{lep}}\nu)$, i.e., the W boson decays hadronically and the tau decays into an electron or a muon, with two neutrinos;

(ii) τ +lepton: with $t\bar{t} \to \bar{b}WH^+ \to b\bar{b}(l\nu)(\tau_{\mathrm{had}}\nu)$, i.e., the W boson decays leptonically (with $\ell = e,\, \mu$) and the tau decays hadronically;

(iii) τ+jets: $t\bar{t} \to \bar{b}WH^+ \to b\bar{b}(q\bar{q}')(\tau_{\mathrm{had}}\nu)$, i.e., both the W boson and the τ decay hadronically.

CMS has also searched for the charged Higgs boson in the decay products of top quark pairs: $t\bar{t} \to H^\pm W^\mp b\bar{b}$ and $t\bar{t} \to H^+H^- b\bar{b}$ as well. Three types of final states with large missing transverse energy and jets originating from b-quark hadronisation have been analysed: the fully-hadronic channel with a hadronically decaying tau in association with jets, the dilepton channel with a hadronically decaying tau in association with an electron or muon and the dilepton channel with an electron-muon pair. The results of the searches at the LHC are illustrated in Figure 11.19.

Both ATLAS and CMS have also searched for high mass charged Higgs bosons decaying to a top and bottom quarks. The main production mode for this search is the associated production with one top quark (5-flavour scheme) or a top quark and and bottom quark (4-flavour scheme) in the final state. The s-channel production mode where the charged Higgs boson is produced alone in the final state at tree level is also considered. This search is particularly intricate and it is sensitive to the modelling of the top pair production background produced in association with additional partons and in particular b-quarks. No excess was found and the results are expressed in terms of exclusion limits of cross section times branching fractions.

ATLAS and CMS have also searched for charged Higgs bosons in top quark decays assuming $\mathrm{BR}(H^+ \to c\bar{s}) = 100\%$ [417, 418], and sets limits of $\approx 20\%$ on $\mathrm{BR}(t \to H^+ b)$ in the $90\,\mathrm{GeV} < m_{H^+} < 160\,\mathrm{GeV}$ mass range.

In 2HDMs, the decay of the charged Higgs boson to a W and a Z boson is allowed only at loop level and is therefore suppressed. However the $H^\pm \to W^\pm Z$ decay channel is allowed in Higgs triplet models. ATLAS [421] has searched for such decays, requiring that the charged Higgs boson is produced through the fusion of vector bosons. No excess with respect to the SM backgrounds has been observed in this channel, and the results are interpreted in the Georgi–Machacek model [349] discussed in Section 11.7.5.2.

At the LHC, various other channels still remain to be explored, in particular searches involving additional neutral scalars in particular in the WH, WA channels (A is the pseudo-scalar MSSM Higgs boson), and in the Wa channel (a is the light CP-odd scalars of the NMSSM).

11.7.7.6 *Interpretation of the measurements of the coupling properties of the Higgs boson*

The 125 GeV Higgs boson being part of any hypothetically extended EWSB sector, it can be used through the compatibility of its measured couplings and mass with those predicted in specific models to provide constraints on these specific models parameters.

As discussed in Section 11.7.1.1, the mass of the Higgs boson limits drastically the MSSM parameter space and can be used to set limits on specific MSSM benchmarks. This is the case for the Mh125 scenario as illustrated in Figure 11.18 and in Figure 11.19, corresponding approximately to a lower limit on $\tan\beta$ in this model [104].

The measurements of the Higgs boson couplings, discussed in Section 11.6, can be interpreted in the framework of a constrained model where the couplings of the Higgs boson to vector bosons, up-type quarks, down-type quarks and leptons, are varied. In 2HDMs, these couplings are functions of the mixing angle α between the observed Higgs boson and the heavy CP-even neutral scalar, and of the ratio of the vacuum expectation values of the two doublets, $\tan\beta$. In the case of the MSSM, the two parameters are the A boson mass and $\tan\beta$ (the sole two parameters needed to describe the MSSM Higgs sector at tree level). The coupling measurements have been interpreted both by ATLAS [213] and CMS [214] in specific MSSM benchmarks and in 2HDMs. The exclusion contour in the hMSSM for the ATLAS combination [213] is illustrated in Figure 11.19.

11.7.7.7 *Searches for a light CP-odd Higgs boson*

A light pseudo-scalar boson a is present in any two Higgs doublet model enhanced with an additional singlet field. A prominent example is the NMSSM. The theoretical motivations for singlet extensions of the MSSM are discussed in Section 11.7.2. There is also a variety of other models with light additional spin-0 bosons such as two Higgs doublet models with a scalar, Little Higgs models or light scalar mediator to a dark sector.

In the framework of the NMSSM, the searches now focus on the low a mass region for several reasons:

(i) in the NMSSM, the light pseudo-scalar a boson can, as a pseudo-Goldstone boson, be a natural candidate for an axion;

(ii) scenarios where $m_a > 2m_b$ and a CP-even state h decaying to a pair of a ($m_h > 2m_a$) are excluded by direct searches at LEP in the four b's channel [429, 436, 465];

(iii) in the pre-discovery era, LEP limits on a CP-even Higgs boson resulted in fine tuning MSSM constraints [466] which could be evaded through non standard decays of the Higgs boson to aa;

(iv) in the NMSSM, a CP-odd a boson with a mass in the range 9.2–12 GeV can also account for the difference observed between the measured anomalous muon magnetic moment and its prediction [467].

The benchmark scenarios have also changed in the light of the Higgs boson discovery. The 125 GeV state could be the lightest or the next-to-lightest of the three CP-even states of the NMSSM. Light pseudo-scalar scenarios are still very interesting in particular for the potential axion candidate. There are three main types of direct searches for the light a boson:

(i) for masses below the Υ resonance, the search is for radiative decays $\Upsilon \to a\gamma$ at B-factories;

(ii) the inclusive search in high energy pp collisions at the LHC;

(iii) the search for decays of the observed CP-even Higgs h boson into a pair of a bosons.

Radiative decays $\Upsilon \to a\gamma$ have been searched for in various colliders, the most recent results are searches for radiative decays of the $\Upsilon(1s)$ to $a\gamma$ with a subsequent decay of the a boson to a pair of taus at CLEO [468], and the radiative decays of the $\Upsilon(1s, 2s, 3s)$ to $a\gamma$ with subsequent decays to a pair of muons or taus by BaBar [432, 433].

Direct inclusive searches for the light pseudo scalar a boson were performed in the $a \to \mu\mu$ channel at the Tevatron by D0 [429] and by ATLAS [425], CMS [426], and LHCb [151] at the LHC.

Finally, searches for the decays of the Higgs boson to a pair of a bosons where performed with subsequent decays to four photons, in the four muons final state, in the two muons and two taus final state, and in the four taus final state.

No significant excess in the searches for a light CP-odd a boson was found and limits on the production times branching fractions of the a boson have been set.

References for all these searches are summarised in Table 11.15.

11.7.7.8 *Searches for doubly charged Higgs bosons* $H^{\pm\pm}$

As discussed in Section 11.7.5, the generation of small neutrino masses via the standard EWSB mechanism described in Section 11.2 requires unnaturally small Yukawa couplings, provided that neutrinos are Dirac-type fermions. A Majorana mass term with a see-saw mechanism for neutrinos, would allow for naturally small masses and would also yield a framework for the appealing scenario of leptogenesis. However, within the SM, Majorana mass terms correspond to (non-renomalizable) dimension-5 operators. Such effective interactions can be generated via renormalisable interactions with an electroweak triplet of complex scalar fields (corresponding to a type-II see-saw mechanism). Other models such as the Zee–Babu model, with the introduction of two $\mathrm{SU}(2)_L$ singlets, also generate Majorana mass terms. The signature of such models would be the presence of doubly charged Higgs bosons $H^{\pm\pm}$.

The main production mechanisms of $H^{\pm\pm}$ bosons at hadron colliders are the pair production in the s-channel through the exchange of a Z boson or a photon and the associated production with a charged Higgs boson through the exchange of a W boson. Various searches for doubly charged Higgs bosons have been performed by ATLAS and CMS at Run 1 [469] and Run 2 [434, 435]. Typically, these searches aim at low values of the Higgs triplet vacuum expectation for which the doubly charged Higgs boson will decay mostly to leptons (for high values, the decay to W bosons will become predominant). These searches assume that the coupling to W bosons is negligible and that the main production mode is through the Drell–Yan process.

11.7.7.9 *Searches for non-standard production processes of the Higgs boson*

The discovery of the Higgs boson has also allowed for searches of BSM processes involving standard decays of the Higgs boson. One example directly pertaining to the search for additional states of the EWSB sector is the search for Higgs bosons in the cascade decay of a heavy CP-even Higgs boson decaying to charged Higgs boson and a W boson, and the charged Higgs boson subsequently decaying to H and another W boson. This search has been performed by ATLAS in $b\bar{b}$ decays of the 125 GeV Higgs boson [470].

11.7.7.10 *Outlook on searches for additional states*

The LHC program of searches for additional states covers a large variety of decay and production channels. Since the Higgs boson discovery, many new channels have been explored at the LHC, e.g., the searches for additional states decaying into hh or Vh or ZA. The search for charged Higgs bosons has been extended to include the WZ, WA and the very difficult $t\bar{b}$ decay channel.

11.8 Summary and outlook

Summary– The discovery of the Higgs boson is a major milestone in the history of particle physics as well as an extraordinary achievement of the LHC machine and the ATLAS and CMS experiments. Seven years after the discovery, substantial progress in the field of Higgs boson physics has been accomplished and a significant number of measurements probing the nature of this unique particle have been made. They are revealing an increasingly precise profile of the Higgs boson.

The LHC has now concluded its Run 2, delivering a dataset of 13 TeV pp collisions corresponding to an integrated luminosity of approximately $140\,\mathrm{fb}^{-1}$ of data collected by ATLAS and CMS. With the substantial increase in production rates at the higher center-of-mass energy and the larger datasets, new landmark results in Higgs physics have been achieved.

Three new results of fundamental importance have been achieved with partial Run 2 datasets by ATLAS and CMS independently: (i) the clear and unambiguous observation of the Higgs boson decay to taus; (ii) the clear and unambiguous observation of the Higgs boson decay to a pair of b quarks; (iii) the clear and unambiguous observation of the production of the Higgs boson through the $t\bar{t}H$ process. These results provide direct evidence for the Yukawa coupling of the Higgs boson to fermions of the third generation: taus, bottom quarks and top quarks, at rates compatible with those expected in the SM. These, and all other experimental measurements, are consistent with the EWSB mechanism of the SM.

New theoretical calculations and developments in Monte-Carlo simulation pertaining to Higgs physics are still occurring at a rapid pace. For example, the theoretical prediction for the dominant gluon fusion production mode now includes the latest N3LO result, which is twice as precise as previous N2LO calculations. With these improvements in the state-of-the-art theory predictions and the increase in luminosity and center-of-mass energy, Higgs physics has definitively entered a precision era. Its impact can already be seen on the latest Run 2 combined measurements of the Higgs boson couplings (see Section 11.6).

Since the discovery of the Higgs boson, new ideas have emerged to probe its rare decays and production modes, as well as to indirectly measure the Higgs boson width through the study of its off-shell couplings, or via on-shell interference effects. The Higgs boson has now become part of the standard toolkit in searches for new physics.

Many extensions of the SM at higher energies call for an enlargement of the EWSB sector. Hence, direct searches for additional scalar states can provide valuable insights on the dynamics of the EWSB mechanism. The ATLAS and CMS experiments have searched for additional Higgs bosons in the Run 2 data, and have imposed constraints in broad ranges of mass and couplings for various scenarios with an extended Higgs sector.

The landscape of Higgs physics has been extended extraordinarily since its discovery. The current dataset is approximately only five percent of the total dataset foreseen for the High Luminosity phase of the LHC project. The current precisions on the measurements of the couplings of the Higgs boson to gauge bosons and third generation fermions are typically of the order of 10–20%. The uncertainty on the Higgs boson coupling to the muon is approximately 100%, and the upper limits on the branching fraction to new invisible or undetected particles are approximately 20%. The sensitivity to the Higgs boson self-coupling has not reached the SM value yet and there is no information on how the Higgs field acquired its VEV in the early times of the Universe. This situation allows for new challenges to ultimately increase further the reach in precision and it also widens the possibilities of unveiling the true nature and the dynamics of the electroweak symmetry breaking.

Outlook– The unitarisation of the vector boson scattering (VBS) amplitudes, dominated at high energies by their longitudinal polarisation, has been the basis of the *no lose* theorem at the LHC, and was a determining consideration in the building of the accelerator and detectors. It motivated the existence of a Higgs boson or the observability of manifestations of strong dynamics at the TeV scale. Now that a Higgs boson has been found and its couplings to gauge bosons are consistent with the SM predictions, perturbative unitarity is preserved to a large extent with the sole exchange of the Higgs boson, and without the need for any additional states. VBS is, however, still an important channel to further investigate in order to better understand the nature of the Higgs sector and the possible completion of the SM at the TeV scale. In association with the double Higgs boson production channel by vector boson fusion, VBS could, for instance, confirm that the Higgs boson is part of a weak doublet and also establish whether it is an elementary object or a composite state that could emerge as a pseudo-Nambu–Goldstone boson from a new underlying broken symmetry.

The fermion-Higgs boson couplings are not governed by local gauge symmetry. Thus, in addition to a new particle, the LHC has also discovered a new force, different in nature from the other fundamental interactions since it is non-universal and distinguishes between the three families of quarks and leptons. The existence of the Higgs boson embodies the problem of an unnatural cancellation among the quantum corrections to its mass if new physics is present at scales significantly higher than the EW scale. The non-observation of additional states which could stabilise the Higgs boson mass is a challenge for natural scenarios like SUSY or models with a new strong interaction in which the Higgs boson is not a fundamental particle. This increasingly pressing paradox starts questioning the principle of naturalness.

The search for the Higgs boson has occupied the particle physics community for the last 50 years. Its discovery has shaped and sharpened the physics programs of the LHC and of prospective future accelerators [471]. With the HL-LHC, the precision will improve by a factor 5–10 on all observables with respect to current data. Table 11.12 displays the expected sensitivities in the characterization of the Higgs boson at HL-LHC: in this table, the parameters κ_i specify by how much the coupling of the Higgs boson to a given particle i deviates from the SM expectation. The only channels which are expected to be limited by data statistics are the rare decays to muons and $Z\gamma$. In all other cases, the experimental systematic uncertainties are similar to the statistical uncertainties, but the dominant source of uncertainty arises from theory, and this remains the case even after assuming that, by the end of the HL-LHC run, the theory uncertainties can be reduced by a factor two compared to the current uncertainties, a hypothesis that appears realistic but still requires dedicated and concerted work [104]. For both hadron and lepton colliders, some theoretical progress is crucial to fully exploit and capitalise on the experimental data. In particular, the expected HL-LHC data together with rapid ongoing progress in theoretical calculations are defining a new era of precision Higgs boson measurements.

12. CKM Quark-Mixing Matrix

Revised March 2020 by A. Ceccucci (CERN), Z. Ligeti (LBNL) and Y. Sakai (KEK).

12.1 Introduction

The masses and mixings of quarks have a common origin in the Standard Model (SM). They arise from the Yukawa interactions with the Higgs condensate,

$$\mathcal{L}_Y = -Y^d_{ij}\,\overline{Q^I_{Li}}\,\phi\,d^I_{Rj} - Y^u_{ij}\,\overline{Q^I_{Li}}\,\epsilon\,\phi^* u^I_{Rj} + \text{h.c.}, \tag{12.1}$$

where $Y^{u,d}$ are 3×3 complex matrices, ϕ is the Higgs field, i,j are generation labels, and ϵ is the 2×2 antisymmetric tensor. Q^I_L are left-handed quark doublets, and d^I_R and u^I_R are right-handed down- and up-type quark singlets, respectively, in the weak-eigenstate basis. When ϕ acquires a vacuum expectation value, $\langle\phi\rangle = (0, v/\sqrt{2})$, Eq. (12.1) yields mass terms for the quarks. The physical states are obtained by diagonalizing $Y^{u,d}$ by four unitary matrices, $V^{u,d}_{L,R}$, as $M^f_{\text{diag}} = V^f_L\, Y^f\, V^{f\dagger}_R (v/\sqrt{2})$, $f = u, d$. As a result, the charged-current $W^\pm$ interactions couple to the physical u_{Lj} and d_{Lk} quarks with couplings given by

$$\frac{-g}{\sqrt{2}}(\overline{u_L},\,\overline{c_L},\,\overline{t_L})\gamma^\mu\, W^+_\mu\, V_{\text{CKM}} \begin{pmatrix} d_L \\ s_L \\ b_L \end{pmatrix} + \text{h.c.},$$
$$V_{\text{CKM}} \equiv V^u_L V^{d\dagger}_L = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix}. \tag{12.2}$$

This Cabibbo-Kobayashi-Maskawa (CKM) matrix [1,2] is a 3×3 unitary matrix. It can be parameterized by three mixing angles and the CP-violating KM phase [2]. Of the many possible conventions, a standard choice has become [3]

$$\begin{aligned} V_{\text{CKM}} &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & c_{23} & s_{23} \\ 0 & -s_{23} & c_{23} \end{pmatrix} \begin{pmatrix} c_{13} & 0 & s_{13}e^{-i\delta} \\ 0 & 1 & 0 \\ -s_{13}e^{i\delta} & 0 & c_{13} \end{pmatrix} \begin{pmatrix} c_{12} & s_{12} & 0 \\ -s_{12} & c_{12} & 0 \\ 0 & 0 & 1 \end{pmatrix} \\ &= \begin{pmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta} \\ -s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta} & c_{12}c_{23} - s_{12}s_{23}s_{13}e^{i\delta} & s_{23}c_{13} \\ s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta} & -c_{12}s_{23} - s_{12}c_{23}s_{13}e^{i\delta} & c_{23}c_{13} \end{pmatrix}, \end{aligned} \tag{12.3}$$

where $s_{ij} = \sin\theta_{ij}$, $c_{ij} = \cos\theta_{ij}$, and δ is the phase responsible for all CP-violating phenomena in flavor-changing processes in the SM. The angles θ_{ij} can be chosen to lie in the first quadrant, so $s_{ij}, c_{ij} \geq 0$.

It is known experimentally that $s_{13} \ll s_{23} \ll s_{12} \ll 1$, and it is convenient to exhibit this hierarchy using the Wolfenstein parameterization. We define [4–6]

$$s_{12} = \lambda = \frac{|V_{us}|}{\sqrt{|V_{ud}|^2 + |V_{us}|^2}}, \qquad s_{23} = A\lambda^2 = \lambda\left|\frac{V_{cb}}{V_{us}}\right|,$$
$$s_{13}e^{i\delta} = V^*_{ub} = A\lambda^3(\rho + i\eta) = \frac{A\lambda^3(\bar\rho + i\bar\eta)\sqrt{1-A^2\lambda^4}}{\sqrt{1-\lambda^2}\,[1 - A^2\lambda^4(\bar\rho + i\bar\eta)]}. \tag{12.4}$$

These relations ensure that $\bar\rho + i\bar\eta = -(V_{ud}V^*_{ub})/(V_{cd}V^*_{cb})$ is phase convention independent, and the CKM matrix written in terms of λ, A, $\bar\rho$, and $\bar\eta$ is unitary to all orders in λ. The definitions of $\bar\rho$, $\bar\eta$ reproduce all approximate results in the literature; *i.e.*, $\bar\rho = \rho(1-\lambda^2/2+\ldots)$ and $\bar\eta = \eta(1-\lambda^2/2+\ldots)$, and one can write V_{CKM} to $\mathcal{O}(\lambda^4)$ either in terms of $\bar\rho, \bar\eta$ or, traditionally,

$$V_{\text{CKM}} = \begin{pmatrix} 1-\lambda^2/2 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda & 1-\lambda^2/2 & A\lambda^2 \\ A\lambda^3(1-\rho-i\eta) & -A\lambda^2 & 1 \end{pmatrix} + \mathcal{O}(\lambda^4). \tag{12.5}$$

The CKM matrix elements are fundamental parameters of the SM, so their precise determination is important. The unitarity of the CKM matrix imposes $\sum_i V_{ij}V^*_{ik} = \delta_{jk}$ and $\sum_j V_{ij}V^*_{kj} = \delta_{ik}$. The six vanishing combinations can be represented as triangles in a complex plane, of which those obtained by taking scalar products of neighboring rows or columns are nearly degenerate. The areas of all triangles are the same, half of the Jarlskog invariant, J [7], which is a phase-convention-independent measure of CP violation, defined by $\text{Im}\big[V_{ij}V_{kl}V^*_{il}V^*_{kj}\big] = J\sum_{m,n}\varepsilon_{ikm}\varepsilon_{jln}$.

The most commonly used unitarity triangle arises from

$$V_{ud}\,V^*_{ub} + V_{cd}\,V^*_{cb} + V_{td}\,V^*_{tb} = 0, \tag{12.6}$$

by dividing each side by the best-known one, $V_{cd}V^*_{cb}$ (see Fig. 12.1). Its vertices are exactly $(0,0)$, $(1,0)$, and, due to the definition in Eq. (12.4), $(\bar\rho, \bar\eta)$. An important goal of flavor physics is to overconstrain the CKM elements, and many measurements can be conveniently displayed and compared in the $\bar\rho, \bar\eta$ plane. While

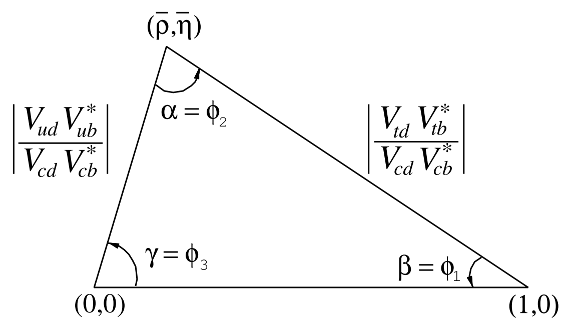

Figure 12.1: Sketch of the unitarity triangle.

the Lagrangian in Eq. (12.1) is renormalized, and the CKM matrix has a well known scale dependence above the weak scale [8], below $\mu = m_W$ the CKM elements can be treated as constants, with all μ-dependence contained in the running of quark masses and higher-dimension operators.

Unless explicitly stated otherwise, we describe all measurements assuming the SM, to extract magnitudes and phases of CKM elements in Sec. 12.2 and 12.3. Processes dominated by loop-level contributions in the SM are particularly sensitive to new physics beyond the SM (BSM). We give the global fit results for the CKM elements in Sec. 12.4, and discuss some implications for beyond standard model physics in Sec. 12.5.

12.2 Magnitudes of CKM elements

12.2.1 $|V_{ud}|$

The most precise determination of $|V_{ud}|$ comes from the study of superallowed $0^+ \to 0^+$ nuclear beta decays, which are pure vector transitions. Taking the average of the fourteen most precise determinations [9] yields [10]

$$|V_{ud}| = 0.97370 \pm 0.00014. \tag{12.7}$$

This value is about 2σ smaller than in the review two years ago, mainly due to adopting a recent calculation of electroweak corrections based on dispersion relations [11]. The dominant and comparable uncertainties are the experimental ones, and from the estimates of the radiative corrections. A less precise determination of $|V_{ud}|$ can be obtained from the measurement of the neutron lifetime. The theoretical uncertainties are very small, but the determination is limited by the knowledge of the ratio of the axial-vector and vector couplings, $g_A = G_A/G_V$ [10]. The PIBETA experiment [12] has improved the measurement of the $\pi^+ \to \pi^0 e^+ \nu$ branching ratio to 0.6%, and quotes $|V_{ud}| = 0.9739 \pm 0.0029$, in agreement with the more precise result listed above. The interest in this measurement is that the determination of $|V_{ud}|$ is very clean theoretically, because it is a pure vector transition and is free from nuclear-structure uncertainties.

12.2.2 $|V_{us}|$

The product of $|V_{us}|$ and the form factor at $q^2 = 0$, $|V_{us}|\, f_+(0)$, has been extracted traditionally from $K^0_L \to \pi e \nu$ decays in order to avoid isospin-breaking corrections ($\pi^0 - \eta$ mixing) that affect $K^\pm$ semileptonic decay, and the complications induced by a second (scalar) form factor present in the muonic decays. The last round of measurements has led to enough experimental constraints to justify the comparison between different decay modes. Systematic errors related to the experimental quantities, *e.g.*, the lifetime of neutral or charged kaons, and the form factor determinations for electron and muonic decays, differ among decay modes, and the consistency between different determinations enhances the confidence in the final result. For this reason, we follow the prescription [13] to average $K^0_L \to \pi e \nu$, $K^0_L \to \pi \mu \nu$, $K^\pm \to \pi^0 e^\pm \nu$, $K^\pm \to \pi^0 \mu^\pm \nu$ and $K^0_S \to \pi e \nu$. The average of these five decay modes yields $|V_{us}|\, f_+(0) = 0.2165 \pm 0.0004$. Results obtained from each decay mode, and exhaustive references to the experimental data, are listed for instance in Ref. [10]. The form factor average $f_+(0) = 0.9706 \pm 0.0027$ [14] from $N_f = 2+1+1$ lattice QCD calculations gives $|V_{us}| = 0.2231 \pm 0.0007$ [10].[1] The broadly used classic calculation of $f_+(0)$ [16] is in good agreement with this value, while other calculations [18] differ by as much as 2%.

The calculation of the ratio of the kaon and pion decay constants enables one to extract $|V_{us}/V_{ud}|$ from $K \to \mu\nu(\gamma)$ and $\pi \to \mu\nu(\gamma)$, where (γ) indicates that radiative decays are included [19]. The value of $\Gamma(K \to \mu\nu(\gamma))$ [10] derived from the KLOE measurement of the corresponding branching ratio [20], combined with the lattice QCD result, $f_K/f_\pi = 1.1932 \pm 0.0019$ [14], leads to $|V_{us}| = 0.2252 \pm 0.0005$, where the accuracy is limited by the knowledge of the ratio of the decay constants. The average of these two determinations, with the error scaled according to the PDG prescription [21] by $\sqrt{\chi^2} = 2.0$, is quoted as [10]

$$|V_{us}| = 0.2245 \pm 0.0008 \,. \tag{12.8}$$

It is important to include both QED and QCD isospin violations in the lattice QCD calculations.

The latest determination from hyperon decays can be found in Ref. [22]. The authors focus on the analysis of the vector form factor, protected from first order $SU(3)$ breaking effects by the Ademollo-Gatto theorem [23], and treat the ratio between the axial and vector form factors g_1/f_1 as experimental input, thus avoiding first order $SU(3)$ breaking effects in the axial-vector contribution. They find $|V_{us}| = 0.2250 \pm 0.0027$, although this does not include an estimate of the theoretical uncertainty due to second-order $SU(3)$ breaking, contrary to Eq. (12.8). Concerning hadronic τ decays to strange particles, averaging the inclusive decay and the exclusive $\tau \to h\nu$ ($h = \pi$, K) measurements yields $|V_{us}| = 0.2221 \pm 0.0013$ [24].

12.2.3 $|V_{cd}|$

The magnitude of V_{cd} can be extracted from semileptonic charm decays, using theoretical knowledge of the form factors. In semileptonic D decays, lattice QCD calculations have predicted the normalization of the $D \to \pi \ell \nu$ and $D \to K \ell \nu$ form factors [14]. The dependence on the invariant mass of the lepton pair, q^2, is determined from lattice QCD and theoretical constraints from analyticity [15]. Using $N_f = 2+1+1$ lattice QCD calculations for $D \to \pi \ell \nu$, $f_+^{D\pi}(0) = 0.612 \pm 0.035$ [14], and the average [24] of the measurements of $D \to \pi \ell \nu$ decays by *BaBar* [25], BESIII [26,27], CLEO-c [28], and Belle [29], one obtains $|V_{cd}| = 0.2330 \pm 0.0029 \pm 0.0133$, where the first uncertainty is experimental, and the second is from the theoretical uncertainty of the form factor.

The determination of $|V_{cd}|$ is also possible from the leptonic decay $D^+ \to \mu^+ \nu$. The experimental uncertainties have not decreased significantly recently. Averaging the BESIII [30] and earlier CLEO [31] measurements, and using the $N_f = 2+1+1$ lattice QCD result, $f_D = 212.0 \pm 0.7$ MeV [14], yields $|V_{cd}| = 0.2173 \pm 0.0051 \pm 0.0007$ [24].[2]

Earlier determinations of $|V_{cd}|$ came from neutrino scattering data. The difference of the ratio of double-muon to single-muon production by neutrino and antineutrino beams is proportional to the charm cross section off valence d quarks, and therefore to $|V_{cd}|^2$ times the average semileptonic branching ratio of charm mesons, $\mathcal{B}_\mu$. The method was used first by CDHS [32] and then by CCFR [33,34] and CHARM II [35]. Averaging these results is complicated, because it requires assumptions about the scale of the QCD corrections, and because $\mathcal{B}_\mu$ is an effective quantity, which depends on the specific neutrino beam characteristics. With no recent experimental input available, we quote the average from a past review, $\mathcal{B}_\mu |V_{cd}|^2 = (0.463 \pm 0.034) \times 10^{-2}$ [36]. Analysis cuts make these experiments insensitive to neutrino energies smaller than 30 GeV. Thus, $\mathcal{B}_\mu$ should be computed using only neutrino interactions with visible energy larger than 30 GeV. An appraisal [37] based on charm-production fractions measured in neutrino interactions [38,39] gives $\mathcal{B}_\mu = 0.088 \pm 0.006$. Data from the CHORUS experiment [40] are sufficiently precise to extract $\mathcal{B}_\mu$ directly, by comparing the number of charm decays with a muon to the total number of charmed hadrons found in the nuclear emulsions. Requiring the visible energy to be larger than 30 GeV, CHORUS found $\mathcal{B}_\mu = 0.085 \pm 0.009 \pm 0.006$. We use the average of these two determinations, $\mathcal{B}_\mu = 0.087 \pm 0.005$, and obtain $|V_{cd}| = 0.230 \pm 0.011$. Averaging the three determinations above, we find

$$|V_{cd}| = 0.221 \pm 0.004 \,. \tag{12.9}$$

12.2.4 $|V_{cs}|$

The direct determination of $|V_{cs}|$ is possible from semileptonic D or leptonic D_s decays, using lattice QCD calculations of the semileptonic D form factor or the D_s decay constant. For muonic decays, the average of Belle [41], CLEO-c [42], *BaBar* [43], and BESIII [44,45] is $\mathcal{B}(D_s^+ \to \mu^+ \nu) = (5.51 \pm 0.16) \times 10^{-3}$ [24]. For decays to τ leptons, the average of CLEO-c [42,46,47], *BaBar* [43], Belle [41], and BESIII [44] gives $\mathcal{B}(D_s^+ \to \tau^+ \nu) = (5.52 \pm 0.24) \times 10^{-2}$ [24]. From each of these values, determinations of $|V_{cs}|$ can be obtained using the PDG values for the mass and lifetime of the D_s, the masses of the leptons, and $f_{D_s} = (249.9 \pm 0.5)$ MeV [14]. The average of these determinations gives $|V_{cs}| = 0.992 \pm 0.012$, where the error is dominated by the experimental uncertainty. In semileptonic D decays, lattice QCD calculations of the $D \to K \ell \nu$ form factor are available [14]. Using $f_+^{DK}(0) = 0.765 \pm 0.031$ and the average [24] of CLEO-c [28], Belle [29], *BaBar* [48], and recent BESIII [26,49] measurements of $D \to K \ell \nu$ decays, one obtains $|V_{cs}| = 0.939 \pm 0.038$, where the dominant uncertainty is from the theoretical calculation of the form factor. Averaging the determinations from leptonic and semileptonic decays, we find

$$|V_{cs}| = 0.987 \pm 0.011 \,. \tag{12.10}$$

Measurements of on-shell $W^\pm$ decays sensitive to $|V_{cs}|$ were made by LEP-2. The W branching ratios depend on the six CKM elements involving quarks lighter than m_W. The W branching ratio to each lepton flavor is $1/\mathcal{B}(W \to \ell \bar{\nu}_\ell) = 3\Big[1 + \sum_{u,c,d,s,b} |V_{ij}|^2\, (1 + \alpha_s(m_W)/\pi) + \ldots\Big]$. Assuming lepton universality, the measurement $\mathcal{B}(W \to \ell \bar{\nu}_\ell) = (10.83 \pm 0.07 \pm 0.07)\,\%$ [50] implies $\sum_{u,c,d,s,b} |V_{ij}|^2 = 2.002 \pm 0.027$. This is a precise test of unitarity; however, only flavor-tagged W-decays determine $|V_{cs}|$

[1] For lattice QCD inputs, we use the averages from Ref. [14], unless the minireviews [10,15] choose different values. We only use unquenched results, and if both $N_f = 2+1+1$ and $2+1$ calculations are available, we use the former.

[2] Hereafter the first error is statistical and the second is systematic, unless mentioned otherwise.

directly, such as DELPHI's tagged $W^+ \to c\bar{s}$ analysis, yielding $|V_{cs}| = 0.94^{+0.32}_{-0.26} \pm 0.13$ [51].

12.2.5 $|V_{cb}|$

This matrix element can be determined from exclusive and inclusive semileptonic decays of B mesons to charm. The inclusive determinations use the semileptonic decay rate measurement, together with (certain moments of) the lepton energy and the hadronic invariant-mass spectra. The theoretical basis is the operator product expansion [52, 53], which allows calculation of the decay rate and various spectra as expansions in α_s and inverse powers of the heavy-quark mass. The dependence on m_b, m_c, and the parameters that occur at subleading order is different for different moments, and a large number of measured moments overconstrain all the parameters, and tests the consistency of the determination. The precise extraction of $|V_{cb}|$ requires using a "threshold" quark mass definition [54, 55]. Inclusive measurements have been performed using B mesons from Z^0 decays at LEP, and at e^+e^- machines operated at the $\Upsilon(4S)$. At LEP, the large boost of B mesons from the Z^0 decay allows the determination of the moments throughout phase space, which is not possible otherwise, but the large statistics available at the B factories lead to more precise determinations. An average of the measurements and a compilation of the references are provided in Ref. [15]: $|V_{cb}| = (42.2 \pm 0.8) \times 10^{-3}$.

Complementary determinations are based on exclusive semileptonic B decays to D and D^*. In the $m_{b,c} \gg \Lambda_{\mathrm{QCD}}$ limit, all form factors are given by a single Isgur-Wise function [56], which depends on the product of the four-velocities of the B and $D^{(*)}$ mesons, $w = v \cdot v'$. Heavy-quark symmetry determines the rate at $w = 1$, the maximum momentum transfer to the $\ell\bar{\nu}$ pair, and $|V_{cb}|$ is obtained from an extrapolation to $w = 1$. The current update of the V_{cb} and V_{ub} minireview quotes from exclusive decays $|V_{cb}| = (39.5 \pm 0.9) \times 10^{-3}$ [15], based on the only unfolded measurement of $B \to D^*$ semileptonic decay distributions [57], and using a more general fit [58] than in earlier B factory measurements. With the uncertainty scaled by $\sqrt{\chi^2} = 2.4$, this yields the combination [15],

$$|V_{cb}| = (41.0 \pm 1.4) \times 10^{-3}\,. \qquad (12.11)$$

Less precise measurements of $|V_{cb}|$, not included in this average, can be obtained from $\mathcal{B}(B \to D^{(*)}\tau\bar{\nu})$. The most precise data involving τ leptons are the $|V_{cb}|$-independent ratios, $\mathcal{B}(B \to D^{(*)}\tau\bar{\nu})/\mathcal{B}(B \to D^{(*)}\ell\bar{\nu})$ measured by BaBar, Belle, and LHCb. If the current, approximately $3\,\sigma$ [24], hint of lepton non-universality prevails, the determination of $|V_{cb}|$ becomes more complicated.

12.2.6 $|V_{ub}|$

The determination of $|V_{ub}|$ from inclusive $B \to X_u\ell\bar{\nu}$ decay is complicated due to large $B \to X_c\ell\bar{\nu}$ backgrounds. In most regions of phase space where the charm background is kinematically forbidden, the hadronic physics enters via unknown nonperturbative functions, so-called shape functions. (In contrast, the nonperturbative physics for $|V_{cb}|$ is encoded in a few parameters.) At leading order in $\Lambda_{\mathrm{QCD}}/m_b$, there is only one shape function, which can be extracted from the photon energy spectrum in $B \to X_s\gamma$ [59, 60], and applied to several spectra in $B \to X_u\ell\bar{\nu}$. The subleading shape functions are modeled in the current determinations. Phase space cuts for which the rate has only subleading dependence on the shape function are also possible [61]. The measurements of both the hadronic and the leptonic systems are important for an optimal choice of phase space. A different approach is to make the measurements more inclusive by extending them deeper into the $B \to X_c\ell\bar{\nu}$ region, and thus reduce the theoretical uncertainties. Analyses of the electron-energy endpoint from CLEO [62], BABAR [63], and Belle [64] quote $B \to X_u e\bar{\nu}$ partial rates for $|\vec{p}_e| \geq 2.0\,\mathrm{GeV}$ and $1.9\,\mathrm{GeV}$, which are well below the charm endpoint. The large and pure $B\overline{B}$ samples at the B factories permit the selection of $B \to X_u\ell\bar{\nu}$ decays in events where the other B is fully reconstructed [65]. With this full-reconstruction tag method, the four-momenta of both the leptonic and the hadronic final states can be measured. It also gives access to a wider kinematic region, because of improved signal purity. Ref. [15] quotes the inclusive average, $|V_{ub}| = (4.25 \pm 0.12\ ^{+0.15}_{-0.14} \pm 0.23) \times 10^{-3}$, where the first error is experimental, the second arises from the model dependence quoted by the individual measurements, and the third is an additional one estimated in Ref. [15].

To extract $|V_{ub}|$ from exclusive decays, the form factors have to be known. Experimentally, better signal-to-background ratios are offset by smaller yields. The $B \to \pi\ell\bar{\nu}$ branching ratio is now known to 5%. Lattice QCD calculations of the $B \to \pi\ell\bar{\nu}$ form factor are available [66] for the high q^2 region ($q^2 > 16$ or $18\,\mathrm{GeV}^2$). A fit to the experimental partial rates and lattice QCD results versus q^2 yields $|V_{ub}| = (3.70 \pm 0.10 \pm 0.12) \times 10^{-3}$ [24]. Light-cone QCD sum rules are supposed to be applicable for $q^2 < 12\,\mathrm{GeV}^2$ [67], yielding a combination, $|V_{ub}| = (3.67 \pm 0.09 \pm 0.12) \times 10^{-3}$ [15, 24].

The uncertainties in extracting $|V_{ub}|$ from inclusive and exclusive decays are different to a large extent. An average of these determinations, with the uncertainty scaled by $\sqrt{\chi^2} = 1.6$, is [15]

$$|V_{ub}| = (3.82 \pm 0.24) \times 10^{-3}\,. \qquad (12.12)$$

A determination of $|V_{ub}|$ not included in this average can be obtained from $\mathcal{B}(B \to \tau\bar{\nu}) = (1.06 \pm 0.19) \times 10^{-4}$ [24]. Using $f_B = (190.0 \pm 1.3)\,\mathrm{MeV}$ [14] and $\tau_{B^\pm} = (1.638 \pm 0.004)\,\mathrm{ps}$ [68], we find the remarkably consistent result, $|V_{ub}| = (4.05 \pm 0.36) \times 10^{-3}$. This decay is sensitive, for example, to tree-level charged Higgs contributions, and the measured rate is consistent with the SM expectation. The LHCb measurement $|V_{ub}/V_{cb}| = 0.079 \pm 0.006$ [69] from the ratio of $\Lambda_b \to p^+\mu^-\bar{\nu}$ and $\Lambda_b \to \Lambda_c^+\mu^-\bar{\nu}$ in different regions of q^2, provides another complementary determination.

12.2.7 $|V_{td}|$ ***and*** $|V_{ts}|$

The CKM elements $|V_{td}|$ and $|V_{ts}|$ are not likely to be precisely measurable in tree-level processes involving top quarks, so one has to rely on determinations from B–$\overline{B}$ oscillations dominated by box diagrams with top quarks, or loop-mediated rare K and B decays. Theoretical uncertainties in hadronic effects limit the accuracy of the current determinations. These can be reduced by taking ratios of processes that are equal in the flavor $SU(3)$ limit to determine $|V_{td}/V_{ts}|$.

The mixing of the two B^0 mesons was discovered by ARGUS [70], and the mass difference is now precisely measured as $\Delta m_d = (0.5065 \pm 0.0019)\,\mathrm{ps}^{-1}$ [71]. In the B_s^0 system, Δm_s was first measured significantly by CDF [72] and the world average, dominated by an LHCb measurement [73], is $\Delta m_s = (17.749 \pm 0.020)\,\mathrm{ps}^{-1}$ [71]. Neglecting corrections suppressed by $|V_{tb}| - 1$, and using the lattice QCD results $f_{B_d}\sqrt{\widehat{B}_{B_d}} = (225 \pm 9)\,\mathrm{MeV}$ and $f_{B_s}\sqrt{\widehat{B}_{B_s}} = (274 \pm 8)\,\mathrm{MeV}$ [14],

$$|V_{td}| = (8.0 \pm 0.3) \times 10^{-3}\,, \qquad |V_{ts}| = (38.8 \pm 1.1) \times 10^{-3}\,. \quad (12.13)$$

The uncertainties are dominated by lattice QCD. Several uncertainties are reduced in the calculation of the ratio $\xi = \big(f_{B_s}\sqrt{\widehat{B}_{B_s}}\big)/\big(f_{B_d}\sqrt{\widehat{B}_{B_d}}\big) = 1.206 \pm 0.038$ [14] and therefore the constraint on $|V_{td}/V_{ts}|$ from $\Delta m_d/\Delta m_s$ is more reliable theoretically. These provide a theoretically clean and significantly improved determination,

$$\big|V_{td}/V_{ts}\big| = 0.205 \pm 0.001 \pm 0.006\,. \qquad (12.14)$$

The inclusive branching ratio $\mathcal{B}(B \to X_s\gamma) = (3.32 \pm 0.15) \times 10^{-4}$ extrapolated to $E_\gamma > E_0 = 1.6\,\mathrm{GeV}$ [24] is also sensitive to $|V_{tb}V_{ts}|$. In addition to t-quark penguins, a substantial part of the rate comes from charm contributions proportional to $V_{cb}V_{cs}^*$ via the application of 3×3 CKM unitarity (which is used here). With the NNLO calculation of $\mathcal{B}(B \to X_s\gamma)_{E_\gamma > E_0}/\mathcal{B}(B \to X_c e\bar{\nu})$ [74], we obtain $|V_{ts}/V_{cb}| = 0.98 \pm 0.04$. The $B_s \to \mu^+\mu^-$ rate is also proportional to $|V_{tb}V_{ts}|^2$ in the SM, and the world average, $\mathcal{B}(B_s \to \mu^+\mu^-) = (3.1 \pm 0.6) \times 10^{-9}$ [24], is consistent with the SM, with sizable uncertainties.

A complementary determination of $|V_{td}/V_{ts}|$ is possible from the ratio of $B \to \rho\gamma$ and $K^*\gamma$ rates. The ratio of the neutral modes is theoretically cleaner than that of the charged ones, because the poorly known spectator-interaction contribution is expected to be smaller (W-exchange vs. weak annihilation). For now, because of low statistics, we average the charged and neutral rates assuming the isospin symmetry and heavy-quark limit motivated relation, $|V_{td}/V_{ts}|^2/\xi_\gamma^2 = [\Gamma(B^+ \to \rho^+\gamma) + 2\Gamma(B^0 \to \rho^0\gamma)]/[\Gamma(B^+ \to K^{*+}\gamma) + \Gamma(B^0 \to K^{*0}\gamma)] = (3.37\pm0.49)\%$ [24]. Here ξ_γ contains the poorly known hadronic physics. Using $\xi_\gamma = 1.2\pm0.2$ [75] gives $|V_{td}/V_{ts}| = 0.220 \pm 0.016 \pm 0.037$, where the first uncertainty is experimental and the second is theoretical.

A theoretically clean determination of $|V_{td}V_{ts}^*|$ is possible from $K^+ \to \pi^+\nu\bar{\nu}$ decay [76]. Experimentally, only a handful of events have been observed [77, 78] and the rate is consistent with the SM with large uncertainties. Much more data are needed for a precision measurement.

12.2.8 $|V_{tb}|$

The determination of $|V_{tb}|$ from top decays uses the ratio of branching fractions $R = \mathcal{B}(t \to Wb)/\mathcal{B}(t \to Wq) = |V_{tb}|^2/(\sum_q |V_{tq}|^2) = |V_{tb}|^2$, where $q = b, s, d$. The CDF and DØ measurements performed on data collected during Run II of the Tevatron give $|V_{tb}| > 0.78$ [79] and $0.99 > |V_{tb}| > 0.90$ [80], respectively, at 95% CL. CMS measured the same quantity at 8 TeV and obtained $|V_{tb}| > 0.975$ [81] at 95% CL.

The direct determination of $|V_{tb}|$, without assuming unitarity, is possible from the single top quark production cross section. The $(3.30^{+0.52}_{-0.40})$ pb combined cross section [82] of DØ and CDF measurements implies $|V_{tb}| = 1.02^{+0.06}_{-0.05}$. The LHC experiments, ATLAS and CMS, have measured single top quark production cross sections (and extracted $|V_{tb}|$) in t-channel, Wt-channel, and s-channel at 7 TeV, 8 TeV, and 13 TeV [83]. The average of these $|V_{tb}|$ values is calculated to be $|V_{tb}| = 1.010 \pm 0.036$, where all systematic errors and theoretical errors are treated to be fully correlated. The average of Tevatron and LHC values gives

$$|V_{tb}| = 1.013 \pm 0.030\,. \tag{12.15}$$

The experimental systematic uncertainties dominate, and a dedicated combination would be welcome.

A weak constraint on $|V_{tb}|$ can be obtained from precision electroweak data, where top quarks enter in loops. The sensitivity is best in $\Gamma(Z \to b\bar{b})$ and yields $|V_{tb}| = 0.77^{+0.18}_{-0.24}$ [84].

12.3 Phases of CKM elements

As can be seen from Fig. 12.1, the angles of the unitarity triangle are

$$\begin{aligned}
\beta = \phi_1 &= \arg\left(-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\right), \\
\alpha = \phi_2 &= \arg\left(-\frac{V_{td}V_{tb}^*}{V_{ud}V_{ub}^*}\right), \\
\gamma = \phi_3 &= \arg\left(-\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}\right).
\end{aligned} \tag{12.16}$$

Since CP violation involves phases of CKM elements, many measurements of CP-violating observables can be used to constrain these angles and the $\bar{\rho}, \bar{\eta}$ parameters.

12.3.1 ϵ *and* ϵ'

The measurement of CP violation in K^0–$\overline{K}^0$ mixing, $|\epsilon| = (2.228 \pm 0.011) \times 10^{-3}$ [85], provides important information about the CKM matrix. The phase of ϵ is determined by long-distance physics, $\epsilon = \frac{1}{2}\, e^{i\phi_\epsilon} \sin\phi_\epsilon \arg(-M_{12}/\Gamma_{12})$, where $\phi_\epsilon = \arctan|2\Delta m_K/\Delta\Gamma_K| \simeq 43.5°$. The SM prediction can be written as

$$\begin{aligned}
\epsilon = \kappa_\epsilon\, e^{i\phi_\epsilon} \frac{G_F^2 m_W^2 m_K}{12\sqrt{2}\,\pi^2 \Delta m_K}\, f_K^2 \widehat{B}_K \Big\{ &\eta_{tt} S(x_t)\, \mathrm{Im}[(V_{ts}V_{td}^*)^2] \\
&+ 2\eta_{ct} S(x_c, x_t)\, \mathrm{Im}(V_{cs}V_{cd}^* V_{ts}V_{td}^*) + \eta_{cc}\, x_c\, \mathrm{Im}[(V_{cs}V_{cd}^*)^2] \Big\},
\end{aligned} \tag{12.17}$$

where $\kappa_\epsilon \simeq 0.94 \pm 0.02$ [86] includes the effects of strangeness changing $\Delta s = 1$ operators and additional dependence on $\phi_\epsilon \neq \pi/4$ (see also Ref. [87]). The displayed terms are the short-distance $\Delta s = 2$ contribution to $\mathrm{Im}M_{12}$ in the usual phase convention, S is an Inami-Lim function [88], $x_q = m_q^2/m_W^2$, and η_{ij} are perturbative QCD corrections. The constraint from ϵ in the $\bar{\rho}, \bar{\eta}$ plane is bounded by approximate hyperbolas. Lattice QCD determined the bag parameter $\widehat{B}_K = 0.717 \pm 0.024$ [14], and the main uncertainties are from $(V_{ts}V_{td}^*)^2$ (approximately given by that of $|V_{cb}|^4$ or A^4), the η_{ij} coefficients, and estimates of κ_ϵ.

The measurement of $6\,\mathrm{Re}(\epsilon'/\epsilon) = 1 - |\eta_{00}/\eta_{+-}|^2$, where each $\eta_{ij} = \langle\pi^i\pi^j|\mathcal{H}|K_L\rangle/\langle\pi^i\pi^j|\mathcal{H}|K_S\rangle$ violates CP, provides a qualitative test of the CKM mechanism, and strong constraints on many BSM scenarios. Its nonzero value, $\mathrm{Re}(\epsilon'/\epsilon) = (1.67\pm0.23)\times10^{-3}$ [85], demonstrated the existence of direct CP violation, a prediction of the KM ansatz. While $\mathrm{Re}(\epsilon'/\epsilon) \propto \mathrm{Im}(V_{td}V_{ts}^*)$, this quantity cannot easily be used to extract CKM parameters, because cancellations between the electromagnetic and gluonic penguin contributions for large m_t [89] enhance the hadronic uncertainties. Most SM estimates [90] agree with the observed value, indicating that $\bar{\eta}$ is positive. Progress in lattice QCD [91] may yield a precise SM prediction in the future, and trigger new work on assessing the consistency of the SM with the measured value [92, 93].

12.3.2 β / ϕ_1

12.3.2.1 *Charmonium modes*

CP-violation measurements in B-meson decays provide direct information on the angles of the unitarity triangle, shown in Fig. 12.1. These overconstraining measurements serve to improve the determination of the CKM elements, and to reveal possible effects beyond the SM.

The time-dependent CP asymmetry of neutral B decays to a final state f common to B^0 and $\overline{B}^0$ is given by [94–96]

$$\begin{aligned}
\mathcal{A}_f &= \frac{\Gamma(\overline{B}^0(t) \to f) - \Gamma(B^0(t) \to f)}{\Gamma(\overline{B}^0(t) \to f) + \Gamma(B^0(t) \to f)}\,, \\
&= S_f \sin(\Delta m_d\, t) - C_f \cos(\Delta m_d\, t)\,,
\end{aligned} \tag{12.18}$$

where

$$S_f = \frac{2\,\mathrm{Im}\lambda_f}{1+|\lambda_f|^2}\,, \qquad C_f = \frac{1-|\lambda_f|^2}{1+|\lambda_f|^2}\,, \qquad \lambda_f = \frac{q}{p}\frac{\bar{A}_f}{A_f}\,. \tag{12.19}$$

Here, q/p describes B^0–$\overline{B}^0$ mixing and, to a good approximation in the SM, $q/p = V_{tb}^*V_{td}/V_{tb}V_{td}^* = e^{-2i\beta+\mathcal{O}(\lambda^4)}$ in the usual phase convention. A_f ($\bar{A}_f$) is the amplitude of the $B^0 \to f$ ($\overline{B}^0 \to f$) decay. If f is a CP eigenstate, and amplitudes with one CKM phase dominate the decay, then $|A_f| = |\bar{A}_f|$, $C_f = 0$, and $S_f = \sin(\arg\lambda_f) = \eta_f \sin 2\phi$, where η_f is the CP eigenvalue of f and 2ϕ is the phase difference between the $B^0 \to f$ and $B^0 \to \overline{B}^0 \to f$ decay paths. A contribution of another amplitude to the decay with a different CKM phase makes the value of S_f sensitive to relative strong-interaction phases between the decay amplitudes (it also makes $C_f \neq 0$ possible).

The $b \to c\bar{c}s$ decays to CP eigenstates ($B^0 \to$ charmonium $K^0_{S,L}$) are the theoretically cleanest examples, measuring $S_f = -\eta_f \sin 2\beta$. The $b \to s$ penguin amplitudes have dominantly the same weak phase as the $b \to c\bar{c}s$ tree amplitude. Since only λ^2-suppressed penguin amplitudes introduce a different CP-violating phase, amplitudes with a single weak phase dominate, and we expect $\big||\bar{A}_{\psi K}/A_{\psi K}| - 1\big| < 0.01$. The e^+e^- asymmetric-energy B-factory experiments, *BaBar* [97] and Belle [98], and LHCb [99] provided precise measurements. The world average, including some other measurements, is [24]

$$\sin 2\beta = 0.699 \pm 0.017\,. \tag{12.20}$$

This measurement has a four-fold ambiguity in β, which can be resolved by a global fit as mentioned in Sec. 12.4. Experimentally, the two-fold ambiguity $\beta \to \pi/2 - \beta$ (but not $\beta \to \pi + \beta$) can be resolved by a time-dependent angular analysis of $B^0 \to J/\psi K^{*0}$ [100,101], or a time-dependent Dalitz plot analysis of $B^0 \to \overline{D}^0 h^0$. The time-dependent Dalitz plot analysis of $B^0 \to \overline{D}^0 h^0$ ($h^0 = \pi^0, \eta, \omega$) with $\overline{D}^0 \to K^0_S \pi^+\pi^-$, jointly performed by Belle and *BaBar*, excludes the $\pi/2 - \beta$ solution with 7.3σ confidence level

[102]. These results indicate that negative $\cos 2\beta$ solutions are very unlikely, in agreement with the global CKM fit result.

The $b \to c\bar{c}d$ mediated transitions, such as $B^0 \to J/\psi\pi^0$ and $B^0 \to D^{(*)+}D^{(*)-}$, also measure approximately $\sin 2\beta$. However, the dominant component of the $b \to d$ penguin amplitude has a different CKM phase ($V_{tb}^* V_{td}$) than the tree amplitude ($V_{cb}^* V_{cd}$), and their magnitudes are of the same order in λ. Therefore, the effect of penguins could be large, resulting in $S_f \neq -\eta_f \sin 2\beta$ and $C_f \neq 0$. Such decay modes have been measured by *BABAR*, Belle, and LHCb. The world averages [24], $S_{J/\psi\pi^0} = -0.86\pm0.14$, $S_{J/\psi\rho^0} = -0.66^{+0.16}_{-0.12}$, $S_{D^+D^-} = -0.84 \pm 0.12$, and $S_{D^{*+}D^{*-}} = -0.71 \pm 0.09$ (where $\eta_f = +1$ for the $J/\psi\pi^0$ and D^+D^- modes, while $J/\psi\rho^0$ and $D^{*+}D^{*-}$ are mixtures of CP even and odd states), are consistent with $\sin 2\beta$ obtained from $B^0 \to$ charmonium K^0 decays, and the C_f's are consistent with zero, although the uncertainties are sizable.

The $b \to c\bar{u}d$ decays $B^0 \to \overline{D}^{0(*)}h^0$, with $\overline{D}^0 \to CP$ eigenstates and $\overline{D}^0 \to K_S^0\pi^+\pi^-$ with Dalitz plot analysis, have no penguin contributions, and provide theoretically clean $\sin 2\beta$ measurements. The average of joint analyses of *BABAR* and Belle data [102, 103] give $\sin 2\beta = 0.71 \pm 0.09$ [24, 104].

12.3.2.2 *Penguin-dominated modes*

The $b \to s\bar{q}q$ penguin-dominated decays have the same CKM phase as the $b \to c\bar{c}s$ tree level decays, up to corrections suppressed by λ^2, since $V_{tb}^* V_{ts} = -V_{cb}^* V_{cs}[1 + \mathcal{O}(\lambda^2)]$. Therefore, decays such as $B^0 \to \phi K^0$ and $\eta' K^0$ provide $\sin 2\beta$ measurements in the SM. Any BSM contribution to the amplitude with a different weak phase would give rise to $S_f \neq -\eta_f \sin 2\beta$, and possibly $C_f \neq 0$. Therefore, the main interest in these modes is not simply to measure $\sin 2\beta$, but to search for new physics. Measurements of many other decay modes in this category, such as $B \to \pi^0 K_S^0$, $K_S^0 K_S^0 K_S^0$, *etc.*, have also been performed by *BABAR* and Belle. The results and their uncertainties are summarized in Fig. 12.3 and Table 12.1 of Ref. [95]. The comparison of CP violation measurements between tree-dominated and penguin-dominated modes in B_s^0 decays provides similar sensitivity to new physics.

12.3.3 α / ϕ_2

Since α is the phase between $V_{tb}^* V_{td}$ and $V_{ub}^* V_{ud}$, only time-dependent CP asymmetries in decay modes dominated by $b \to u\bar{u}d$ transition can directly measure $\sin 2\alpha$, in contrast to $\sin 2\beta$, where several different quark-level transitions can be used. Since $b \to d$ penguin amplitudes have a different CKM phase than $b \to u\bar{u}d$ tree amplitudes, and their magnitudes are of the same order in λ, the penguin contribution can be sizable, which makes the determination of α complicated. To date, α has been measured in $B \to \pi\pi$, $\rho\pi$ and $\rho\rho$ decay modes.

12.3.3.1 $B \to \pi\pi$

It is well established from the data that there is a sizable contribution of $b \to d$ penguin amplitudes in $B \to \pi\pi$ decays. Thus, $S_{\pi^+\pi^-}$ in the time-dependent $B^0 \to \pi^+\pi^-$ analysis does not measure $\sin 2\alpha$, but

$$S_{\pi^+\pi^-} = \sqrt{1 - C^2_{\pi^+\pi^-}}\, \sin(2\alpha + 2\Delta\alpha)\,, \qquad (12.21)$$

where $2\Delta\alpha$ is the phase difference between $e^{2i\gamma}\bar{A}_{\pi^+\pi^-}$ and $A_{\pi^+\pi^-}$. The value of $\Delta\alpha$, and hence α, can be extracted using the isospin relation among the amplitudes of $B^0 \to \pi^+\pi^-$, $B^0 \to \pi^0\pi^0$, and $B^+ \to \pi^+\pi^0$ decays [105],

$$\frac{1}{\sqrt{2}}\, A_{\pi^+\pi^-} + A_{\pi^0\pi^0} - A_{\pi^+\pi^0} = 0\,, \qquad (12.22)$$

and a similar expression for the $\bar{A}_{\pi\pi}$'s. This method utilizes the fact that a pair of pions from $B \to \pi\pi$ decay must be in a zero angular momentum state, and, because of Bose statistics, they must have even isospin. Consequently, $\pi^\pm\pi^0$ is in a pure isospin-2 state, while the penguin amplitudes only contribute to the isospin-0 final state. The latter does not hold for the electroweak penguin amplitudes, but their effect is expected to be small. The isospin analysis uses the world averages of *BABAR*, Belle, and LHCb measurements, $S_{\pi^+\pi^-} = -0.63 \pm 0.04$, $C_{\pi^+\pi^-} = -0.32 \pm 0.04$, the decay widths of all three modes, and the direct CP asymmetry $C_{\pi^0\pi^0} = -0.33 \pm 0.22$ [24]. This analysis leads to 16 mirror solutions for $0 \leq \alpha < 2\pi$. Because of this, and due to the experimental uncertainties, some of these solutions are not well separated [96].

12.3.3.2 $B \to \rho\rho$

The decay $B^0 \to \rho^+\rho^-$ contains two vector mesons in the final state, and so in general is a mixture of CP-even and CP-odd components. Therefore, it was thought that extracting α from this mode would be complicated.

However, the longitudinal polarization fractions in $B^+ \to \rho^+\rho^0$ and $B^0 \to \rho^+\rho^-$ decays were measured to be close to unity [106], which implies that the final states are almost purely CP-even. Furthermore, $\mathcal{B}(B^0 \to \rho^0\rho^0) = (0.95 \pm 0.16) \times 10^{-6}$ is much smaller than $\mathcal{B}(B^0 \to \rho^+\rho^-) = (27.7 \pm 1.9) \times 10^{-6}$ and $\mathcal{B}(B^+ \to \rho^+\rho^0) = (24.0^{+1.9}_{-2.0}) \times 10^{-6}$ [24], which implies that the effect of the penguin contributions is small. The isospin analysis using the world averages, $S_{\rho^+\rho^-} = -0.14 \pm 0.13$ and $C_{\rho^+\rho^-} = 0.00 \pm 0.09$ [24], together with the time-dependent CP asymmetry, $S_{\rho^0\rho^0} = -0.3\pm0.7$ and $C_{\rho^0\rho^0} = -0.2\pm0.9$ [107], and the above mentioned branching fractions and longitudinal polarization fractions, gives two solutions (with mirror solutions at $3\pi/2 - \alpha$) [96]. A possible small violation of Eq. (12.22) due to the finite width of the ρ [108] is so far neglected.

12.3.3.3 $B \to \rho\pi$

The final state in $B^0 \to \rho^+\pi^-$ decay is not a CP eigenstate, but this decay proceeds via the same quark-level diagrams as $B^0 \to \pi^+\pi^-$, and both B^0 and $\overline{B}^0$ can decay to $\rho^+\pi^-$, while the final state in $B^0 \to \rho^0\pi^0$ is a CP eigenstate. Consequently, mixing-induced CP violation can occur in B^0 and $\overline{B}^0$ decays to $\rho^\pm\pi^\mp$ and $\rho^0\pi^0$. The time-dependent Dalitz plot analysis of $B^0 \to \pi^+\pi^-\pi^0$ decays permits the extraction of α with a single discrete ambiguity, $\alpha \to \alpha + \pi$, since one knows the variation of the strong phases in the interference regions of the $\rho^+\pi^-$, $\rho^-\pi^+$, and $\rho^0\pi^0$ amplitudes in the Dalitz plot [109]. The combination of Belle [110] and *BABAR* [111] measurements gives only moderate constraints [96].

Combining the $B \to \pi\pi$, $\rho\pi$, and $\rho\rho$ decay modes [24, 96], α is constrained as

$$\alpha = \left(84.9^{+5.1}_{-4.5}\right)^\circ. \qquad (12.23)$$

Similar results can be found in Refs. [112, 113].

12.3.4 γ / ϕ_3

By virtue of Eq. (12.16), γ does not depend on CKM elements involving the top quark, so it can be measured in tree-level B decays. This is an important distinction from the measurements of α and β, and implies that measurements of γ are unlikely to be affected by physics beyond the SM.

12.3.4.1 $B_{(s)} \to D_{(s)}K^{(*)}$

The interference of $B^- \to D^0K^-$ ($b \to c\bar{u}s$) and $B^- \to \overline{D}^0K^-$ ($b \to u\bar{c}s$) transitions can be studied in final states accessible in both D^0 and $\overline{D}^0$ decays [94]. In principle, it is possible to extract the B and D decay amplitudes, the relative strong phases, and the weak phase γ from the data [96].

A practical complication is that the precision depends sensitively on the ratio of the interfering amplitudes

$$r_B = \left| A(B^- \to \overline{D}^0K^-) \big/ A(B^- \to D^0K^-) \right|, \qquad (12.24)$$

which is around 0.1. The original GLW method [114, 115] considers D decays to CP eigenstates, such as $B^\pm \to D^{(*)}_{CP}(\to \pi^+\pi^-)K^{(*)\pm}$. To alleviate the smallness of r_B and make the interfering amplitudes (which are products of the B and D decay amplitudes) comparable in magnitude, the ADS method [116] considers final states where Cabibbo-allowed $\overline{D}^0$ and doubly-Cabibbo-suppressed D^0 decays interfere. Measurements have been made by the B factories, CDF, and LHCb, using both methods [24]. The GLW method currently gives only a loose constraint on γ, $14.9^\circ < \gamma < 30.8^\circ$, $69.9^\circ < \gamma < 87.9^\circ$, $92.1^\circ < \gamma < 110.1^\circ$, and $149.2^\circ < \gamma < 165.1^\circ$ at 68% CL; while the ADS method provides $\gamma = (72^{+12}_{-14})^\circ$ [24, 104].

The BPGGSZ method [117, 118] utilizes that both D^0 and $\overline{D}^0$ can have large branching fractions to CP self-conjugate three-body final states, such as $K^0_S\pi^+\pi^-$, and the analysis can be optimized by studying the Dalitz plot dependence of the interferences. The best present determination of γ comes from this method. Combining the measurements by Belle [119], *BABAR* [120] and LHCb [121], $\gamma = (73.8^{+6.8}_{-7.0})^\circ$ is obtained [24, 104]. The error is sensitive to the central value of the amplitude ratio r_B (and r_B^* for the D^*K mode), for which Belle found somewhat larger central values than *BABAR* and LHCb. The same values of $r_B^{(*)}$ enter the ADS analyses, and the data can be combined to fit for $r_B^{(*)}$ and γ. The effect of D^0–$\overline{D}^0$ mixing on γ is far below the present experimental accuracy [122], unless D^0–$\overline{D}^0$ mixing is due to CP-violating new physics, in which case it can be included in the analysis [123].

The amplitude ratio is much larger in the analogous $B^0_s \to D^\pm_s K^\mp$ decays, which allows a model-independent extraction of $\gamma - 2\beta_s$ [124] (here $\beta_s = \arg(-V_{ts}V^*_{tb}/V_{cs}V^*_{cb})$ is related to the phase of B_s mixing). A recent measurement by LHCb [125] gives $\gamma = (127^{+17}_{-22})^\circ$ using a constraint on $2\beta_s$ (see Sec. 12.5).

Combining all the above measurements [24, 96], γ is constrained as

$$\gamma = \left(72.1^{+4.1}_{-4.5}\right)^\circ . \tag{12.25}$$

Similar results can be found in Refs. [112, 113].

12.3.4.2 $B^0 \to D^{(*)\pm}\pi^\mp$

The interference of $b \to u$ and $b \to c$ transitions can be studied in $\overline{B}^0 \to D^{(*)+}\pi^-$ ($b \to c\bar{u}d$) and $\overline{B}^0 \to B^0 \to D^{(*)+}\pi^-$ ($\bar{b} \to \bar{u}c\bar{d}$) decays and their CP conjugates, since both B^0 and $\overline{B}^0$ decay to $D^{(*)\pm}\pi^\mp$ (or $D^\pm\rho^\mp$, *etc.*). Since there are only tree and no penguin contributions to these decays, in principle, it is possible to extract from the four time-dependent rates the magnitudes of the two hadronic amplitudes, their relative strong phase, and the weak phase between the two decay paths, which is $2\beta + \gamma$.

A complication is that the ratio of the interfering amplitudes is very small, $r_{D\pi} = A(B^0 \to D^+\pi^-)/A(\overline{B}^0 \to D^+\pi^-) = \mathcal{O}(0.01)$ (and similarly for $r_{D^*\pi}$ and $r_{D\rho}$), and therefore it has not been possible to measure it. To obtain $2\beta + \gamma$, $SU(3)$ flavor symmetry and dynamical assumptions have been used to relate $A(\overline{B}^0 \to D^-\pi^+)$ to $A(\overline{B}^0 \to D^-_s\pi^+)$, so this measurement is not model independent at present. Combining the $D^\pm\pi^\mp$, $D^{*\pm}\pi^\mp$ and $D^\pm\rho^\mp$ measurements [126] gives $\sin(2\beta + \gamma) > 0.68$ at 68% CL [112], consistent with the previously discussed results for β and γ.

12.4 Global fit in the Standard Model

Using the independently measured CKM elements mentioned in the previous sections, the unitarity of the CKM matrix can be checked. We obtain $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 0.9985 \pm 0.0005$ (1st row), $|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 = 1.025 \pm 0.022$ (2nd row), $|V_{ud}|^2 + |V_{cd}|^2 + |V_{td}|^2 = 0.9970 \pm 0.0018$ (1st column), and $|V_{us}|^2 + |V_{cs}|^2 + |V_{ts}|^2 = 1.026 \pm 0.022$ (2nd column), respectively. Due to the recent reduction of the value of $|V_{ud}|$, there is a 3σ tension with unitarity in the 1st row, leading also to poor consistency of the SM fit below. The uncertainties in the second row and column are dominated by that of $|V_{cs}|$. For the second row, another check is obtained from the measurement of $\sum_{u,c,d,s,b}|V_{ij}|^2$ in Sec. 12.2.4, minus the sum in the first row above: $|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 = 1.002 \pm 0.027$. These provide strong tests of the unitarity of the CKM matrix. With the significantly improved direct determination of $|V_{tb}|$, the unitarity checks for the third row and column have also become fairly precise, leaving decreasing room for mixing with other states. The sum of the three angles of the unitarity triangle, $\alpha + \beta + \gamma = \left(179^{+7}_{-6}\right)^\circ$, is also consistent with the SM expectation.

The CKM matrix elements can be most precisely determined using a global fit to all available measurements and imposing the SM constraints (*i.e.*, three generation unitarity). The fit must also use theory predictions for hadronic matrix elements, which

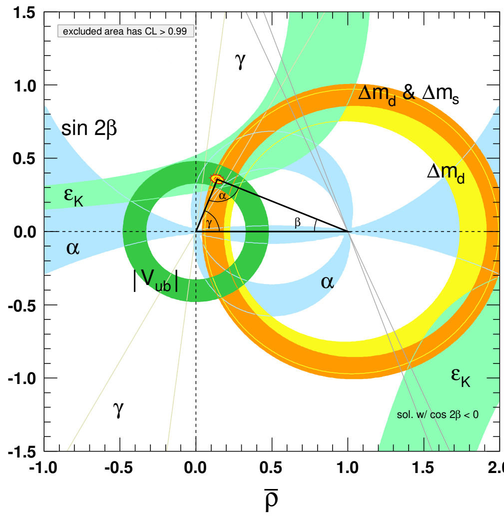

Figure 12.2: Constraints on the $\bar{\rho}, \bar{\eta}$ plane. The shaded areas have 99% CL.

sometimes have significant uncertainties. There are several approaches to combining the experimental data. CKMfitter [6, 112] and Ref. [127] (which develops [128, 129] further) use frequentist statistics, while UTfit [113, 130] uses a Bayesian approach. These approaches provide similar results.

The constraints implied by the unitarity of the three generation CKM matrix significantly reduce the allowed range of some of the CKM elements. The fit for the Wolfenstein parameters defined in Eq. (12.4) gives

$$\begin{aligned} \lambda &= 0.22650 \pm 0.00048\,, & A &= 0.790^{+0.017}_{-0.012}\,, \\ \bar{\rho} &= 0.141^{+0.016}_{-0.017}\,, & \bar{\eta} &= 0.357 \pm 0.011\,. \end{aligned} \tag{12.26}$$

These values are obtained using the method of Refs. [6, 112]. Using the prescription of Refs. [113, 130] gives $\lambda = 0.22658 \pm 0.00044$, $A = 0.818 \pm 0.012$, $\bar{\rho} = 0.139 \pm 0.014$, $\bar{\eta} = 0.356 \pm 0.010$ [131]. The fit results for the magnitudes of all nine CKM elements are

$$V_{\rm CKM} = \begin{pmatrix} 0.97401 \pm 0.00011 & 0.22650 \pm 0.00048 & 0.00361^{+0.00011}_{-0.00009} \\ 0.22636 \pm 0.00048 & 0.97320 \pm 0.00011 & 0.04053^{+0.00083}_{-0.00061} \\ 0.00854^{+0.00023}_{-0.00016} & 0.03978^{+0.00082}_{-0.00060} & 0.999172^{+0.000024}_{-0.000035} \end{pmatrix}, \tag{12.27}$$

and the Jarlskog invariant is $J = \left(3.00^{+0.15}_{-0.09}\right) \times 10^{-5}$. The parameters in Eq. (12.3) are

$$\begin{aligned} \sin\theta_{12} &= 0.22650 \pm 0.00048\,, & \sin\theta_{13} &= 0.00361^{+0.00011}_{-0.00009}\,, \\ \sin\theta_{23} &= 0.04053^{+0.00083}_{-0.00061}\,, & \delta &= 1.196^{+0.045}_{-0.043}\,. \end{aligned} \tag{12.28}$$

Fig. 12.2 illustrates the constraints on the $\bar{\rho}, \bar{\eta}$ plane from various measurements, and the global fit result. The CL of each of the shaded regions was increased from 95% to 99% for this edition, because the reduction in $|V_{ud}|$ discussed above leads to poor consistency between the fit result (for $\bar{\rho}$ and $\bar{\eta}$) and the individual constraints shown in the plot. The shaded 99% CL regions all overlap consistently around the global fit region.

If one uses only tree-level inputs (magnitudes of CKM elements not coupling to the top quark and the angle γ), the resulting fit is almost identical for λ in Eq. (12.26), while the other parameters' central values can change by about a sigma and their uncertainties double, yielding $\lambda = 0.22653 \pm 0.00048$, $A = 0.799^{+0.027}_{-0.028}$, $\bar{\rho} = 0.123^{+0.032}_{-0.028}$, and $\bar{\eta} = 0.382^{+0.029}_{-0.028}$. This illustrates how the constraints can be less tight in the presence of BSM physics.

12.5 Implications beyond the SM

The effects in B, B_s, K, and D decays and mixings due to high-scale physics (W, Z, t, H in the SM, and unknown heavier particles) can be parameterized by operators composed of SM fields, obeying the $SU(3)\times SU(2)\times U(1)$ gauge symmetry. Flavor-changing neutral currents, suppressed in the SM, are especially sensitive to beyond SM contributions. Processes studied in great detail, both experimentally and theoretically, include neutral meson mixings, $B_{(s)} \to X\gamma$, $X\ell^+\ell^-$, $\ell^+\ell^-$, $K \to \pi\nu\bar{\nu}$, etc. The BSM contributions to these operators are suppressed by powers of the scale at which they are generated. Already at lowest order, there are many dimension-6 operators, and the observable effects of BSM interactions are encoded in their coefficients. In the SM, these coefficients are determined by just the four CKM parameters, and the W, Z, and quark masses. For example, Δm_d, $\Gamma(B \to \rho\gamma)$, $\Gamma(B \to \pi\ell^+\ell^-)$, and $\Gamma(B \to \ell^+\ell^-)$ are all proportional to $|V_{td}V_{tb}|^2$ in the SM, however, they may receive unrelated BSM contributions. These BSM contributions may or may not obey the SM relations. (For example, the flavor sector of the MSSM contains 69 CP-conserving parameters and 41 CP-violating phases, *i.e.*, 40 new ones [132]). Thus, similar to the measurements of $\sin 2\beta$ in tree- and loop-dominated decay modes, overconstraining measurements of the magnitudes and phases of flavor-changing neutral-current amplitudes gives good sensitivity to BSM.

To illustrate the level of suppression required for BSM contributions, consider a class of models in which the unitarity of the CKM matrix is maintained, and the dominant BSM effects modify the neutral meson mixing amplitudes [133] by $(z_{ij}/\Lambda^2)(\overline{q}_i\gamma^\mu P_L q_j)^2$, where z_{ij} is an unknown coefficient and Λ is the scale suppressing this BSM contribution (see, [134, 135]). It is only known since the measurements of γ and α that the SM gives the leading contribution to $B^0-\overline{B}^0$ mixing [6, 136]. Nevertheless, new physics with a generic weak phase may still contribute to neutral meson mixings at a significant fraction of the SM [130, 137, 138]. The existing data imply that $\Lambda/|z_{ij}|^{1/2}$ has to exceed about 10^4 TeV for $K^0-\overline{K}^0$ mixing, 10^3 TeV for $D^0-\overline{D}^0$ mixing, 500 TeV for $B^0-\overline{B}^0$ mixing, and 100 TeV for $B^0_s-\overline{B}^0_s$ mixing [130, 135]. (Some other operators are even better constrained [130].) The constraints are the strongest in the kaon sector, because the CKM suppression is the most severe. Thus, if there is new physics at the TeV scale, $|z_{ij}| \ll 1$ is required. Even if $|z_{ij}|$ are suppressed by a loop factor and $|V^*_{ti}V_{tj}|^2$ (in the down quark sector), similar to the SM, one expects percent-level effects, which may be observable in forthcoming flavor physics experiments. To constrain such extensions of the SM, many measurements irrelevant for the SM-CKM fit, such as the CP asymmetry in semileptonic $B^0_{d,s}$ decays, $A^{d,s}_{\rm SL}$, are important [139]. The current world averages [24] are consistent with the SM, with experimental uncertainties far greater than those of the theory predictions.

There are many key measurements sensitive to BSM physics, which do not constrain the unitarity triangle in Fig. 12.1. For example, a key quantity in the B_s system is $\beta_s = \arg(-V_{ts}V^*_{tb}/V_{cs}V^*_{cb})$, which is the small, λ^2-suppressed, angle of a "squashed" unitarity triangle, obtained by taking the scalar product of the second and third columns of the CKM matrix. This angle can be measured via time-dependent CP violation in $B^0_s \to J/\psi\,\phi$, similar to β in $B^0 \to J/\psi K^0$. Since the $J/\psi\,\phi$ final state is not a CP eigenstate, an angular analysis of the decay products is needed to separate the CP-even and CP-odd components, which give opposite asymmetries. In the SM, the asymmetry for the CP-even part is $2\beta_s$, when one neglects subdominant amplitudes with a weak phase V_{ub}. (Sometimes the notation $\phi_s = -2\beta_s$ plus a possible BSM contribution to the B_s mixing phase is used.) Testing if the data agree with the SM prediction, $2\beta_s = 0.0383^{+0.0012}_{-0.0011}$ [112], is another sensitive probe of the SM. The current world average, dominated by LHC measurements [140] including the $B_s \to J/\psi\,K^+K^-$ and $J/\psi\,\pi^+\pi^-$ decay modes, is $2\beta_s = 0.051 \pm 0.023$ [71]. Since the uncertainty is much larger than that in the SM, a lot will be learned from more precise future measurements. Searches for CP violation in the charm sector, in particular in $D^0-\overline{D}^0$ mixing, provide complementary sensitivity to BSM.

In the kaon sector, the CP-violating observables, ϵ and ϵ', are tiny, so models in which all sources of CP violation are small were viable before the B-factory measurements. Since the measurement of $\sin 2\beta$, we know that CP violation can be an $\mathcal{O}(1)$ effect, and only flavor mixing is suppressed between the three quark generations. Thus, many models with spontaneous CP violation were excluded. In the kaon sector, clean tests of the SM can come from measurements of $K^+ \to \pi^+\nu\bar{\nu}$ [78] and $K^0_L \to \pi^0\nu\bar{\nu}$ [141]. These loop-induced rare decays are sensitive to BSM, and will allow precise tests [142] of the CKM paradigm, independent of B decays.

The CKM elements are fundamental parameters, so they should be measured as precisely as possible. The overconstraining measurements of CP asymmetries, mixing, semileptonic, and rare decays severely constrain the magnitudes and phases of possible BSM contributions to flavor-changing interactions. If new particles are observed at the LHC, it will be important to explore their flavor parameters as precisely as possible to understand the underlying physics.

13. *CP* Violation in the Quark Sector

Revised August 2019 by T. Gershon (Warwick U.) and Y. Nir (Weizmann Inst.).

The CP transformation combines charge conjugation C with parity P. Under C, particles and antiparticles are interchanged, by conjugating all internal quantum numbers, *e.g.*, $Q \to -Q$ for electromagnetic charge. Under P, the handedness of space is reversed, $\vec{x} \to -\vec{x}$. Thus, for example, a left-handed electron e_L^- is transformed under CP into a right-handed positron, e_R^+.

If CP were an exact symmetry, the laws of Nature would be the same for matter and for antimatter. We observe that most phenomena are C- and P-symmetric, and therefore, also CP-symmetric. In particular, these symmetries are respected by the gravitational, electromagnetic, and strong interactions. The weak interactions, on the other hand, violate C and P in the strongest possible way. For example, the charged W bosons couple to left-handed electrons, e_L^-, and to their CP-conjugate right-handed positrons, e_R^+, but to neither their C-conjugate left-handed positrons, e_L^+, nor their P-conjugate right-handed electrons, e_R^-. While weak interactions violate C and P separately, CP is still preserved in most weak interaction processes. The CP symmetry is, however, violated in certain rare processes, as discovered in neutral K decays in 1964 [1], and established later in B (2001) and D (2019) decays. A K_L meson decays more often to $\pi^- e^+ \nu_e$ than to $\pi^+ e^- \overline{\nu}_e$, thus allowing electrons and positrons to be unambiguously distinguished, but the decay-rate asymmetry is only at the 0.003 level. The CP-violating effects observed in the B system are larger: the parameter describing the CP asymmetry in the decay time distribution of $B^0/\overline{B}^0$ meson transitions to CP eigenstates like $J/\psi K_S$ is about 0.7 [2, 3]. These effects are related to K^0–$\overline{K}^0$ and B^0–$\overline{B}^0$ mixing, but CP violation arising solely from decay amplitudes has also been observed, first in $K \to \pi\pi$ decays [4–6], subsequently in B^0 [7, 8], B^+ [9–11], and B_s^0 [12] decays, and most recently in charm decays [13]. Similar effects could also occur in decays of baryons, but have not yet been observed. Moreover, CP violation has not yet been observed in processes involving the top quark, nor in flavor-conserving processes such as electric dipole moments, nor in the lepton sector; for all of these any significant observation would be a clear indication of physics beyond the Standard Model.

In addition to parity and to continuous Lorentz transformations, there is one other spacetime operation that could be a symmetry of the interactions: time reversal T, $t \to -t$. Violations of T symmetry have been observed in neutral K decays [14]. More recently, exploiting the fact that for neutral B mesons both flavor tagging and CP tagging can be used [15], T violation has been observed between states that are not CP-conjugate [16]. Moreover, T violation is expected as a corollary of CP violation if the combined CPT transformation is a fundamental symmetry of Nature [17]. All observations indicate that CPT is indeed a symmetry of Nature. Furthermore, one cannot build a locally Lorentz-invariant quantum field theory with a Hermitian Hamiltonian that violates CPT. (At several points in our discussion, we avoid assumptions about CPT, in order to identify cases where evidence for CP violation relies on assumptions about CPT.)

Within the Standard Model, CP symmetry is broken by complex phases in the Yukawa couplings (that is, the couplings of the Higgs scalar to quarks). When all manipulations to remove unphysical phases in this model are exhausted, one finds that there is a single CP-violating parameter [18]. In the basis of mass eigenstates, this single phase appears in the 3×3 unitary matrix that gives the W-boson couplings to an up-type antiquark and a down-type quark. (If the Standard Model is supplemented with Majorana mass terms for the neutrinos, the analogous mixing matrix for leptons has three CP-violating phases.) The beautifully consistent and economical Standard-Model description of CP violation in terms of Yukawa couplings, known as the Kobayashi-Maskawa (KM) mechanism [18], agrees with all measurements to date. (Some measurements are in tension with the predictions, and are discussed in more detail below. Pending verification, the results are not considered to change the overall picture of agreement with the Standard Model.) Furthermore, one can fit the data allowing new physics contributions to loop processes to compete with, or even dominate over, the Standard Model amplitudes [19, 20]. Such an analysis provides model-independent proof that the KM phase is different from zero, and that the matrix of three-generation quark mixing is the dominant source of CP violation in meson decays.

The current level of experimental accuracy and the theoretical uncertainties involved in the interpretation of the various observations leave room, however, for additional subdominant sources of CP violation from new physics. Indeed, almost all extensions of the Standard Model imply that there are such additional sources. Moreover, CP violation is a necessary condition for baryogenesis, the process of dynamically generating the matter-antimatter asymmetry of the Universe [21]. Despite the phenomenological success of the KM mechanism, it fails (by several orders of magnitude) to accommodate the observed asymmetry [22]. This discrepancy strongly suggests that Nature provides additional sources of CP violation beyond the KM mechanism. The evidence for neutrino masses implies that CP can be violated also in the lepton sector. This situation makes leptogenesis [23,24], a scenario where CP-violating phases in the Yukawa couplings of the neutrinos play a crucial role in the generation of the baryon asymmetry, a very attractive possibility. The expectation of new sources motivates the large ongoing experimental effort to find deviations from the predictions of the KM mechanism.

CP violation can be experimentally searched for in a variety of processes, such as hadron decays, electric dipole moments of neutrons, electrons and nuclei, and neutrino oscillations. Hadron decays via the weak interaction probe flavor-changing CP violation. The search for electric dipole moments may find (or constrain) sources of CP violation that, unlike the KM phase, are not related to flavor-changing couplings. Following the discovery of the Higgs boson [25, 26], searches for CP violation in the Higgs sector are becoming feasible. Future searches for CP violation in neutrino oscillations might provide further input on leptogenesis.

The present measurements of CP asymmetries provide some of the strongest constraints on the weak couplings of quarks. Future measurements of CP violation in K, D, B, and B_s^0 meson decays will provide additional constraints on the flavor parameters of the Standard Model, and can probe new physics. In this review, we give the formalism and basic physics that are relevant to present and near future measurements of CP violation in the quark sector.

Before going into details, we list here the observables where CP violation has been observed at a level above 5σ [27–29]:

- Indirect CP violation in $K \to \pi\pi$ and $K \to \pi\ell\nu$ decays, and in the $K_L \to \pi^+\pi^- e^+ e^-$ decay, is given by

$$|\epsilon| = (2.228 \pm 0.011) \times 10^{-3} \,. \tag{13.1}$$

- Direct CP violation in $K \to \pi\pi$ decays is given by

$$\mathcal{R}e(\epsilon'/\epsilon) = (1.65 \pm 0.26) \times 10^{-3} \,. \tag{13.2}$$

- CP violation in the interference of mixing and decay in the tree-dominated $b \to c\bar{c}s$ transitions, such as $B^0 \to \psi K^0$, is given by (we use K^0 throughout to denote results that combine K_S and K_L modes, but use the sign appropriate to K_S):

$$S_{\psi K^0} = +0.699 \pm 0.017 \,. \tag{13.3}$$

- CP violation in the interference of mixing and decay in modes governed by the tree-dominated $b \to c\bar{u}d$ transitions is given by

$$S_{D^{(*)}h^0} = +0.71 \pm 0.09 \,, \tag{13.4}$$

- CP violation in the interference of mixing and decay in various modes related to $b \to c\bar{c}d$ transitions is given by

$$\begin{aligned} S_{\psi\pi^0} &= -0.86 \pm 0.14 \,, \\ S_{D^+D^-} &= -0.84 \pm 0.12 \,, \\ S_{D^{*+}D^{*-}} &= -0.71 \pm 0.09 \,. \end{aligned} \tag{13.5}$$

- *CP* violation in the interference of mixing and decay in various modes related to $b \to q\bar{q}s$ (penguin) transitions is given by

$$\begin{aligned} S_{\phi K^0} &= +0.74\,^{+0.11}_{-0.13}\,, \\ S_{\eta' K^0} &= +0.63 \pm 0.06\,, \\ S_{f_0 K^0} &= +0.69\,^{+0.10}_{-0.12}\,, \\ S_{K^+K^-K_S} &= +0.68\,^{+0.09}_{-0.10}\,. \end{aligned} \tag{13.6}$$

- *CP* violation in the interference of mixing and decay in the $B^0 \to \pi^+\pi^-$ mode is given by

$$S_{\pi^+\pi^-} = -0.63 \pm 0.04\,. \tag{13.7}$$

- Direct *CP* violation in the $B^0 \to \pi^+\pi^-$ mode is given by

$$C_{\pi^+\pi^-} = -0.32 \pm 0.04\,. \tag{13.8}$$

- Direct *CP* violation in $B^+ \to D_+K^+$ decays (D_+ is the *CP*-even neutral D state) is given by

$$\mathcal{A}_{B^+\to D_+K^+} = +0.129 \pm 0.012\,, \tag{13.9}$$

  while the corresponding quantity in the case that the neutral D meson is reconstructed in the suppressed $K^-\pi^+$ final state is

$$\mathcal{A}_{B^+\to D_{K^-\pi^+}K^+} = -0.41 \pm 0.06\,, \tag{13.10}$$

- Direct *CP* violation has also been observed in $B^+ \to DK^+$ decays through differences between the Dalitz plot distributions of subsequent $D \to K_S\pi^+\pi^-$ decays.
- Direct *CP* violation in the $\overline{B}^0 \to K^-\pi^+$ mode is given by

$$\mathcal{A}_{\overline{B}^0\to K^-\pi^+} = -0.084 \pm 0.004\,. \tag{13.11}$$

- Direct *CP* violation in the $\overline{B}{}^0_s \to K^+\pi^-$ mode is given by

$$\mathcal{A}_{\overline{B}{}^0_s\to K^+\pi^-} = +0.213 \pm 0.017\,. \tag{13.12}$$

- Direct *CP* violation in $B^+ \to K^+K^-\pi^+$ decays is given by

$$\mathcal{A}_{B^+\to K^+K^-\pi^+} = -0.118 \pm 0.022\,. \tag{13.13}$$

  An amplitude analysis has established a large *CP* violation effect associated with $\pi\pi \leftrightarrow KK$ S-wave rescattering in $B^+ \to K^+K^-\pi^+$ decays.
- Large *CP* violation effects have also been observed in certain regions of the phase space of $B^+ \to K^+K^-K^+$, $\pi^+\pi^-K^+$ and $\pi^+\pi^-\pi^+$ decays.
- Direct *CP* violation has been established in the difference of asymmetries for $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ decays

$$\Delta a_{CP} = (-0.164 \pm 0.028) \times 10^{-3}\,. \tag{13.14}$$

13.1 Formalism

The phenomenology of *CP* violation for neutral flavored mesons is particularly interesting, since many of the observables can be cleanly interpreted. Although the phenomenology is superficially different for K^0, D^0, B^0, and B^0_s decays, this is primarily because each of these systems is governed by a different balance between decay rates, oscillations, and lifetime splitting. However, the general considerations presented in this section are identical for all flavored neutral pseudoscalar mesons. The phenomenology of *CP* violation for neutral mesons that do not carry flavor quantum numbers (such as the $\eta^{(\prime)}$ state) is quite different: such states are their own antiparticles and have definite *CP* eigenvalues, so the signature of *CP* violation is simply the decay to a final state with the opposite *CP*. Such decays are mediated by the electromagnetic or (OZI-suppressed) strong interaction, where *CP* violation is not expected and has not yet been observed. In the remainder of this review, we restrict ourselves to considerations of weakly decaying hadrons.

In this section, we present a general formalism for, and classification of, *CP* violation in the decay of a weakly decaying hadron, denoted M. We pay particular attention to the case that M is a K^0, D^0, B^0, or B^0_s meson. Subsequent sections describe the *CP*-violating phenomenology, approximations, and alternative formalisms that are specific to each system.

13.1.1 *Charged- and neutral-hadron decays*

We define decay amplitudes of M (which could be charged or neutral) and its *CP* conjugate $\overline{M}$ to a multi-particle final state f and its *CP* conjugate $\overline{f}$ as

$$A_f = \langle f\,|\mathcal{H}|\,M\rangle\,, \quad \overline{A}_f = \langle f\,|\mathcal{H}|\,\overline{M}\rangle\,, \tag{13.15a}$$

$$A_{\overline{f}} = \langle \overline{f}\,|\mathcal{H}|\,M\rangle\,, \quad \overline{A}_{\overline{f}} = \langle \overline{f}\,|\mathcal{H}|\,\overline{M}\rangle\,, \tag{13.15b}$$

where $\mathcal{H}$ is the Hamiltonian governing weak interactions. The action of *CP* on these states introduces phases ξ_M and ξ_f that depend on their flavor content, according to

$$CP|M\rangle = e^{+i\xi_M}\,|\overline{M}\rangle\,, \quad CP|f\rangle = e^{+i\xi_f}\,|\overline{f}\rangle\,, \tag{13.16a}$$

$$CP|\overline{M}\rangle = e^{-i\xi_M}\,|M\rangle\,, \quad CP|\overline{f}\rangle = e^{-i\xi_f}\,|f\rangle\,, \tag{13.16b}$$

so that $(CP)^2 = 1$. The phases ξ_M and ξ_f are arbitrary and unobservable because of the flavor symmetry of the strong interaction. If *CP* is conserved by the dynamics, $[CP, \mathcal{H}] = 0$, then A_f and $\overline{A}_{\overline{f}}$ have the same magnitude and an arbitrary unphysical relative phase

$$\overline{A}_{\overline{f}} = e^{i(\xi_f - \xi_M)}\,A_f\,. \tag{13.17}$$

13.1.2 *Neutral-meson mixing*

A state that is initially a superposition of M^0 and $\overline{M}^0$, say

$$|\psi(0)\rangle = a(0)|M^0\rangle + b(0)|\overline{M}^0\rangle\,, \tag{13.18}$$

will evolve in time acquiring components that describe all possible decay final states $\{f_1, f_2, \ldots\}$, that is,

$$|\psi(t)\rangle = a(t)|M^0\rangle + b(t)|\overline{M}^0\rangle + c_1(t)|f_1\rangle + c_2(t)|f_2\rangle + \cdots\,. \tag{13.19}$$

If we are interested in computing only the values of $a(t)$ and $b(t)$ (and not the values of all $c_i(t)$), and if the times t in which we are interested are much larger than the typical strong interaction scale, then we can use a much simplified formalism [30]. The simplified time evolution is determined by a 2×2 effective Hamiltonian $\mathbf{H}$ that is not Hermitian, since otherwise the mesons would only oscillate and not decay. Any complex matrix, such as $\mathbf{H}$, can be written in terms of Hermitian matrices $\mathbf{M}$ and $\mathbf{\Gamma}$ as

$$\mathbf{H} = \mathbf{M} - \frac{i}{2}\,\mathbf{\Gamma}\,. \tag{13.20}$$

$\mathbf{M}$ and $\mathbf{\Gamma}$ are associated with $(M^0, \overline{M}^0) \leftrightarrow (M^0, \overline{M}^0)$ transitions via off-shell (dispersive), and on-shell (absorptive) intermediate states, respectively. Diagonal elements of $\mathbf{M}$ and $\mathbf{\Gamma}$ are associated with the flavor-conserving transitions $M^0 \to M^0$ and $\overline{M}^0 \to \overline{M}^0$, while off-diagonal elements are associated with flavor-changing transitions $M^0 \leftrightarrow \overline{M}^0$.

The eigenvectors of $\mathbf{H}$ have well-defined masses and decay widths. To specify the components of the strong interaction eigenstates, M^0 and $\overline{M}^0$, in the light (M_L) and heavy (M_H) mass eigenstates, we introduce three complex parameters: p, q, and, for the case that both *CP* and *CPT* are violated in mixing, z:

$$|M_L\rangle \propto p\sqrt{1-z}\,|M^0\rangle + q\sqrt{1+z}\,|\overline{M}^0\rangle\,, \tag{13.21a}$$

$$|M_H\rangle \propto p\sqrt{1+z}\,|M^0\rangle - q\sqrt{1-z}\,|\overline{M}^0\rangle\,, \tag{13.21b}$$

with the normalization $|q|^2 + |p|^2 = 1$ when $z = 0$. (Another possible choice of labelling, which is in standard usage for K mesons, defines the mass eigenstates according to their lifetimes: K_S for the short-lived and K_L for the long-lived state. The K_L is experimentally found to be the heavier state. Yet another choice is often used for the D mesons [31]: the eigenstates are labelled according to their dominant *CP* content.)

The real and imaginary parts of the eigenvalues $\omega_{L,H}$ corresponding to $|M_{L,H}\rangle$ represent their masses and decay widths, respectively. The mass and width splittings are

$$\Delta m \equiv m_H - m_L = \mathcal{R}e(\omega_H - \omega_L) , \tag{13.22a}$$
$$\Delta\Gamma \equiv \Gamma_H - \Gamma_L = -2\,\mathcal{I}m(\omega_H - \omega_L) . \tag{13.22b}$$

Note that here Δm is positive by definition, while the sign of $\Delta\Gamma$ must be experimentally determined. The sign of $\Delta\Gamma$ has not yet been established for B^0 mesons, while $\Delta\Gamma < 0$ is established for K and B_s^0 mesons. The Standard Model predicts $\Delta\Gamma < 0$ for $B^0_{(s)}$ mesons; for this reason, $\Delta\Gamma = \Gamma_L - \Gamma_H$, which is still a signed quantity, is often used in the $B^0_{(s)}$ literature and is the convention used in the PDG experimental summaries.

Solving the eigenvalue problem for $\mathbf{H}$ yields

$$\left(\frac{q}{p}\right)^2 = \frac{\mathbf{M}_{12}^* - (i/2)\mathbf{\Gamma}_{12}^*}{\mathbf{M}_{12} - (i/2)\mathbf{\Gamma}_{12}} \tag{13.23}$$

and

$$z \equiv \frac{\delta m - (i/2)\delta\Gamma}{\Delta m - (i/2)\Delta\Gamma} , \tag{13.24}$$

where

$$\delta m \equiv \mathbf{M}_{11} - \mathbf{M}_{22} , \quad \delta\Gamma \equiv \mathbf{\Gamma}_{11} - \mathbf{\Gamma}_{22} \tag{13.25}$$

are the differences in effective mass and decay-rate expectation values for the strong interaction states M^0 and $\overline{M}^0$.

If either *CP* or *CPT* is a symmetry of $\mathbf{H}$ (independently of whether *T* is conserved or violated), then the values of δm and $\delta\Gamma$ are both zero, and hence $z = 0$. We also find that

$$\omega_H - \omega_L = 2\sqrt{\left(\mathbf{M}_{12} - \frac{i}{2}\mathbf{\Gamma}_{12}\right)\left(\mathbf{M}_{12}^* - \frac{i}{2}\mathbf{\Gamma}_{12}^*\right)} . \tag{13.26}$$

If either *CP* or *T* is a symmetry of $\mathbf{H}$ (independently of whether *CPT* is conserved or violated), then $\mathbf{\Gamma}_{12}/\mathbf{M}_{12}$ is real, leading to

$$\left(\frac{q}{p}\right)^2 = e^{2i\xi_M} \quad \Rightarrow \quad \left|\frac{q}{p}\right| = 1 , \tag{13.27}$$

where ξ_M is the arbitrary unphysical phase introduced in Eq. (13.16). If, and only if, *CP* is a symmetry of $\mathbf{H}$ (independently of *CPT* and *T*), then both of the above conditions hold, with the result that the mass eigenstates are orthogonal

$$\langle M_H | M_L \rangle = |p|^2 - |q|^2 = 0 . \tag{13.28}$$

13.1.3 *CP-violating observables*

All *CP*-violating observables in M and $\overline{M}$ decays to final states f and $\overline{f}$ can be expressed in terms of phase-convention-independent combinations of A_f, $\overline{A}_f$, $A_{\overline{f}}$, and $\overline{A}_{\overline{f}}$, together with, for neutral meson decays only, q/p. *CP* violation in charged meson and all baryon decays depends only on the combination $|\overline{A}_{\overline{f}}/A_f|$, while *CP* violation in flavored neutral meson decays is complicated by $M^0 \leftrightarrow \overline{M}^0$ oscillations, and depends, additionally, on $|q/p|$ and on $\lambda_f \equiv (q/p)(\overline{A}_f/A_f)$.

The decay rates of the two neutral kaon mass eigenstates, K_S and K_L, are different enough ($\Gamma_S/\Gamma_L \sim 500$) that one can, in most cases, actually study their decays independently. For D^0, B^0, and B_s^0 mesons, however, values of $\Delta\Gamma/\Gamma$ (where $\Gamma \equiv (\Gamma_H + \Gamma_L)/2$) are relatively small, and so both mass eigenstates must be considered in their evolution. We denote the state of an initially pure $|M^0\rangle$ or $|\overline{M}^0\rangle$ after an elapsed proper time t as $|M^0_{\rm phys}(t)\rangle$ or $|\overline{M}^0_{\rm phys}(t)\rangle$, respectively. Using the effective Hamiltonian approximation, but not assuming *CPT* to be a good symmetry, we obtain

$$|M^0_{\rm phys}(t)\rangle = (g_+(t) + z\, g_-(t))\,|M^0\rangle - \sqrt{1-z^2}\,\frac{q}{p}\, g_-(t)|\overline{M}^0\rangle , \tag{13.29a}$$

$$|\overline{M}^0_{\rm phys}(t)\rangle = (g_+(t) - z\, g_-(t))\,|\overline{M}^0\rangle - \sqrt{1-z^2}\,\frac{p}{q}\, g_-(t)|M^0\rangle , \tag{13.29b}$$

where

$$g_\pm(t) \equiv \frac{1}{2}\left[\exp\left(-im_H t - \frac{1}{2}\Gamma_H t\right) \pm \exp\left(-im_L t - \frac{1}{2}\Gamma_L t\right)\right] \tag{13.30}$$

and $z = 0$ if either *CPT* or *CP* is conserved.

Defining $x \equiv \Delta m/\Gamma$ and $y \equiv \Delta\Gamma/(2\Gamma)$, and assuming $z = 0$, one obtains the following time-dependent decay rates:

$$\begin{aligned}\frac{d\Gamma\left[M^0_{\rm phys}(t) \to f\right]/dt}{e^{-\Gamma t}\mathcal{N}_f} &= \left(|A_f|^2 + |(q/p)\overline{A}_f|^2\right)\cosh(y\Gamma t)\\ &+ \left(|A_f|^2 - |(q/p)\overline{A}_f|^2\right)\cos(x\Gamma t)\\ &+ 2\,\mathcal{R}e((q/p)A_f^*\overline{A}_f)\sinh(y\Gamma t)\\ &- 2\,\mathcal{I}m((q/p)A_f^*\overline{A}_f)\sin(x\Gamma t) ,\end{aligned} \tag{13.31a}$$

$$\begin{aligned}\frac{d\Gamma\left[\overline{M}^0_{\rm phys}(t) \to f\right]/dt}{e^{-\Gamma t}\mathcal{N}_f} &= \left(|(p/q)A_f|^2 + |\overline{A}_f|^2\right)\cosh(y\Gamma t)\\ &- \left(|(p/q)A_f|^2 - |\overline{A}_f|^2\right)\cos(x\Gamma t)\\ &+ 2\,\mathcal{R}e((p/q)A_f\overline{A}_f^*)\sinh(y\Gamma t)\\ &- 2\,\mathcal{I}m((p/q)A_f\overline{A}_f^*)\sin(x\Gamma t) ,\end{aligned} \tag{13.31b}$$

where $\mathcal{N}_f$ is a common, time-independent, normalization factor that can be determined bearing in mind that the range of t is $0 < t < \infty$. Decay rates to the *CP*-conjugate final state $\overline{f}$ are obtained analogously, with $\mathcal{N}_f = \mathcal{N}_{\overline{f}}$ and the substitutions $A_f \to A_{\overline{f}}$ and $\overline{A}_f \to \overline{A}_{\overline{f}}$ in Eqs. (13.31a) and (13.31b). Terms proportional to $|A_f|^2$ or $|\overline{A}_f|^2$ are associated with decays that occur without any net $M^0 \leftrightarrow \overline{M}^0$ oscillation, while terms proportional to $|(q/p)\overline{A}_f|^2$ or $|(p/q)A_f|^2$ are associated with decays following a net oscillation. The $\sinh(y\Gamma t)$ and $\sin(x\Gamma t)$ terms of Eqs. (13.31a) and (13.31b) are associated with the interference between these two cases. Note that, in multi-body decays, amplitudes are functions of variables that describe the phase-space of the final state. Interference may be present in some regions but not others, and is strongly influenced by resonant substructure.

When neutral pseudoscalar mesons are produced coherently in pairs from the decay of a vector resonance, $V \to M^0\overline{M}^0$ (for example, $\Upsilon(4S) \to B^0\overline{B}^0$, $\psi(3770) \to D^0\overline{D}^0$ or $\phi \to K^0\overline{K}^0$), the time-dependence of their subsequent decays to final states f_1 and f_2 has a similar form to Eqs. (13.31a) and (13.31b):

$$\begin{aligned}\frac{d\Gamma\left[V_{\rm phys}(t_1,t_2) \to f_1 f_2\right]/d(\Delta t)}{e^{-\Gamma|\Delta t|}\mathcal{N}_{f_1 f_2}} &= \left(|a_+|^2 + |a_-|^2\right)\cosh(y\Gamma\Delta t)\\ &+ \left(|a_+|^2 - |a_-|^2\right)\cos(x\Gamma\Delta t)\\ &- 2\,\mathcal{R}e(a_+^* a_-)\sinh(y\Gamma\Delta t)\\ &+ 2\,\mathcal{I}m(a_+^* a_-)\sin(x\Gamma\Delta t) ,\end{aligned} \tag{13.32}$$

where $\Delta t \equiv t_2 - t_1$ is the difference in the production times, t_1 and t_2, of f_1 and f_2, respectively, and the dependence on the average decay time and on decay angles has been integrated out. The normalisation factor $\mathcal{N}_{f_1 f_2}$ can be evaluated, noting that the range of Δt is $-\infty < \Delta t < \infty$. The coefficients in Eq. (13.32) are determined by the amplitudes for no net oscillation from $t_1 \to t_2$, $\overline{A}_{f_1}A_{f_2}$, and $A_{f_1}\overline{A}_{f_2}$, and for a net oscillation, $(q/p)\overline{A}_{f_1}\overline{A}_{f_2}$ and $(p/q)A_{f_1}A_{f_2}$, via

$$a_+ \equiv \overline{A}_{f_1}A_{f_2} - A_{f_1}\overline{A}_{f_2} , \tag{13.33a}$$

$$\begin{aligned}a_- \equiv &-\sqrt{1-z^2}\left(\frac{q}{p}\overline{A}_{f_1}\overline{A}_{f_2} - \frac{p}{q}A_{f_1}A_{f_2}\right)\\ &+ z\left(\overline{A}_{f_1}A_{f_2} + A_{f_1}\overline{A}_{f_2}\right) .\end{aligned} \tag{13.33b}$$

Assuming *CPT* conservation, $z = 0$, and identifying $\Delta t \to t$ and $f_2 \to f$, we find that Eqs. (13.32) and (13.33) reduce to

Eq. (13.31a) with $A_{f_1} = 0$, $\overline{A}_{f_1} = 1$, or to Eq. (13.31b) with $\overline{A}_{f_1} = 0$, $A_{f_1} = 1$. Indeed, such a situation plays an important role in experiments that exploit the coherence of $V \to M^0\overline{M}^0$ production. Final states f_1 with $A_{f_1} = 0$ or $\overline{A}_{f_1} = 0$ are called tagging states, because they identify the decaying pseudoscalar meson as, respectively, $\overline{M}^0$ or M^0. Before one of M^0 or $\overline{M}^0$ decays, they evolve in phase, so that there is always one M^0 and one $\overline{M}^0$ present. A tagging decay of one meson sets the clock for the time evolution of the other: it starts at t_1 as purely M^0 or $\overline{M}^0$, with time evolution that depends only on $t_2 - t_1$.

When f_1 is a state that both M^0 and $\overline{M}^0$ can decay into, then Eq. (13.32) contains interference terms proportional to $A_{f_1}\overline{A}_{f_1} \neq 0$ that are not present in Eqs. (13.31a) and (13.31b). Even when f_1 is dominantly produced by M^0 decays rather than $\overline{M}^0$ decays, or vice versa, $A_{f_1}\overline{A}_{f_1}$ can be non-zero owing to doubly-CKM-suppressed decays (with amplitudes suppressed by at least two powers of λ relative to the dominant amplitude, in the language of Section 13.3), and these terms should be considered for precision studies of *CP* violation in coherent $V \to M^0\overline{M}^0$ decays [32]. The correlations in $V \to M^0\overline{M}^0$ decays can also be exploited to determine strong phase differences between favored and suppressed decay amplitudes [33].

13.1.4 *Classification of CP-violating effects*

We distinguish three types of *CP*-violating effects that can occur in the quark sector:

I. *CP* violation in decay is defined by

$$|\overline{A}_{\overline{f}}/A_f| \neq 1 \,. \tag{13.34}$$

In charged meson (and all baryon) decays, where mixing effects are absent, this is the only possible source of *CP* asymmetries:

$$\mathcal{A}_{f^\pm} \equiv \frac{\Gamma(M^- \to f^-) - \Gamma(M^+ \to f^+)}{\Gamma(M^- \to f^-) + \Gamma(M^+ \to f^+)} = \frac{|\overline{A}_{f^-}/A_{f^+}|^2 - 1}{|\overline{A}_{f^-}/A_{f^+}|^2 + 1} \,. \tag{13.35}$$

Note that the usual sign convention for *CP* asymmetries of hadrons is for the difference between the rate involving the particle that contains a heavy quark and that which contains an antiquark. Hence Eq. (13.35) corresponds to the definition for $B^\pm$ mesons, but the opposite sign is used for $D^\pm_{(s)}$ decays.

II. *CP* (and *T*) violation in mixing is defined by

$$|q/p| \neq 1 \,. \tag{13.36}$$

In charged-current semileptonic neutral meson decays $M, \overline{M} \to \ell^\pm X$ (taking $|A_{\ell^+X}| = |\overline{A}_{\ell^-X}|$ and $A_{\ell^-X} = \overline{A}_{\ell^+X} = 0$, as is the case in the Standard Model, to lowest order in G_F, and in most of its reasonable extensions), this is the only source of *CP* violation, and can be measured via the asymmetry of "wrong-sign" decays induced by oscillations:

$$\mathcal{A}_{\rm SL}(t) \equiv \frac{d\Gamma/dt\left[\overline{M}^0_{\rm phys}(t) \to \ell^+X\right] - d\Gamma/dt\left[M^0_{\rm phys}(t) \to \ell^-X\right]}{d\Gamma/dt\left[\overline{M}^0_{\rm phys}(t) \to \ell^+X\right] + d\Gamma/dt\left[M^0_{\rm phys}(t) \to \ell^-X\right]} \,, \tag{13.37a}$$

$$= \frac{1 - |q/p|^4}{1 + |q/p|^4} \,. \tag{13.37b}$$

Note that this asymmetry of time-dependent decay rates is actually time-independent.

III. *CP* violation in interference between a decay without mixing, $M^0 \to f$, and a decay with mixing, $M^0 \to \overline{M}^0 \to f$ (such an effect occurs only in decays to final states that are common to M^0 and $\overline{M}^0$, including all *CP* eigenstates), is defined by

$$\arg(\lambda_f) + \arg(\lambda_{\bar{f}}) \neq 0 \,, \qquad \text{with} \qquad \lambda_f \equiv \frac{q}{p}\frac{\overline{A}_f}{A_f} \,. \tag{13.38}$$

For final *CP* eigenstates, f_{CP}, the condition Eq. (13.38) simplifies to

$$\mathcal{I}m(\lambda_{f_{CP}}) \neq 0 \,, \tag{13.39}$$

This form of *CP* violation can be observed, for example, using the asymmetry of neutral meson decays into *CP* eigenstates

$$\mathcal{A}_{f_{CP}}(t) \equiv \frac{d\Gamma/dt\left[\overline{M}^0_{\rm phys}(t) \to f_{CP}\right] - d\Gamma/dt\left[M^0_{\rm phys}(t) \to f_{CP}\right]}{d\Gamma/dt\left[\overline{M}^0_{\rm phys}(t) \to f_{CP}\right] + d\Gamma/dt\left[M^0_{\rm phys}(t) \to f_{CP}\right]} \,. \tag{13.40}$$

If $\Delta\Gamma = 0$, as expected to a good approximation for B^0 mesons but not for K^0 and B^0_s mesons, and $|q/p| = 1$, then $\mathcal{A}_{f_{CP}}$ has a particularly simple form (see Eq. (13.89), below). If, in addition, the decay amplitudes fulfill $|\overline{A}_{f_{CP}}| = |A_{f_{CP}}|$, the interference between decays with and without mixing is the only source of asymmetry and $\mathcal{A}_{f_{CP}}(t) = \mathcal{I}m(\lambda_{f_{CP}})\sin(x\Gamma t)$.

Examples of these three types of *CP* violation will be given in Sections 13.4, 13.5, and 13.6.

13.2 Theoretical Interpretation: General Considerations

Consider the $M \to f$ decay amplitude A_f, and the *CP* conjugate process, $\overline{M} \to \overline{f}$, with decay amplitude $\overline{A}_{\overline{f}}$. There are two types of phases that may appear in these decay amplitudes. Complex parameters in any Lagrangian term that contributes to the amplitude will appear in complex conjugate form in the *CP*-conjugate amplitude. Thus, their phases appear in A_f and $\overline{A}_{\overline{f}}$ with opposite signs. In the Standard Model, these phases occur only in the couplings of the $W^\pm$ bosons, and hence, are often called "weak phases." The weak phase of any single term is convention-dependent. However, the difference between the weak phases in two different terms in A_f is convention-independent. A second type of phase can appear in scattering or decay amplitudes, even when the Lagrangian is real. This phase originates from the possible contribution from intermediate on-shell states in the decay process. Since such phases are generated by *CP*-invariant interactions, they are the same in A_f and $\overline{A}_{\overline{f}}$. Usually the dominant rescattering is due to strong interactions; hence the designation "strong phases" for the phase shifts so induced. Again, only the relative strong phases between different terms in the amplitude are physically meaningful.

The "weak" and "strong" phases discussed here appear in addition to the spurious *CP*-transformation phases of Eq. (13.17). Those spurious phases are due to an arbitrary choice of phase convention, and do not originate from any dynamics or induce any *CP* violation. For simplicity, we set them to zero from here on.

It is useful to write each contribution a_i to A_f in three parts: its magnitude $|a_i|$, its weak phase ϕ_i, and its strong phase δ_i. If, for example, there are two such contributions, $A_f = a_1 + a_2$, we have

$$A_f = |a_1|e^{i(\delta_1+\phi_1)} + |a_2|e^{i(\delta_2+\phi_2)} \,, \tag{13.41a}$$

$$\overline{A}_{\overline{f}} = |a_1|e^{i(\delta_1-\phi_1)} + |a_2|e^{i(\delta_2-\phi_2)} \,. \tag{13.41b}$$

Similarly, for neutral mesons, it is useful to write

$$\mathbf{M}_{12} = |\mathbf{M}_{12}|e^{i\phi_M} \,, \quad \mathbf{\Gamma}_{12} = |\mathbf{\Gamma}_{12}|e^{i\phi_\Gamma} \,. \tag{13.42}$$

Each of the phases appearing in Eqs. (13.41) and (13.42) is convention-dependent, but combinations such as $\delta_1 - \delta_2$, $\phi_1 - \phi_2$, $\phi_M - \phi_\Gamma$, and $\phi_M + \phi_1 - \overline{\phi}_1$ (where $\overline{\phi}_1$ is a weak phase contributing to $\overline{A}_f$) are physical.

It is now straightforward to evaluate the various asymmetries in terms of the theoretical parameters introduced here. We will do so with approximations that are often relevant to the most interesting measured asymmetries.

1. The *CP* asymmetry in charged meson and all baryon decays [Eq. (13.35)] is given by

$$\mathcal{A}_f = -\frac{2|a_1a_2|\sin(\delta_2 - \delta_1)\sin(\phi_2 - \phi_1)}{|a_1|^2 + |a_2|^2 + 2|a_1a_2|\cos(\delta_2 - \delta_1)\cos(\phi_2 - \phi_1)} \,. \tag{13.43}$$

The quantity of most interest to theory is the weak phase difference $\phi_2 - \phi_1$. Its extraction from the asymmetry requires, however, that the amplitude ratio $|a_2/a_1|$ and the strong phase difference $\delta_2 - \delta_1$ are known. Both quantities depend on non-perturbative hadronic parameters that are difficult to calculate, but in some cases can be obtained from experiment.

2. In the approximation that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}| \ll 1$ (valid for B^0 and B^0_s mesons), the *CP* asymmetry in semileptonic neutral-meson decays [Eq. (13.37)] is given by

$$\mathcal{A}_{\rm SL} = -\left|\frac{\mathbf{\Gamma}_{12}}{\mathbf{M}_{12}}\right| \sin(\phi_M - \phi_\Gamma)\,. \tag{13.44}$$

The quantity of most interest to theory is the weak phase $\phi_M - \phi_\Gamma$. Its extraction from the asymmetry requires, however, that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}|$ is known. State of the art calculations of this quantity for the B^0 and B^0_s mesons have uncertainties of around 15–20% [34].

3. In the approximations that only a single weak phase contributes to decay, $A_f = |a_f|e^{i(\delta_f+\phi_f)}$, and that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}| = 0$, we obtain $|\lambda_f| = 1$, and the *CP* asymmetries in decays to a final *CP* eigenstate f [Eq. (13.40)] with eigenvalue $\eta_f = \pm 1$ are given by

$$\mathcal{A}_{f_{CP}}(t) = \mathcal{I}m(\lambda_f)\ \sin(\Delta m t) \ \text{ with } \ \mathcal{I}m(\lambda_f) = \eta_f \sin(\phi_M + 2\phi_f)\,. \tag{13.45}$$

Note that the phase measured is purely a weak phase, and no hadronic parameters are involved in the extraction of its value from $\mathcal{I}m(\lambda_f)$.

The discussion above allows us to introduce another classification of *CP*-violating effects:

1. *Indirect CP violation* is consistent with taking $\phi_M \neq 0$ and setting all other *CP* violating phases to zero. *CP* violation in mixing (type II) belongs to this class.
2. *Direct CP violation* cannot be accounted for by just $\phi_M \neq 0$. *CP* violation in decay (type I) belongs to this class.

The historical significance of this classification is related to theory. In superweak models [35], *CP* violation appears only in diagrams that contribute to $\mathbf{M}_{12}$, hence they predict that there is no direct *CP* violation. In most models and, in particular, in the Standard Model, *CP* violation is both direct and indirect. As concerns type III *CP* violation, a single observation of such an effect would be consistent with indirect *CP* violation, but observing $\eta_{f_1}\mathcal{I}m(\lambda_{f_1}) \neq \eta_{f_2}\mathcal{I}m(\lambda_{f_2})$ (for the same decaying meson and two different final *CP* eigenstates f_1 and f_2) would establish direct *CP* violation. The experimental observation of $\epsilon' \neq 0$, which was achieved by establishing that $\mathcal{I}m(\lambda_{\pi^+\pi^-}) \neq \mathcal{I}m(\lambda_{\pi^0\pi^0})$ (see Section 13.4), excluded the superweak scenario.

13.3 Theoretical Interpretation: The KM Mechanism

Of all the Standard Model quark parameters, only the Kobayashi-Maskawa (KM) phase is *CP*-violating. Having a single source of *CP* violation, the Standard Model is very predictive for *CP* asymmetries: some vanish, and those that do not are correlated.

To be precise, *CP* could be violated also by strong interactions. The experimental upper bound on the electric-dipole moment of the neutron implies, however, that $\theta_{\rm QCD}$, the non-perturbative parameter that determines the strength of this type of *CP* violation, is tiny, if not zero. (The smallness of $\theta_{\rm QCD}$ constitutes a theoretical puzzle, known as "the strong *CP* problem.") In particular, it is irrelevant to our discussion of hadron decays.

The charged current interactions (that is, the $W^\pm$ interactions) for quarks are given by

$$-\mathcal{L}_{W^\pm} = \frac{g}{\sqrt{2}}\ \overline{u_{Li}}\ \gamma^\mu\ (V_{\rm CKM})_{ij}\ d_{Lj}\ W^+_\mu + \text{h.c.} \tag{13.46}$$

Here $i, j = 1, 2, 3$ are generation numbers. The Cabibbo-Kobayashi-Maskawa (CKM) mixing matrix for quarks is a 3×3 unitary matrix [36]. Ordering the quarks by their masses, *i.e.*, $(u_1, u_2, u_3) \to (u, c, t)$ and $(d_1, d_2, d_3) \to (d, s, b)$, the elements of $V_{\rm CKM}$ are written as follows:

$$V_{\rm CKM} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix}. \tag{13.47}$$

While a general 3×3 unitary matrix depends on three real angles and six phases, the freedom to redefine the phases of the quark mass eigenstates can be used to remove five of the phases, leaving a single physical phase, the Kobayashi-Maskawa phase, that is responsible for all *CP* violation in the Standard Model.

The fact that one can parametrize $V_{\rm CKM}$ by three real and only one imaginary physical parameters can be made manifest by choosing an explicit parametrization. The Wolfenstein parametrization [37,38] is particularly useful:

$$V_{\rm CKM} = \begin{pmatrix} 1 - \frac{1}{2}\lambda^2 - \frac{1}{8}\lambda^4 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda + \frac{1}{2}A^2\lambda^5[1 - 2(\rho + i\eta)] & 1 - \frac{1}{2}\lambda^2 - \frac{1}{8}\lambda^4(1 + 4A^2) & A\lambda^2 \\ A\lambda^3[1 - (1 - \frac{1}{2}\lambda^2)(\rho + i\eta)] & -A\lambda^2 + \frac{1}{2}A\lambda^4[1 - 2(\rho + i\eta)] & 1 - \frac{1}{2}A^2\lambda^4 \end{pmatrix}. \tag{13.48}$$

Here $\lambda \approx 0.23$ (not to be confused with λ_f), the sine of the Cabibbo angle, plays the role of an expansion parameter, and η represents the *CP*-violating phase. Terms of $\mathcal{O}(\lambda^6)$ have been neglected.

The unitarity of the CKM matrix, $(VV^\dagger)_{ij} = (V^\dagger V)_{ij} = \delta_{ij}$, leads to twelve distinct complex relations among the matrix elements. The six relations with $i \neq j$ can be represented geometrically as triangles in the complex plane. Two of these,

$$V_{ud}V^*_{ub} + V_{cd}V^*_{cb} + V_{td}V^*_{tb} = 0\,, \tag{13.49a}$$
$$V_{td}V^*_{ud} + V_{ts}V^*_{us} + V_{tb}V^*_{ub} = 0\,, \tag{13.49b}$$

have terms of equal order, $\mathcal{O}(A\lambda^3)$, and so have corresponding triangles whose interior angles are all $\mathcal{O}(1)$ physical quantities that can be independently measured. The angles of the first triangle (see Fig. 13.1) are given by

$$\alpha \equiv \varphi_2 \equiv \arg\left(-\frac{V_{td}V^*_{tb}}{V_{ud}V^*_{ub}}\right) \simeq \arg\left(-\frac{1-\rho-i\eta}{\rho+i\eta}\right)\,, \tag{13.50a}$$

$$\beta \equiv \varphi_1 \equiv \arg\left(-\frac{V_{cd}V^*_{cb}}{V_{td}V^*_{tb}}\right) \simeq \arg\left(\frac{1}{1-\rho-i\eta}\right)\,, \tag{13.50b}$$

$$\gamma \equiv \varphi_3 \equiv \arg\left(-\frac{V_{ud}V^*_{ub}}{V_{cd}V^*_{cb}}\right) \simeq \arg(\rho + i\eta)\,. \tag{13.50c}$$

The angles of the second triangle are equal to (α, β, γ) up to corrections of $\mathcal{O}(\lambda^2)$. The notations (α, β, γ) and $(\varphi_1, \varphi_2, \varphi_3)$ are both in common usage but, for convenience, we only use the first convention in the following.

Another relation that can be represented as a triangle,

$$V_{us}V^*_{ub} + V_{cs}V^*_{cb} + V_{ts}V^*_{tb} = 0\,, \tag{13.51}$$

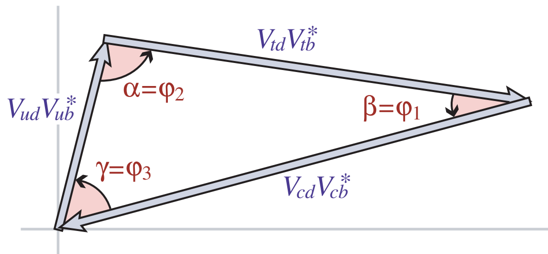

Figure 13.1: Graphical representation of the unitarity constraint $V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0$ as a triangle in the complex plane.

and, in particular, its small angle, of $\mathcal{O}(\lambda^2)$,

$$\beta_s \equiv \arg\left(-\frac{V_{ts}V_{tb}^*}{V_{cs}V_{cb}^*}\right), \tag{13.52}$$

is convenient for analyzing *CP* violation in the B_s^0 sector.

All unitarity triangles have the same area, commonly denoted by $J/2$ [39]. If *CP* is violated, J is different from zero and can be taken as the single *CP*-violating parameter. In the Wolfenstein parametrization of Eq. (13.48), $J \simeq \lambda^6 A^2 \eta$.

13.4 Kaons

CP violation was discovered in $K \to \pi\pi$ decays in 1964 [1]. The same mode provided the first observation of direct *CP* violation [4–6].

The decay amplitudes actually measured in neutral K decays refer to the mass eigenstates K_L and K_S, rather than to the K and $\overline{K}$ states referred to in Eq. (13.15). The final $\pi^+\pi^-$ and $\pi^0\pi^0$ states are *CP*-even. In the *CP* conservation limit, K_S (K_L) would be *CP*-even (odd), and therefore would (would not) decay to two pions. We define *CP*-violating amplitude ratios for two-pion final states,

$$\eta_{00} \equiv \frac{\langle \pi^0\pi^0|\mathcal{H}|K_L\rangle}{\langle \pi^0\pi^0|\mathcal{H}|K_S\rangle}, \quad \eta_{+-} \equiv \frac{\langle \pi^+\pi^-|\mathcal{H}|K_L\rangle}{\langle \pi^+\pi^-|\mathcal{H}|K_S\rangle}. \tag{13.53}$$

Another important observable is the asymmetry of time-integrated semileptonic decay rates:

$$\delta_L \equiv \frac{\Gamma(K_L \to \ell^+\nu_\ell\pi^-) - \Gamma(K_L \to \ell^-\overline{\nu}_\ell\pi^+)}{\Gamma(K_L \to \ell^+\nu_\ell\pi^-) + \Gamma(K_L \to \ell^-\overline{\nu}_\ell\pi^+)}. \tag{13.54}$$

CP violation has been observed as an appearance of K_L decays to two-pion final states [27],

$$|\eta_{00}| = (2.220 \pm 0.011) \times 10^{-3}, \tag{13.55a}$$

$$|\eta_{+-}| = (2.232 \pm 0.011) \times 10^{-3}, \tag{13.55b}$$

$$|\eta_{00}/\eta_{+-}| = 0.9950 \pm 0.0007, \tag{13.55c}$$

where the phase ϕ_{ij} of the amplitude ratio η_{ij} has been determined both assuming *CPT* invariance:

$$\phi_{00} = (43.52 \pm 0.05)^\circ, \qquad \phi_{+-} = (43.51 \pm 0.05)^\circ, \tag{13.56}$$

and without assuming *CPT* invariance:

$$\phi_{00} = (43.7 \pm 0.6)^\circ, \qquad \phi_{+-} = (43.4 \pm 0.5)^\circ. \tag{13.57}$$

CP violation has also been observed in semileptonic K_L decays [27]

$$\delta_L = (3.32 \pm 0.06) \times 10^{-3}, \tag{13.58}$$

where δ_L is a weighted average of muon and electron measurements, as well as in K_L decays to $\pi^+\pi^-\gamma$ and $\pi^+\pi^-e^+e^-$ [27]. *CP* violation in $K \to 3\pi$ decays has not yet been observed [27, 40].

Historically, *CP* violation in neutral K decays has been described in terms of the complex parameters ϵ and ϵ'. The observables η_{00}, η_{+-}, and δ_L are related to these parameters, and to those of Section 13.1, by

$$\eta_{00} = \frac{1-\lambda_{\pi^0\pi^0}}{1+\lambda_{\pi^0\pi^0}} = \epsilon - 2\epsilon', \tag{13.59a}$$

$$\eta_{+-} = \frac{1-\lambda_{\pi^+\pi^-}}{1+\lambda_{\pi^+\pi^-}} = \epsilon + \epsilon', \tag{13.59b}$$

$$\delta_L = \frac{1-|q/p|^2}{1+|q/p|^2} = \frac{2\mathcal{R}e(\epsilon)}{1+|\epsilon|^2}, \tag{13.59c}$$

where, in the last line, we have assumed that $\left|A_{\ell^+\nu_\ell\pi^-}\right| = \left|\overline{A}_{\ell^-\overline{\nu}_\ell\pi^+}\right|$ and $\left|A_{\ell^-\overline{\nu}_\ell\pi^+}\right| = \left|\overline{A}_{\ell^+\nu_\ell\pi^-}\right| = 0$. (The convention-dependent parameter $\tilde{\epsilon} \equiv (1-q/p)/(1+q/p)$, sometimes used in the literature, is, in general, different from ϵ but yields a similar expression, $\delta_L = 2\mathcal{R}e(\tilde{\epsilon})/(1+|\tilde{\epsilon}|^2)$.) A fit to the $K \to \pi\pi$ data yields [27]

$$|\epsilon| = (2.228 \pm 0.011) \times 10^{-3}, \tag{13.60a}$$

$$\mathcal{R}e(\epsilon'/\epsilon) = (1.66 \pm 0.23) \times 10^{-3}. \tag{13.60b}$$

In discussing two-pion final states, it is useful to express the amplitudes $A_{\pi^0\pi^0}$ and $A_{\pi^+\pi^-}$ in terms of their isospin components via

$$A_{\pi^0\pi^0} = \sqrt{\frac{1}{3}}\,|A_0|\,e^{i(\delta_0+\phi_0)} - \sqrt{\frac{2}{3}}\,|A_2|\,e^{i(\delta_2+\phi_2)}, \tag{13.61a}$$

$$A_{\pi^+\pi^-} = \sqrt{\frac{2}{3}}\,|A_0|\,e^{i(\delta_0+\phi_0)} + \sqrt{\frac{1}{3}}\,|A_2|\,e^{i(\delta_2+\phi_2)}, \tag{13.61b}$$

where we parameterize the amplitude $A_I(\overline{A}_I)$ for $K^0(\overline{K}^0)$ decay into two pions with total isospin $I = 0$ or 2 as

$$A_I \equiv \langle (\pi\pi)_I\,|\mathcal{H}|\,K^0\rangle = |A_I|\,e^{i(\delta_I+\phi_I)}, \tag{13.62a}$$

$$\overline{A}_I \equiv \langle (\pi\pi)_I\,|\mathcal{H}|\,\overline{K}^0\rangle = |A_I|\,e^{i(\delta_I-\phi_I)}. \tag{13.62b}$$

The smallness of $|\eta_{00}|$ and $|\eta_{+-}|$ allows us to approximate

$$\epsilon \simeq \frac{1}{2}(1-\lambda_{(\pi\pi)_{I=0}}), \qquad \epsilon' \simeq \frac{1}{6}\left(\lambda_{\pi^0\pi^0} - \lambda_{\pi^+\pi^-}\right). \tag{13.63}$$

The parameter ϵ represents indirect *CP* violation, while ϵ' parameterizes direct *CP* violation: $\mathcal{R}e(\epsilon')$ measures *CP* violation in decay (type I), $\mathcal{R}e(\epsilon)$ measures *CP* violation in mixing (type II), and $\mathcal{I}m(\epsilon)$ and $\mathcal{I}m(\epsilon')$ measure the interference between decays with and without mixing (type III).

The following expressions for ϵ and ϵ' are useful for theoretical evaluations:

$$\epsilon \simeq \frac{e^{i\pi/4}}{\sqrt{2}}\frac{\mathcal{I}m(\mathbf{M}_{12})}{\Delta m}, \qquad \epsilon' = \frac{i}{\sqrt{2}}\left|\frac{A_2}{A_0}\right| e^{i(\delta_2-\delta_0)}\sin(\phi_2-\phi_0). \tag{13.64}$$

The expression for ϵ is only valid in a phase convention where $\phi_2 = 0$, corresponding to a real $V_{ud}V_{us}^*$, and in the approximation that also $\phi_0 = 0$. The phase of ϵ, $\arg(\epsilon) \approx \arctan(-2\Delta m/\Delta\Gamma)$, is determined by non-perturbative QCD dynamics and is experimentally determined to be about $\pi/4$. The calculation of ϵ benefits from the fact that $\mathcal{I}m(\mathbf{M}_{12})$ is dominated by short distance physics. Consequently, the main sources of uncertainty in theoretical interpretations of ϵ are the values of matrix elements, such as $\langle K^0\,|(\overline{s}d)_{V-A}(\overline{s}d)_{V-A}|\,\overline{K}^0\rangle$. The expression for ϵ' is valid to first order in $|A_2/A_0| \sim 1/20$. The phase of ϵ' is experimentally determined, $\pi/2 + \delta_2 - \delta_0 \approx \pi/4$, and is independent of the electroweak model. Note that, accidentally, ϵ'/ϵ is real to a good approximation. Determination of weak phase information from the measurement of $\mathcal{R}e(\epsilon'/\epsilon)$ given in Eq. (13.60) has until now been precluded by uncertainties in the hadronic parameters, but recent advances in lattice QCD calculations [41, 42] suggest that it may become possible [43].

A future measurement of much interest is that of *CP* violation in the rare $K \to \pi\nu\overline{\nu}$ decays. The signal for *CP* violation is simply observing the $K_L \to \pi^0\nu\overline{\nu}$ decay. The effect here is that of interference between decays with and without mixing (type III) [44]:

$$\frac{\Gamma(K_L \to \pi^0\nu\overline{\nu})}{\Gamma(K^+ \to \pi^+\nu\overline{\nu})} = \frac{1}{2}\left[1 + |\lambda_{\pi\nu\overline{\nu}}|^2 - 2\,\mathcal{R}e(\lambda_{\pi\nu\overline{\nu}})\right] \simeq 1 - \mathcal{R}e(\lambda_{\pi\nu\overline{\nu}})\,, \tag{13.65}$$

where in the last equation we neglect CP violation in decay and in mixing (expected, model-independently, to be of order 10^{-5} and 10^{-3}, respectively). Such a measurement is experimentally very challenging but would be theoretically very rewarding [45]. Similar to the CP asymmetry in $B^0 \to J/\psi K_S$, the CP violation in $K \to \pi\nu\overline{\nu}$ decay is predicted to be large (that is, the ratio in Eq. (13.65) is neither CKM- nor loop-suppressed) and can be very cleanly interpreted.

Within the Standard Model, the $K_L \to \pi^0\nu\overline{\nu}$ decay is dominated by an intermediate top quark contribution and, consequently, can be interpreted in terms of CKM parameters [46]. (For the charged mode, $K^+ \to \pi^+\nu\overline{\nu}$, the contribution from an intermediate charm quark is not negligible, and constitutes a source of hadronic uncertainty.) In particular, $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu})$ provides a theoretically clean way to determine the Wolfenstein parameter η [47]:

$$\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) = \kappa_L[X(m_t^2/m_W^2)]^2 A^4\eta^2\,, \tag{13.66}$$

where the hadronic parameter $\kappa_L \sim 2\times 10^{-10}$ incorporates the value of the four-fermion matrix element which is deduced, using isospin relations, from $\mathcal{B}(K^+ \to \pi^0 e^+\nu_e)$, and $X(m_t^2/m_W^2)$ is a known function of the top mass. An explicit calculation gives $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) = (3.00 \pm 0.30)\times 10^{-11}$ [48].

The currently tightest experimental limit is $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) < 3.0\times 10^{-9}$ [49], which does not yet reach the bound that can be derived from Eq. (13.65), $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) < 4.4 \times \mathcal{B}(K^+ \to \pi^+\nu\overline{\nu})$ [44]. Significant further progress is anticipated from experiments searching for $K \to \pi\nu\overline{\nu}$ decays in the next few years [50,51].

13.5 Charm

The existence of D^0–$\overline{D}^0$ mixing is well established [52–55], with the latest experimental constraints giving [29, 56] $x \equiv \Delta m/\Gamma = (0.39\,^{+0.11}_{-0.12})\times 10^{-2}$ and $y \equiv \Delta\Gamma/(2\Gamma) = (0.65\,^{+0.06}_{-0.07})\times 10^{-2}$. Thus, the data clearly show that $y \neq 0$, but improved measurements are needed to be sure of the size of x. Long-distance contributions make it difficult to calculate Standard Model predictions for the D^0–$\overline{D}^0$ mixing parameters. Therefore, the goal of the search for D^0–$\overline{D}^0$ mixing is not to constrain the CKM parameters, but rather to probe new physics. Here CP violation plays an important role. Within the Standard Model, the CP-violating effects are predicted to be small, since the mixing and the relevant decays are described, to an excellent approximation, by the physics of the first two generations only. The expectation is that the Standard Model size of CP violation in D decays is $\mathcal{O}(10^{-3})$ or less. At present, the most sensitive searches involve the $D^0 \to K^+K^-$, $D^0 \to \pi^+\pi^-$ and $D^0 \to K^\pm\pi^\mp$ modes.

The neutral D mesons decay via a singly-Cabibbo-suppressed transition to the CP eigenstates K^+K^- and $\pi^+\pi^-$. These decays are dominated by Standard-Model tree diagrams. Thus, we can write, for $f = K^+K^-$ or $\pi^+\pi^-$,

$$A_f = A_f^T e^{+i\phi_f^T}\left[1 + r_f e^{i(\delta_f+\phi_f)}\right]\,, \tag{13.67a}$$

$$\bar{A}_f = A_f^T e^{-i\phi_f^T}\left[1 + r_f e^{i(\delta_f-\phi_f)}\right]\,, \tag{13.67b}$$

where $A_f^T e^{\pm i\phi_f^T}$ is the Standard Model tree-level contribution, ϕ_f^T and ϕ_f are weak, CP violating phases, δ_f is a strong phase difference, and r_f is the ratio between a subleading ($r_f \ll 1$) contribution with a weak phase different from ϕ_f^T and the Standard Model tree-level contribution. Neglecting r_f, λ_f is universal, and we can define an observable phase ϕ_D via

$$\lambda_f \equiv -|q/p|e^{i\phi_D}\,. \tag{13.68}$$

(In the limit of CP conservation, choosing $\phi_D = 0$ is equivalent to defining the mass eigenstates by their CP eigenvalue: $|D_\mp\rangle = p|D^0\rangle \pm q|\overline{D}^0\rangle$, with D_- (D_+) being the CP-odd (CP-even) state; that is, the state that does not (does) decay into K^+K^-.)

We define the time integrated CP asymmetry for a final CP eigenstate f as follows:

$$a_f \equiv \frac{\int_0^\infty \Gamma(D^0_{\rm phys}(t)\to f)dt - \int_0^\infty \Gamma(\overline{D}^0_{\rm phys}(t)\to f)dt}{\int_0^\infty \Gamma(D^0_{\rm phys}(t)\to f)dt + \int_0^\infty \Gamma(\overline{D}^0_{\rm phys}(t)\to f)dt}\,. \tag{13.69}$$

(This expression corresponds to the D meson being tagged at production, hence the integration goes from 0 to $+\infty$; measurements are also possible with $\psi(3770) \to D^0\overline{D}^0$, in which case the integration goes from $-\infty$ to $+\infty$ giving slightly different results; see the discussion in Section 13.1.3.) We take $x, y, r_f \ll 1$ and expand to leading order in these parameters. We can then separate the contribution to a_f into three parts [57],

$$a_f = a_f^d + a_f^m + a_f^i\,, \tag{13.70}$$

with the following underlying mechanisms:

1. a_f^d signals CP violation in decay (similar to Eq. (13.35)):
$$a_f^d = 2r_f \sin\phi_f \sin\delta_f\,. \tag{13.71}$$
2. a_f^m signals CP violation in mixing (similar to Eq. (13.44)). With our approximations, it is universal:
$$a^m = -\frac{y}{2}\left(\left|\frac{q}{p}\right| - \left|\frac{p}{q}\right|\right)\cos\phi_D\,. \tag{13.72}$$
3. a_f^i signals CP violation in the interference of mixing and decay (similar to Eq. (13.45)). With our approximations, it is universal:
$$a^i = \frac{x}{2}\left(\left|\frac{q}{p}\right| + \left|\frac{p}{q}\right|\right)\sin\phi_D\,. \tag{13.73}$$

One can isolate the effects of direct CP violation by taking the difference between the CP asymmetries in the K^+K^- and $\pi^+\pi^-$ modes:

$$\Delta a_{CP} \equiv a_{K^+K^-} - a_{\pi^+\pi^-} = a^d_{K^+K^-} - a^d_{\pi^+\pi^-}\,, \tag{13.74}$$

where we neglected a residual, experiment-dependent, contribution from indirect CP violation due to the fact that there may be a decay time-dependent acceptance function that can be different for the K^+K^- and $\pi^+\pi^-$ channels. The current average gives [29]:

$$a^d_{K^+K^-} - a^d_{\pi^+\pi^-} = (-0.164 \pm 0.028)\times 10^{-3}\,, \tag{13.75}$$

demonstrating CP violation in charm decay.

One can also isolate the effects of indirect CP violation in the following way. Consider the time-dependent decay rates in Eq. (13.31a) and Eq. (13.31b). The mixing processes modify the time dependence from a pure exponential. However, given the small values of x and y, the time dependences can be recast, to a good approximation, into purely exponential form, but with modified decay-rate parameters [58,59] (given here for the K^+K^- final state):

$$\Gamma_{D^0\to K^+K^-} = \Gamma \times [1 + |q/p|\,(y\cos\phi_D - x\sin\phi_D)]\,, \tag{13.76a}$$

$$\Gamma_{\overline{D}^0\to K^+K^-} = \Gamma \times [1 + |p/q|\,(y\cos\phi_D + x\sin\phi_D)]\,. \tag{13.76b}$$

One can define CP-conserving and CP-violating combinations of these two observables (normalized to the true width Γ):

$$y_{CP} \equiv \frac{\Gamma_{\overline{D}^0\to K^+K^-} + \Gamma_{D^0\to K^+K^-}}{2\Gamma} - 1 = (y/2)\,(|q/p| + |p/q|)\cos\phi_D - (x/2)\,(|q/p| - |p/q|)\sin\phi_D\,, \tag{13.77a}$$

$$A_\Gamma \equiv \frac{\Gamma_{D^0\to K^+K^-} - \Gamma_{\overline{D}^0\to K^+K^-}}{2\Gamma} = -(a^m + a^i)\,. \tag{13.77b}$$

In the limit of *CP* conservation (and, in particular, within the Standard Model), $y_{CP} = (\Gamma_+ - \Gamma_-)/2\Gamma = y$ (where $\Gamma_+(\Gamma_-)$ is the decay width of the *CP*-even (-odd) mass eigenstate) and $A_\Gamma = 0$. Indeed, present measurements imply that *CP* violation is small [29],

$$y_{CP} = (+0.72 \pm 0.11) \times 10^{-2}\,, \tag{13.78a}$$
$$A_\Gamma = (-0.032 \pm 0.026) \times 10^{-2}\,. \tag{13.78b}$$

The $K^\pm\pi^\mp$ states are not *CP* eigenstates, but they are still common final states for D^0 and $\overline{D}^0$ decays. Since $D^0(\overline{D}^0) \to K^-\pi^+$ is a Cabibbo-favored (doubly-Cabibbo-suppressed) process, these processes are particularly sensitive to x and/or $y = \mathcal{O}(\lambda^2)$. Taking into account that $|\lambda_{K^-\pi^+}|, \left|\lambda^{-1}_{K^+\pi^-}\right| \ll 1$ and $x, y \ll 1$, assuming that there is no direct *CP* violation (these are Standard Model tree-level decays dominated by a single weak phase, and there is no contribution from penguin-like and chromomagnetic operators), and expanding the time-dependent rates for $xt, yt \lesssim \Gamma^{-1}$, one obtains

$$\Gamma[D^0_{\rm phys}(t) \to K^+\pi^-] = e^{-\Gamma t}|\overline{A}_{K^-\pi^+}|^2 \times \left[r_d^2 + r_d\left|\frac{q}{p}\right|(y'\cos\phi_D - x'\sin\phi_D)\Gamma t + \left|\frac{q}{p}\right|^2\frac{y^2+x^2}{4}(\Gamma t)^2\right], \tag{13.79a}$$

$$\Gamma[\overline{D}^0_{\rm phys}(t) \to K^-\pi^+] = e^{-\Gamma t}|\overline{A}_{K^-\pi^+}|^2 \times \left[r_d^2 + r_d\left|\frac{p}{q}\right|(y'\cos\phi_D + x'\sin\phi_D)\Gamma t + \left|\frac{p}{q}\right|^2\frac{y^2+x^2}{4}(\Gamma t)^2\right], \tag{13.79b}$$

where

$$y' \equiv y\cos\delta - x\sin\delta \quad \text{and} \quad x' \equiv x\cos\delta + y\sin\delta\,. \tag{13.80}$$

The weak phase ϕ_D is the same as that of Eq. (13.68) (a consequence of neglecting direct *CP* violation) and $r_d = \mathcal{O}(\tan^2\theta_c)$ is the amplitude ratio, $r_d = \left|\overline{A}_{K^-\pi^+}/A_{K^-\pi^+}\right| = \left|A_{K^+\pi^-}/\overline{A}_{K^+\pi^-}\right|$, that is, $\lambda_{K^-\pi^+} = r_d|q/p|e^{-i(\delta-\phi_D)}$ and $\lambda^{-1}_{K^+\pi^-} = r_d|p/q|e^{-i(\delta+\phi_D)}$. The parameter δ is a strong-phase difference for these processes, that can be obtained from measurements of quantum correlated $\psi(3770) \to D^0\overline{D}^0$ decays [60,61]. By fitting to the six coefficients of the various time-dependences, one can determine r_d, $|q/p|$, (x^2+y^2), $y'\cos\phi_D$, and $x'\sin\phi_D$. In particular, finding *CP* violation ($|q/p| \neq 1$ and/or $\sin\phi_D \neq 0$) at a level much higher than 10^{-3} would constitute evidence for new physics. The most stringent constraints to date on *CP* violation in charm mixing have been obtained with this method [62] and from the A_Γ measurement [63].

A fit to all data [29], including also results from time-dependent analyses of $D^0 \to K_S\pi^+\pi^-$ decays, from which x, y, $|q/p|$ and ϕ_D can be determined directly, yields no evidence for indirect *CP* violation:

$$1 - |q/p| = +0.031\,^{+0.045}_{-0.050}\,, \tag{13.81a}$$
$$\phi_D = \left(-3.9\,^{+4.5}_{-4.6}\right)^\circ\,. \tag{13.81b}$$

With the additional assumption of no direct *CP* violation in doubly-Cabibbo-suppressed D decays [64–66], tighter constraints are obtained:

$$1 - |q/p| = +0.002 \pm 0.008\,, \tag{13.82a}$$
$$\phi_D = (+0.08 \pm 0.31)^\circ\,. \tag{13.82b}$$

More details on various theoretical and experimental aspects of D^0–$\overline{D}^0$ mixing can be found in Ref. [31].

Searches for *CP* violation in charged $D_{(s)}$ decays have been performed in many modes. Searches in decays mediated by Cabibbo-suppressed amplitudes are particularly interesting, since in other channels effects are likely to be too small to be observable in current experiments. Examples of relevant two-body modes are $D^+ \to \pi^+\pi^0$, K_SK^+, $\phi\pi^+$ and $D_s^+ \to K^+\pi^0$, $K_S\pi^+$, ϕK^+. The most precise results are $\mathcal{A}_{D^+\to K_SK^+} = +0.0011 \pm 0.0017$ and $\mathcal{A}_{D_s^+\to K_S\pi^+} = +0.0038 \pm 0.0048$ [29]. The precision of experiments is now sufficient that the effect from *CP* violation in the neutral kaon system can be seen in $D^+ \to K_S\pi^+$ decays [67,68].

Three- and four-body final states provide additional possibilities to search for *CP* violation, since effects may vary over the phase-space [69]. A number of methods have been proposed to exploit this feature and search for *CP* violation in ways that do not require modelling of the decay distribution [70–73]. Such methods are useful for analysis of charm decays since they are less sensitive to biases from production asymmetries, and are well suited to address the issue of whether or not *CP* violation effects are present. They can also be applied to tagged neutral D meson as well as to charged $D_{(s)}$ decays (flavor tagging is typically achieved from the charge of the pion producted in $D^{*+} \to D^0\pi^+$ decays). The results of all searches to date are consistent with the absence of *CP* violation, with the most significant hint at the level of 2.7σ [74].

13.6 Beauty

13.6.1 *CP violation in mixing of* B^0 *and* B_s^0 *mesons*

The upper bound on the *CP* asymmetry in semileptonic B decays [28] implies that *CP* violation in B^0–$\overline{B}^0$ mixing is a small effect (we use $\mathcal{A}_{\rm SL}/2 \approx 1 - |q/p|$, see Eq. (13.37)):

$$\mathcal{A}^d_{\rm SL} = (-2.1 \pm 1.7) \times 10^{-3} \implies |q/p| = 1.0010 \pm 0.0008\,. \tag{13.83}$$

The Standard Model prediction is

$$\mathcal{A}^d_{\rm SL} = \mathcal{O}\left[(m_c^2/m_t^2)\sin\beta\right] \lesssim 0.001\,. \tag{13.84}$$

An explicit calculation gives $(-4.7 \pm 0.6) \times 10^{-4}$ [34].

The experimental constraint on *CP* violation in B_s^0–$\overline{B}_s^0$ mixing is somewhat weaker than that in the B^0–$\overline{B}^0$ system [28]

$$\mathcal{A}^s_{\rm SL} = (-0.6 \pm 2.8) \times 10^{-3} \implies |q/p| = 1.0003 \pm 0.0014\,. \tag{13.85}$$

The Standard Model prediction is $\mathcal{A}^s_{\rm SL} = \mathcal{O}\left[(m_c^2/m_t^2)\sin\beta_s\right] \lesssim 10^{-4}$, with an explicit calculation giving $(2.22 \pm 0.27) \times 10^{-5}$ [34].

The fit to experimental data that results in the averages quoted above has a χ^2 probability of 4.5% indicating some tension between the different measurements [29]. This originates in part from a result from the D0 collaboration for the inclusive same-sign dimuon asymmetry that deviates from the Standard Model prediction by 3.6σ [75]. As yet, this has not been confirmed by independent studies.

In models where $\mathbf{\Gamma}_{12}/\mathbf{M}_{12}$ is approximately real, such as the Standard Model, an upper bound on $\Delta\Gamma/\Delta m \approx \mathcal{R}e(\mathbf{\Gamma}_{12}/\mathbf{M}_{12})$ provides yet another upper bound on the deviation of $|q/p|$ from one. This constraint does not hold if $\mathbf{\Gamma}_{12}/\mathbf{M}_{12}$ is approximately imaginary. (An alternative parameterization uses $q/p = (1 - \tilde{\epsilon}_B)/(1 + \tilde{\epsilon}_B)$, leading to $\mathcal{A}_{\rm SL} \simeq 4\mathcal{R}e(\tilde{\epsilon}_B)$.)

13.6.2 *CP violation in interference of* B^0 *decays with and without mixing*

The small deviation (less than one percent) of $|q/p|$ from 1 implies that, at the present level of experimental precision, *CP* violation in B^0 mixing is a negligible effect. Thus, for the purpose of analyzing *CP* asymmetries in hadronic B^0 decays, we can use

$$\lambda_f = e^{-i\phi_{M(B^0)}}(\overline{A}_f/A_f)\,, \tag{13.86}$$

where $\phi_{M(B^0)}$ refers to the phase of $\mathbf{M}_{12}$ appearing in Eq. (13.42) that is appropriate for B^0–$\overline{B}^0$ oscillations. Within the Standard Model, the corresponding phase factor is given by

$$e^{-i\phi_{M(B^0)}} = (V^*_{tb}V_{td})/(V_{tb}V^*_{td})\,. \tag{13.87}$$

The class of *CP* violation effects in interference between mixing and decay is studied with final states that are common to B^0 and $\overline{B}^0$ decays [76–78]. It is convenient to rewrite Eq. (13.40) for B^0 decays as [79–81]

$$\mathcal{A}_f(t) = S_f\sin(\Delta m t) - C_f\cos(\Delta m t)\,, \tag{13.88}$$

$$S_f \equiv \frac{2\mathcal{I}m(\lambda_f)}{1+\left|\lambda_f\right|^2}\,, \quad C_f \equiv \frac{1-\left|\lambda_f\right|^2}{1+\left|\lambda_f\right|^2}\,, \tag{13.89}$$

where we assume that $\Delta\Gamma = 0$ and $|q/p| = 1$. An alternative notation in use is $A_f \equiv -C_f$ – this A_f should not be confused with the A_f of Eq. (13.15), but in the limit that $|q/p| = 1$ is equivalent with the $\mathcal{A}_f$ of Eq. (13.35).

A large class of interesting processes proceed via quark transitions of the form $\overline{b} \to \overline{q}q\overline{q}'$ with $q' = s$ or d. For $q = c$ or u, there are contributions from both tree (t) and penguin (p^{q_u}, where $q_u = u, c, t$ is the quark in the loop) diagrams (see Fig. 13.2) which carry different weak phases:

$$A_f = \left(V_{qb}^* V_{qq'}\right) t_f + \sum_{q_u=u,c,t} \left(V_{q_u b}^* V_{q_u q'}\right) p_f^{q_u}\,. \tag{13.90}$$

(The distinction between tree and penguin contributions is a heuristic one; the separation by the operator that enters is more precise. A more detailed discussion of the operator product expansion approach, which also includes higher order QCD corrections, can be found in Ref. [82] for example.) Using CKM unitarity, these decay amplitudes can always be written in terms of just two CKM combinations. For example, for $f = \pi\pi$, which proceeds via a $\overline{b} \to \overline{u}u\overline{d}$ transition, we can write

$$A_{\pi\pi} = \left(V_{ub}^* V_{ud}\right) T_{\pi\pi} + \left(V_{tb}^* V_{td}\right) P_{\pi\pi}^t\,, \tag{13.91}$$

where $T_{\pi\pi} = t_{\pi\pi} + p_{\pi\pi}^u - p_{\pi\pi}^c$ and $P_{\pi\pi}^t = p_{\pi\pi}^t - p_{\pi\pi}^c$. *CP*-violating phases in Eq. (13.91) appear only in the CKM elements, so that

$$\frac{\overline{A}_{\pi\pi}}{A_{\pi\pi}} = \frac{\left(V_{ub} V_{ud}^*\right) T_{\pi\pi} + \left(V_{tb} V_{td}^*\right) P_{\pi\pi}^t}{\left(V_{ub}^* V_{ud}\right) T_{\pi\pi} + \left(V_{tb}^* V_{td}\right) P_{\pi\pi}^t}\,. \tag{13.92}$$

For $f = J/\psi K$, which proceeds via a $\overline{b} \to \overline{c}c\overline{s}$ transition, we can write

$$A_{\psi K} = \left(V_{cb}^* V_{cs}\right) T_{\psi K} + \left(V_{ub}^* V_{us}\right) P_{\psi K}^u\,, \tag{13.93}$$

where $T_{\psi K} = t_{\psi K} + p_{\psi K}^c - p_{\psi K}^t$ and $P_{\psi K}^u = p_{\psi K}^u - p_{\psi K}^t$. A subtlety arises in this decay that is related to the fact that B^0 decays into a final $J/\psi K^0$ state while $\overline{B}^0$ decays into a final $J/\psi \overline{K}^0$ state. A common final state, *e.g.*, $J/\psi K_S$, is reached only via K^0–$\overline{K}^0$ mixing. Consequently, the phase factor (defined in Eq. (13.42)) corresponding to neutral K mixing, $e^{-i\phi_{M(K)}} = (V_{cd}^* V_{cs})/(V_{cd} V_{cs}^*)$, plays a role:

$$\frac{\overline{A}_{\psi K_S}}{A_{\psi K_S}} = -\frac{\left(V_{cb} V_{cs}^*\right) T_{\psi K} + \left(V_{ub} V_{us}^*\right) P_{\psi K}^u}{\left(V_{cb}^* V_{cs}\right) T_{\psi K} + \left(V_{ub}^* V_{us}\right) P_{\psi K}^u} \times \frac{V_{cd}^* V_{cs}}{V_{cd} V_{cs}^*}\,. \tag{13.94}$$

For $q = s$ or d, there are only penguin contributions to A_f, that is, $t_f = 0$ in Eq. (13.90). (The tree $\overline{b} \to \overline{u}u\overline{q}'$ transition followed by $\overline{u}u \to \overline{q}q$ rescattering is included below in the P^u terms.) Again, CKM unitarity allows us to write A_f in terms of two CKM combinations. For example, for $f = \phi K_S$, which proceeds via a $\overline{b} \to \overline{s}s\overline{s}$ transition, we can write

$$\frac{\overline{A}_{\phi K_S}}{A_{\phi K_S}} = -\frac{\left(V_{cb} V_{cs}^*\right) P_{\phi K}^c + \left(V_{ub} V_{us}^*\right) P_{\phi K}^u}{\left(V_{cb}^* V_{cs}\right) P_{\phi K}^c + \left(V_{ub}^* V_{us}\right) P_{\phi K}^u} \times \frac{V_{cd}^* V_{cs}}{V_{cd} V_{cs}^*}\,, \tag{13.95}$$

where $P_{\phi K}^c = p_{\phi K}^c - p_{\phi K}^t$ and $P_{\phi K}^u = p_{\phi K}^u - p_{\phi K}^t$.

Since in general the amplitude A_f involves two different weak phases, the corresponding decays can exhibit both *CP* violation in the interference of decays with and without mixing, $S_f \neq 0$, and *CP* violation in decay, $C_f \neq 0$. (At the present level of experimental precision, the contribution to C_f from *CP* violation in mixing is negligible, see Eq. (13.83).) If the contribution from a second weak phase is suppressed, then the interpretation of S_f in terms of Lagrangian *CP*-violating parameters is clean, while C_f is small. If such a second contribution is not suppressed, S_f depends on hadronic parameters and, if the relevant strong phase difference is large, C_f is large.

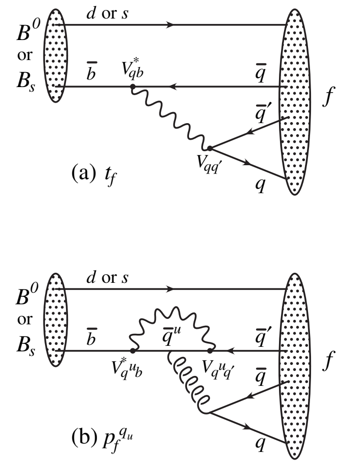

Figure 13.2: Feynman diagrams for (a) tree and (b) penguin amplitudes contributing to $B^0 \to f$ or $B_s^0 \to f$ via a $\overline{b} \to \overline{q}q\overline{q}'$ quark-level process.

A summary of $\overline{b} \to \overline{q}q\overline{q}'$ modes with $q' = s$ or d is given in Table 13.1. The $\overline{b} \to \overline{d}d\overline{q}$ transitions lead to final states that are similar to those from $\overline{b} \to \overline{u}u\overline{q}$ transitions and have similar phase dependence. Final states that consist of two vector mesons ($\psi\phi$ and $\phi\phi$) are not *CP* eigenstates, and angular analysis is needed to separate the *CP*-even from the *CP*-odd contributions.

The cleanliness of the theoretical interpretation of S_f can be assessed from the information in the last column of Table 13.1. In case of small uncertainties, the expression for S_f in terms of CKM phases can be deduced from the fourth column of Table 13.1 in combination with Eq. (13.87) (and, for $b \to q\overline{q}s$ decays, the example in Eq. (13.94)). Here we consider several interesting examples.

For $B^0 \to J/\psi K_S$ and other $\overline{b} \to \overline{c}c\overline{s}$ processes, we can neglect the P^u contribution to A_f, in the Standard Model, to an approximation that is better than one percent, giving:

$$\lambda_{\psi K_S} = -e^{-2i\beta} \;\Rightarrow\; S_{\psi K_S} = \sin 2\beta\,, \quad C_{\psi K_S} = 0\,. \tag{13.96}$$

It is important to verify experimentally the level of suppression of the penguin contribution. Methods based on flavor symmetries [83–86] allow limits to be obtained. All are currently consistent with the P^u term being negligible. Explicit calculations [86–89] also support this conclusion.

In the presence of new physics, A_f is still likely to be dominated by the T term, but the mixing amplitude might be modified. We learn that, model-independently, $C_f \approx 0$ while S_f cleanly determines the mixing phase ($\phi_M - 2\arg(V_{cb}V_{cd}^*)$). The experimental measurement [29], $S_{\psi K} = +0.699 \pm 0.017$, gave the first precision test of the Kobayashi-Maskawa mechanism, and its consistency with the predictions for $\sin 2\beta$ makes it very likely that this mechanism is indeed the dominant source of *CP* violation in the quark sector.

For $B^0 \to \phi K_S$ and other $\overline{b} \to \overline{s}s\overline{s}$ processes (as well as some $\overline{b} \to \overline{u}u\overline{s}$ processes), we can neglect the subdominant contributions, in the Standard Model, to an approximation that is good to the order of a few percent:

$$\lambda_{\phi K_S} = -e^{-2i\beta} \;\Rightarrow\; S_{\phi K_S} = \sin 2\beta\,, \quad C_{\phi K_S} = 0\,. \tag{13.97}$$

A review of explicit calculations of the effects of subleading amplitudes can be found in Ref. [90]. In the presence of new physics, both A_f and $\mathbf{M}_{12}$ can have contributions that are comparable in size to those of the Standard Model and carry new weak phases. Such a situation gives several interesting consequences for penguin-dominated $\overline{b} \to \bar{q}q\overline{s}$ decays ($q = u, d, s$) to a final state f:

1. The value of $-\eta_f S_f$ may be different from $S_{\psi K_S}$ by more than a few percent, where η_f is the *CP* eigenvalue of the final state.

Table 13.1: Summary of $\bar{b} \to \bar{q}q\bar{q}'$ modes with $q' = s$ or d. The second and third columns give examples of hadronic final states (usually those which are experimentally most convenient to study). The fourth column gives the CKM dependence of the amplitude A_f, using the notation of Eqs. ((13.91), (13.93), (13.95)), with the dominant term first and the subdominant second. The suppression factor of the second term compared to the first is given in the last column. "Loop" refers to a penguin versus tree-suppression factor (it is mode-dependent and roughly $\mathcal{O}(0.2-0.3)$) and $\lambda \simeq 0.23$ is the expansion parameter of Eq. (13.48).

$\bar{b} \to \bar{q}q\bar{q}'$	$B^0 \to f$	$B_s^0 \to f$	CKM dependence of A_f	Suppression
$\bar{b} \to \bar{c}c\bar{s}$	ψK_S	$\psi\phi$	$(V_{cb}^* V_{cs})T + (V_{ub}^* V_{us})P^u$	loop $\times \lambda^2$
$\bar{b} \to \bar{s}s\bar{s}$	ϕK_S	$\phi\phi$	$(V_{cb}^* V_{cs})P^c + (V_{ub}^* V_{us})P^u$	λ^2
$\bar{b} \to \bar{u}u\bar{s}$	$\pi^0 K_S$	K^+K^-	$(V_{cb}^* V_{cs})P^c + (V_{ub}^* V_{us})T$	λ^2/loop
$\bar{b} \to \bar{c}c\bar{d}$	D^+D^-	ψK_S	$(V_{cb}^* V_{cd})T + (V_{tb}^* V_{td})P^t$	loop
$\bar{b} \to \bar{s}s\bar{d}$	$K_S K_S$	ϕK_S	$(V_{tb}^* V_{td})P^t + (V_{cb}^* V_{cd})P^c$	$\lesssim 1$
$\bar{b} \to \bar{u}u\bar{d}$	$\pi^+\pi^-$	$\rho^0 K_S$	$(V_{ub}^* V_{ud})T + (V_{tb}^* V_{td})P^t$	loop
$\bar{b} \to \bar{c}u\bar{d}$	$D_{CP}\pi^0$	$D_{CP}K_S$	$(V_{cb}^* V_{ud})T + (V_{ub}^* V_{cd})T'$	λ^2
$\bar{b} \to \bar{c}u\bar{s}$	$D_{CP}K_S$	$D_{CP}\phi$	$(V_{cb}^* V_{us})T + (V_{ub}^* V_{cs})T'$	$\lesssim 1$

2. The values of $\eta_f S_f$ for different final states f may be different from each other by more than a few percent (for example, $S_{\phi K_S} \neq S_{\eta' K_S}$).
3. The value of C_f may be different from zero by more than a few percent.

While a clear interpretation of such signals in terms of Lagrangian parameters will be difficult because, under these circumstances, hadronic parameters play a role, any of the above three options will clearly signal new physics. In addition flavor symmetry relations, such as those which relate observables in $B \to K\pi$ decays [91, 92] can be used to provide further tests of the Standard Model. Fig. 13.3 summarizes the present experimental results: none of the possible signatures listed above is unambiguously established, but there is definitely still room for new physics.

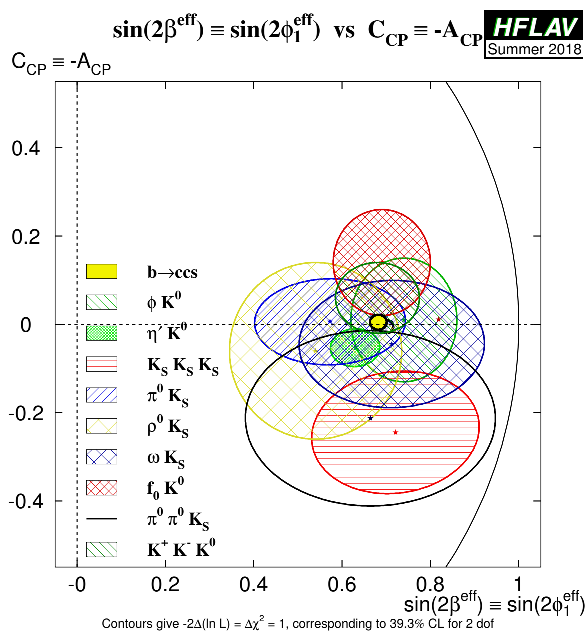

Figure 13.3: Summary of the results [29] of time-dependent analyses of $b \to q\bar{q}s$ decays, which are potentially sensitive to new physics.

For the $\bar{b} \to \bar{u}u\bar{d}$ process $B \to \pi\pi$ and other related channels, the penguin-to-tree ratio can be estimated using SU(3) relations and experimental data on related $B \to K\pi$ decays. The result (for $\pi\pi$) is that the suppression is at the level of $0.2-0.3$ and so cannot be neglected. The expressions for $S_{\pi\pi}$ and $C_{\pi\pi}$ to leading order in $R_{PT} \equiv (|V_{tb}V_{td}|\, P^t_{\pi\pi})/(|V_{ub}V_{ud}|\, T_{\pi\pi})$ are:

$$\lambda_{\pi\pi} = e^{2i\alpha}\left[(1-R_{PT}e^{-i\alpha})/(1-R_{PT}e^{+i\alpha})\right] \;\Rightarrow \tag{13.98}$$

$$S_{\pi\pi} \approx \sin 2\alpha + 2\,\mathcal{R}e(R_{PT})\cos 2\alpha \sin\alpha\,, \quad C_{\pi\pi} \approx 2\,\mathcal{I}m(R_{PT})\sin\alpha\,. \tag{13.99}$$

Note that R_{PT} is mode-dependent and, in particular, could be different for $\pi^+\pi^-$ and $\pi^0\pi^0$. If strong phases can be neglected, then R_{PT} is real, resulting in $C_{\pi\pi} = 0$. The size of $C_{\pi\pi}$ is an indicator of how large the strong phase is. The present experimental average is $C_{\pi^+\pi^-} = -0.32 \pm 0.04$ [29]. As concerns $S_{\pi\pi}$, it is clear from Eq. (13.99) that the relative size or strong phase of the penguin contribution must be known to extract α. This is the problem of penguin pollution.

The cleanest solution involves isospin relations among the $B \to \pi\pi$ amplitudes [93]:

$$\frac{1}{\sqrt{2}}A_{\pi^+\pi^-} + A_{\pi^0\pi^0} = A_{\pi^+\pi^0}\,. \tag{13.100}$$

The method exploits the fact that the penguin contribution to $P^t_{\pi\pi}$ is pure $\Delta I = 1/2$ (this is not true for the electroweak penguins which, however, are expected to be small), while the tree contribution to $T_{\pi\pi}$ contains pieces that are both $\Delta I = 1/2$ and $\Delta I = 3/2$. A simple geometric construction then allows one to find R_{PT} and extract α cleanly from $S_{\pi^+\pi^-}$. The key experimental difficulty is that one must measure accurately the separate rates for B^0 and $\overline{B}^0 \to \pi^0\pi^0$.

CP asymmetries in $B \to \rho\pi$ and $B \to \rho\rho$ can also be used to determine α. In particular, the $B \to \rho\rho$ measurements are presently very significant in constraining α. The extraction proceeds via isospin analysis similar to that of $B \to \pi\pi$. There are, however, several important differences. First, due to the finite width of the ρ mesons, a final $(\rho\rho)_{I=1}$ state is possible [94]. The effect is, however, of the order of $(\Gamma_\rho/m_\rho)^2 \sim 0.04$. Second, due to the presence of three helicity states for the two vector mesons, angular analysis is needed to separate the *CP*-even and *CP*-odd components. The theoretical expectation is that the *CP*-odd component is small, which is supported by experiments which find that the $\rho^+\rho^-$ and $\rho^\pm\rho^0$ modes are dominantly longitudinally polarized. Third, an important advantage of the $\rho\rho$ modes is that the penguin contribution is expected to be small due to different hadronic dynamics. This expectation is confirmed by the smallness of $\mathcal{B}(B^0 \to \rho^0\rho^0) = (0.95 \pm 0.16) \times 10^{-6}$ [29, 95] compared to $\mathcal{B}(B^0 \to \rho^+\rho^-) = (24.2 \pm 3.1) \times 10^{-6}$ [29]. Thus, $S_{\rho^+\rho^-}$ is not far from $\sin 2\alpha$. Finally, both $S_{\rho^0\rho^0}$ and $C_{\rho^0\rho^0}$ are experimentally accessible, which may allow a precision determination of α. However, a full isospin analysis should allow that the fractions of longitudinal polarisation in B and $\overline{B}$ decays may differ, which has not yet been done by the experiments.

Detailed discussion of the determination of α with these methods, and the latest world average, can be found in Refs. [36, 96]. The consistency between the range of α determined by the $B \to \pi\pi$, $\rho\pi$ and $\rho\rho$ measurements and the range allowed by CKM fits (excluding these direct determinations) provides further support to the Kobayashi-Maskawa mechanism.

All modes discussed in this Section so far have possible contributions from penguin amplitudes. As shown in Table 13.1, *CP* violation can also be studied with final states, typically containing charmed mesons, where no such contribution is possible. The neutral charmed meson must be reconstructed in a final state, such as a *CP* eigenstate, common to D^0 and $\overline{D}^0$ so that the amplitudes for the B and $\overline{B}$ meson decays interfere. Although there is a second tree amplitude with a different weak phase, the contributions of the different diagrams can in many cases be separated experimentally (for example by exploiting different decays of the neutral D mesons) making these channels very clean theoretically. The first determination of $\sin(2\beta)$, with significance of *CP* violation over 5σ, with this method has recently been reported [97]. Moreover, the interference between the two tree diagrams gives sensitivity to γ, as will be discussed in Section 13.6.4.

13.6.3 *CP violation in interference of B_s^0 decays with and without mixing*

As discussed in Section 13.6.1, the world average for $|q/p|$ in the B_s^0 system currently deviates from the Standard Model expectation due to an anomalous value of the dimuon asymmetry. Attributing the dimuon asymmetry result to a fluctuation, we again neglect the deviation of $|q/p|$ from 1, and use

$$\lambda_f = e^{-i\phi_M(B_s^0)}(\overline{A}_f/A_f) \, . \tag{13.101}$$

Within the Standard Model,

$$e^{-i\phi_M(B_s^0)} = (V_{tb}^* V_{ts})/(V_{tb} V_{ts}^*) \, . \tag{13.102}$$

Note that $\Delta\Gamma/\Gamma = 0.132 \pm 0.008$ [29] and therefore y should not be put to zero in Eqs. (13.31a) and (13.31b). However, $|q/p| = 1$ is expected to hold to an even better approximation than for B^0 mesons. One therefore obtains

$$\mathcal{A}_f(t) = \frac{S_f \sin(\Delta m t) - C_f \cos(\Delta m t)}{\cosh(\Delta\Gamma t/2) - A_f^{\Delta\Gamma} \sinh(\Delta\Gamma t/2)} \, , \tag{13.103}$$

$$A_f^{\Delta\Gamma} \equiv \frac{-2\,\mathcal{R}e(\lambda_f)}{1 + \left|\lambda_f\right|^2} \, . \tag{13.104}$$

The presence of the $A_f^{\Delta\Gamma}$ term implies that information on λ_f can be obtained from analyses that do not use tagging of the initial flavor, through so-called effective lifetime measurements [98].

The $B_s^0 \to J/\psi\phi$ decay proceeds via the $\overline{b} \to \overline{c}c\overline{s}$ transition. The *CP* asymmetry in this mode thus determines (with angular analysis to disentangle the *CP*-even and *CP*-odd components of the final state) $\sin 2\beta_s$, where β_s is defined in Eq. (13.52) [99]. The $B_s^0 \to J/\psi\pi^+\pi^-$ decay, which has a large contributions from $J/\psi f_0(980)$ and is assumed to also proceed dominantly via the $\overline{b} \to \overline{c}c\overline{s}$ transition, has also been used to determine β_s. In this case no angular analysis is necessary, since the final state has been shown to be dominated by the *CP*-odd component [100]. The combination of measurements yields [29]

$$-2\beta_s = -0.021 \pm 0.031 \, , \tag{13.105}$$

consistent with the Standard Model prediction, $\beta_s = 0.0184 \pm 0.0004$ [19].

The experimental investigation of *CP* violation in the B_s^0 sector is still at a relatively early stage, and far fewer modes have been studied than in the B^0 system. First results on the $\overline{b} \to \overline{q}q\overline{s}$ decays $B_s^0 \to \phi\phi$, K^+K^- and $K^{*0}\overline{K}^{*0}$ have been reported. More channels are expected to be studied in the near future.

13.6.4 *Direct CP violation in the B system*

An interesting class of decay modes is that of the tree-level decays $B^\pm \to D^{(*)}K^\pm$. These decays provide golden methods for a clean determination of the angle γ [101–106]. The method uses the decays $B^+ \to D^0K^+$, which proceeds via the quark transition $\overline{b} \to \overline{u}c\overline{s}$, and $B^+ \to \overline{D}^0K^+$, which proceeds via the quark transition $\overline{b} \to \overline{c}u\overline{s}$, with the D^0 and $\overline{D}^0$ decaying into a common final state. The decays into common final states, such $(\pi^0K_S)_DK^+$, involve interference effects between the two amplitudes, with sensitivity to the relative phase, $\delta + \gamma$ (δ is the relevant strong phase difference). The *CP*-conjugate processes are sensitive to $\delta - \gamma$. Measurements of branching ratios and *CP* asymmetries allow the determination of γ and δ from amplitude triangle relations. The method suffers from discrete ambiguities but, since all hadronic parameters can be determined from the data, has negligible theoretical uncertainty [107].

Unfortunately, the smallness of the CKM-suppressed $b \to u$ transitions makes it difficult to use the simplest methods alone [101–103] to determine γ. These difficulties are overcome (and the discrete ambiguities are removed) by performing a Dalitz plot analysis for multi-body D decays [104–106]. Detailed discussion of the determination of γ with these methods can be found in Ref. [36].

Constraints on γ from combinations of results on various $B \to D^{(*)}K^{(*)}$ processes have been obtained by experiments [108,109]. The latest world average is [29]:

$$\gamma = \left(71.1\,^{+4.6}_{-5.3}\right)^\circ \, . \tag{13.106}$$

The consistency between the range of γ determined by the $B \to DK$ measurements and the range allowed by CKM fits (excluding these direct determinations) provides further support to the Kobayashi-Maskawa mechanism. As more data become available, determinations of γ from $B_s^0 \to D_s^\mp K^\pm$ [110, 111] and $B^0 \to DK^{*0}$ [112–115] are expected to also give competitive measurements.

Decays to the final state $K^\mp\pi^\pm$ provided the first observations of direct *CP* violation in both B^0 and B_s^0 systems. The asymmetry arises due to interference between tree and penguin diagrams [116], similar to the effect discussed in Section 13.6.2. In principle, measurements of $\mathcal{A}_{\overline{B}^0\to K^-\pi^+}$ and $\mathcal{A}_{\overline{B}_s^0\to K^+\pi^-}$ could be used to determine the weak phase difference γ, but lack of knowledge of the relative magnitude and strong phase of the contributing amplitudes limits the achievable precision. The uncertainties on these hadronic parameters can be reduced by exploiting flavor symmetries, which predict a number of relations between asymmetries in different modes. One such relation is that the partial rate differences for B^0 and B_s^0 decays to $K^\mp\pi^\pm$ are expected to be approximately equal and opposite [117], which is consistent with current data. It is also expected that the partial rate asymmetries for $\overline{B}^0 \to K^-\pi^+$ and $B^- \to K^-\pi^0$ should be approximately equal; however, the experimental results currently show a significant discrepancy [29]:

$$\mathcal{A}_{\overline{B}^0\to K^-\pi^+} = -0.084\pm0.004 \, , \quad \mathcal{A}_{B^-\to K^-\pi^0} = +0.040\pm0.021 \, . \tag{13.107}$$

It is therefore of great interest to understand whether this originates from Standard Model QCD corrections, or whether it is a signature of new dynamics. Improved tests of a more precise relation between the partial rate differences of all four $K\pi$ final states [118–121], currently limited by knowledge of the *CP* asymmetry in $\overline{B}^0 \to K_S\pi^0$ decays, may help to resolve the situation.

It is also of interest to investigate whether similar patterns appear among the *CP* violating asymmetries in B meson decays to final states containing one pseudoscalar and one vector meson. Since the vector resonance decays to two particles, such channels can be studied through Dalitz plot analysis of the three-body final state. Model-independent analyses of $B^+ \to K^+K^-K^+$, $\pi^+\pi^-K^+$, $\pi^+\pi^-\pi^+$ and $K^+K^-\pi^+$ decays have revealed large *CP* violation effects in certain regions of phase space [122]. For the $B^+ \to K^+K^-\pi^+$ decay, an amplitude analysis has established a large *CP* violation effect associated with $\pi\pi \leftrightarrow KK$ S-wave rescattering [123]. For the other channels it remains to be seen whether the *CP* violation effects are associated to particular resonances or to interference effects, which will be necessary to understand the underlying dynamics.

13.7 Summary and Outlook

CP violation has been experimentally established in K, D and B meson decays. A full list of *CP* asymmetries that have been measured at a level higher than 5σ is given in the introduction to this review. In Section 13.1.4 we introduced three types of *CP*-violating effects. Examples of these three types include the following:

1. All three types of *CP* violation have been observed in $K \to \pi\pi$

decays:

$$\mathcal{R}e(\epsilon') = \frac{1}{6}\left(\left|\frac{\overline{A}_{\pi^0\pi^0}}{A_{\pi^0\pi^0}}\right| - \left|\frac{\overline{A}_{\pi^+\pi^-}}{A_{\pi^+\pi^-}}\right|\right) = (2.5 \pm 0.4) \times 10^{-6}\,, \quad \text{(I)} \quad (13.108a)$$

$$\mathcal{R}e(\epsilon) = \frac{1}{2}\left(1 - \left|\frac{q}{p}\right|\right) = (1.66 \pm 0.02) \times 10^{-3}\,, \quad \text{(II)} \quad (13.108b)$$

$$\mathcal{I}m(\epsilon) = -\frac{1}{2}\mathcal{I}m(\lambda_{(\pi\pi)_{I=0}}) = (1.57 \pm 0.02) \times 10^{-3}\,. \quad \text{(III)} \quad (13.108c)$$

2. For D mesons, CP violation in decay has been established in the difference of asymmetries for $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ decays.

$$\Delta a_{CP} = \frac{|\overline{A}_{K^+K^-}/A_{K^+K^-}|^2 - 1}{|\overline{A}_{K^+K^-}/A_{K^+K^-}|^2 + 1} - \frac{|\overline{A}_{\pi^+\pi^-}/A_{\pi^+\pi^-}|^2 - 1}{|\overline{A}_{\pi^+\pi^-}/A_{\pi^+\pi^-}|^2 + 1} = (-0.164 \pm 0.028) \times 10^{-3}\,, \quad \text{(I)} \quad (13.109)$$

3. In the B meson system, CP violation in decay has been observed in, for example, $B^0 \to K^+\pi^-$ transitions, while CP violation in interference of decays with and without mixing has been observed in, for example, the $B^0 \to J/\psi K_S$ channel:

$$\mathcal{A}_{K^+\pi^-} = \frac{|\overline{A}_{K^-\pi^+}/A_{K^+\pi^-}|^2 - 1}{|\overline{A}_{K^-\pi^+}/A_{K^+\pi^-}|^2 + 1} = -0.084 \pm 0.004\,, \quad \text{(I)} \quad (13.110a)$$

$$S_{\psi K} = \mathcal{I}m(\lambda_{\psi K}) = +0.699 \pm 0.017\,. \quad \text{(III)} \quad (13.110b)$$

Based on Standard Model predictions, further observations of CP violation in B^0, B^+ and B_s^0 decays seem likely in the near future, at both LHCb and its upgrades [124–126] as well as the Belle II experiment [127]. The first observation of CP violation in b baryons is also likely to be within reach of LHCb. Further improvements in the sensitivity to CP violation effects in the charm sector can also be anticipated, though uncertainty in the Standard Model predictions makes it difficult to forecast whether or not additional discoveries will be forthcoming. A number of upcoming experiments have potential to make significant progress on rare kaon decays. Observables that are subject to clean theoretical interpretation, such as β from $S_{\psi K_S}$, β_s from $B_s^0 \to J/\psi\phi$, $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu})$ and γ from CP violation in $B \to DK$ decays, are of particular value for constraining the values of the CKM parameters and probing the flavor sector of extensions to the Standard Model. Progress in lattice QCD calculations is also needed to complement the anticipated experimental results. Other probes of CP violation now being pursued experimentally include the electric dipole moments of the neutron and electron, and the decays of tau leptons. Additional processes that are likely to play an important role in future CP studies include top-quark production and decay, Higgs boson decays and neutrino oscillations.

All measurements of CP violation to date are consistent with the predictions of the Kobayashi-Maskawa mechanism of the Standard Model. In fact, it is now established that the KM mechanism plays a major role in the CP violation measured in the quark sector. However, a dynamically-generated matter-antimatter asymmetry of the universe requires additional sources of CP violation, and such sources are naturally generated by extensions to the Standard Model. New sources might eventually reveal themselves as small deviations from the predictions of the KM mechanism, or else might not be observable in the quark sector at all, but observable with future probes such as neutrino oscillations or electric dipole moments. The fundamental nature of CP violation demands a vigorous search.

A number of excellent reviews of CP violation are available [128–135], where the interested reader may find a detailed discussion of the various topics that are briefly reviewed here.

We thank David Kirkby for significant contributions to earlier versions of this review.

14.1 Neutrinos in the Standard Model: Massless Neutrinos

The gauge symmetry principle is one of the pillars of the great success of modern particle physics as it establishes an unambiguous connection between local (gauge) symmetries and forces mediated by spin-1 particles. In the Standard Model (SM) of particle physics the strong, weak, and electromagnetic interactions are connected to gauge symmetry under $SU(3)_{\rm C} \times SU(2)_L \times U(1)_Y$ where C stands for colour, L for left-handedness, and Y for hypercharge. The SM gauge symmetry is spontaneously broken to $SU(3)_{\rm C} \times U(1)_{\rm EM}$ where $U(1)_{\rm EM}$ couples to the electromagnetic charge $Q_{\rm EM} = T_{L3} + Y$ (T_{L3} is the weak isospin which is the third generator of $SU(2)_L$). The model explains all the interactions of the known fermions once they are assigned to well defined representation of the gauge group. The construction and tests of the Standard Model as a gauge theory are covered in the review sections on "Quantum chromodynamics" and "Electroweak model and constraints on new physics" respectively. In here we emphasize that the gauge invariance principle requires that all terms in the Lagrangian, including the mass terms, respect the local symmetry. This has important implications for the neutrino and in particular for the question of the neutrino mass [1].

In the SM, neutrinos are fermions that do not have strong nor electromagnetic interactions. Consequently they are singlets of the subgroup $SU(3)_C \times U(1)_{\rm EM}$. They are part of the lepton doublets $L_{L\ell} = \begin{pmatrix} \nu_\ell \\ \ell \end{pmatrix}_L$ where f_L is the left-handed component of the fermion f, $f_L = P_L f \equiv \frac{1-\gamma_5}{2} f$. In what follows we will refer as *active* neutrinos to neutrinos that are part of these lepton doublets. In the SM there is one active neutrino for each charged leptons, $\ell = e, \mu, \tau$. $SU(2)_L$ gauge invariance dictates the form of weak charged current (CC) interactions between the neutrinos and their corresponding charged leptons and neutral current (NC) among themselves to be:

$$-\mathcal{L}_{\rm CC} = \frac{g}{\sqrt{2}} \sum_\ell \bar{\nu}_{L\ell} \gamma^\mu \ell^-_L W^+_\mu + \text{h.c.}\,, \qquad (14.1)$$

$$-\mathcal{L}_{\rm NC} = \frac{g}{2\cos\theta_W} \sum_\ell \bar{\nu}_{L\ell} \gamma^\mu \nu_{L\ell} Z^0_\mu\,. \qquad (14.2)$$

In the above equations g is the coupling constant associated to $SU(2)$ and θ_W is the Weinberg angle.

Equations(14.1) and (14.2) describe all the neutrino interactions in the SM. In particular, Eq.(14.2) determines the decay width of the Z^0 boson into light ($m_\nu \leq m_{Z^0}/2$) left-handed neutrinos states. Thus from the measurement of the total decay width of the Z^0 one can infer the number of such states. At present the measurement implies $N_\nu = 2.984 \pm 0.008$ (see Particle Listing). As a result any extension of the SM should contain three, and only three, light active neutrinos.

Sterile neutrinos are defined as having no SM gauge interactions, that is, they are singlets of the complete SM gauge group. Thus the SM, as the gauge theory able to describe all known particle interactions, contains no sterile neutrinos.

The SM with its gauge symmetry and the particle content required for the gauge interactions, that is, in the absence of SM singlets, respects an accidental global symmetry which is not imposed but appears as consequence of the gauge symmetry and the representation of the matter fields:

$$G^{\rm global}_{\rm SM} = U(1)_B \times U(1)_{L_e} \times U(1)_{L_\mu} \times U(1)_{L_\tau}\,, \qquad (14.3)$$

where $U(1)_B$ is the baryon number symmetry, and $U(1)_{L_e,L_\mu,L_\tau}$ are the three lepton flavour symmetries. The total lepton number, $L_e + L_\mu + L_\tau$, is then also an accidental symmetry since is a subgroup of $G^{\rm global}_{\rm SM}$. This fact has consequences which are relevant to the question of the neutrino mass as we argue next.

In the SM, the masses of the fermions are generated via a Yukawa coupling of the scalar Higgs doublet ϕ with a fermion right-handed and left-handed component. The former is an $SU(2)_L$ singlet, the latter is part of a doublet. For leptons, we can one can build such term coupling the left-handed lepton doublets L_L with the right-handed charged lepton fields E_R:

$$-\mathcal{L}_{\rm Yukawa,lep} = Y^\ell_{ij} \bar{L}_{Li} \phi E_{Rj} + \text{h.c.}\,. \qquad (14.4)$$

After spontaneous symmetry breaking these terms lead to charged lepton masses

$$m^\ell_{ij} = Y^\ell_{ij} \frac{v}{\sqrt{2}}\,, \qquad (14.5)$$

where v is the vacuum expectation value of the Higgs field. However, since the model does not contain right-handed neutrinos, no such Yukawa interaction can be built for the neutrinos, which are consequently massless at the Lagrangian level.

In principle, a neutrino mass term could be generated at loop level. With the particle content of the SM the only possible neutrino mass term that could be constructed is the bilinear $\bar{L}_L L^c_L$, where L^c_L is the charge conjugated field, $L^c_L = C\bar{L}_L^{\,T}$ and C is the charge conjugation matrix. However this term is forbidden in the SM because it violates the total lepton symmetry by two units and therefore it cannot be induced by loop corrections because it breaks the accidental symmetry of the model. Also, because $U(1)_{B-L}$ is a non-anomalous subgroup of $G^{\rm global}_{\rm SM}$, the bilinear $\bar{L}_L L^c_L$, cannot be induced by nonperturbative corrections either since it breaks $B - L$.

We conclude that within the SM neutrinos are precisely massless. Consequently one must go beyond the SM in order to add a mass to the neutrino.

14.2 Extending the Standard Model to Introduce Massive Neutrinos

From the above discussion we conclude that it is not possible to construct a renormalizable mass term for the neutrinos with the

[1]The physics of massive neutrinos has been the subject of excellent books such as [1–5] and multiple review articles. The contents of the present review is built upon the structure and the contents of the review articles [6, 7].

fermionic content and gauge symmetry of the SM. The obvious consequence is that in order to introduce a neutrino mass in the theory one must extend the particle content of the model, depart from gauge invariance and/or renormalizability, or do both.

As a matter of fact, neutrino mass terms can be constructed in different ways. In the following we shall assume to maintain the gauge symmetry and explore the different possibilities to introduce a neutrino mass term adding to the SM an arbitrary number of sterile neutrinos ν_{si} $(i = 1, \dots m)$.

In the SM extended with the addition of m number of sterile neutrinos one can construct two gauge invariant renormalizable operators leading to two type of mass terms

$$-\mathcal{L}_{M_\nu} = M_{D\,ij}\bar{\nu}_{si}\nu_{Lj} + \frac{1}{2}M_{N\,ij}\bar{\nu}_{si}\nu^c_{sj} + \text{h.c.}\,, \tag{14.6}$$

where ν^c is the neutrino charge conjugated field (defined in section 14.1). M_D is a complex matrix of dimension $m \times 3$ and M_N is a symmetric $m \times m$ matrix.

The first term is generated after spontaneous electroweak symmetry breaking from Yukawa interactions,

$$Y^\nu_{ij}\bar{\nu}_{si}\tilde{\phi}^\dagger L_{Lj} \Rightarrow M_{D\,ij} = Y^\nu_{ij}\frac{v}{\sqrt{2}}\,, \tag{14.7}$$

in similarity to Eqs.(14.4) and (14.5) for the charged fermion masses. It is correspondingly called a Dirac mass term. It conserves total lepton number but it can break the lepton flavour number symmetries.

The second term in Eq.(14.6) is a Majorana mass term and it differs from the Dirac mass terms in several relevant aspects. First, it is a singlet of the SM gauge group and, as such, it can appear as a bare mass term in the Lagrangian. Second, since it involves two neutrino fields (right-handed in this case), it breaks lepton number by two units. In general such a term is not allowed if the neutrinos carry any additive conserved charge.

It is possible to rewrite Eq.(14.6) as:

$$-\mathcal{L}_{M_\nu} = \frac{1}{2}(\overline{\vec{\nu}^c_L}, \overline{\vec{\nu}_s})\begin{pmatrix} 0 & M_D^T \\ M_D & M_N \end{pmatrix}\begin{pmatrix} \vec{\nu}_L \\ \vec{\nu}^c_s \end{pmatrix} + \text{h.c.} \equiv \overline{\vec{\nu}^c}M_\nu\vec{\nu} + \text{h.c.}\,, \tag{14.8}$$

where $\vec{\nu} = (\vec{\nu}_L, \vec{\nu^c_s})^T$ is a $(3+m)$-dimensional vector. The matrix M_ν is complex and symmetric [2]. Thus it can be diagonalized by a unitary matrix V^ν of dimension$(3+m)$, so

$$(V^\nu)^T M_\nu V^\nu = \text{diag}(m_1, m_2, \dots, m_{3+m})\,. \tag{14.9}$$

One can express the original weak eigenstates in terms of the resulting $3+m$ mass eigenstates

$$\vec{\nu}_{\text{mass}} = (V^\nu)^\dagger\vec{\nu}\,, \tag{14.10}$$

and in terms of the mass eigenstates Eq.(14.8) takes the form:

$$\begin{aligned} -\mathcal{L}_{M_\nu} &= \frac{1}{2}\sum_{k=1}^{3+m} m_k\left(\bar{\nu}^c_{\text{mass},k}\nu_{\text{mass},k} + \bar{\nu}_{\text{mass},k}\nu^c_{\text{mass},k}\right) \\ &= \frac{1}{2}\sum_{k=1}^{3+m} m_k\bar{\nu}_{Mk}\nu_{Mk}\,, \end{aligned} \tag{14.11}$$

where

$$\nu_{Mk} = \nu_{\text{mass},k} + \nu^c_{\text{mass},k} = (V^{\nu\dagger}\vec{\nu})_k + (V^{\nu\dagger}\vec{\nu})^c_k\,. \tag{14.12}$$

So these states obey the Majorana condition

$$\nu_M = \nu^c_M\,, \tag{14.13}$$

and are referred to as Majorana neutrinos. The Majorana condition implies that only one field describes both neutrino and antineutrino states, unlike in the case of a charge for which particle and antiparticle are described by two different fields. So a Majorana neutrino can be described by a two-component spinor unlike the charged fermions, which are Dirac particles, and are represented by four-component spinors.

Inverting Eq.(14.12) we can write the weak-doublet components of the neutrino fields as:

$$\nu_{Li} = P_L\sum_{j=1}^{3+m} V^\nu_{ij}\nu_{Mj} \quad i = 1, 2, 3\,, \tag{14.14}$$

where P_L is the left projector.

In what follows we will discuss some interesting particular cases of this general framework: light Dirac neutrinos in Sec.14.2.1, and light Majorana neutrinos and the see-saw mechanism in Sec.14.2.2. A special case of the second one is the possibility of light-sterile neutrinos discussed in Sec.14.2.3. In Sec.14.2.4 we shall discuss the effective generation of neutrino masses from non-renormalizable operators (of which the see-saw mechanism is a particular realization).

14.2.1 *Dirac Neutrinos*

Imposing $M_N = 0$ is equivalent to imposing lepton number symmetry on the model. Doing so only the first term in Eq.(14.6), the Dirac mass term, is allowed. If sterile neutrinos are three ($m = 3$), we can identify them with the right-handed component of a four-spinor neutrino field. In this case the Dirac mass term can be diagonalized with two 3×3 unitary matrices, V^ν and V^ν_R as:

$$V^{\nu\,\dagger}_R M_D V^\nu = \text{diag}(m_1, m_2, m_3)\,. \tag{14.15}$$

The neutrino mass term can be written as:

$$-\mathcal{L}_{M_\nu} = \sum_{k=1}^{3} m_k\bar{\nu}_{Dk}\nu_{Dk}\,, \tag{14.16}$$

where

$$\nu_{Dk} = (V^{\nu\,\dagger}\vec{\nu}_L)_k + (V^{\nu\,\dagger}_R\vec{\nu}_s)_k\,, \tag{14.17}$$

so the weak-doublet components of the neutrino fields are

$$\nu_{Li} = P_L\sum_{j=1}^{3} V^\nu_{ij}\nu_{Dj}\,. \qquad i = 1, 2, 3\,. \tag{14.18}$$

Let's stress that in this case both the low energy matter content and the assumed symmetries are different from those of the SM. Consequently the SM is not even a good low-energy effective theory. Furthermore, this scenario does not explain the fact that neutrinos are much lighter than the corresponding charged fermions, because all acquire their mass via the same mechanism.

14.2.2 *The See-saw Mechanism*

If the mass eigenvalues of M_N are much higher than the scale of electroweak symmetry breaking v, the diagonalization of M_ν leads to three light neutrinos, ν_l, and m heavy neutrinos, N:

$$-\mathcal{L}_{M_\nu} = \frac{1}{2}\bar{\nu}_l M^l\nu_l + \frac{1}{2}\bar{N}M^h N\,, \tag{14.19}$$

with

$$M^l \simeq -V_l^T M_D^T M_N^{-1} M_D V_l\,, \qquad M^h \simeq V_h^T M_N V_h\,, \tag{14.20}$$

and

[2] Notice that Eq.(14.8) corresponds to the tree-level neutrino mass matrix. Corrections are induced at the loop level, which in particular lead to non-vanishing $\bar{\nu}^c_L\nu_L$ entry [8].

$$V^\nu \simeq \begin{bmatrix} \left(1-\frac{1}{2}M_D^\dagger M_N^{*}{}^{-1}M_N^{-1}M_D\right) V_l & M_D^\dagger M_N^{*}{}^{-1}V_h \\ -M_N^{-1}M_D V_l & \left(1-\frac{1}{2}M_N{}^{-1}M_D M_D^\dagger M_N^{*}{}^{-1}\right)V_h \end{bmatrix}, \qquad (14.21)$$

where V_l and V_h are 3×3 and $m\times m$ unitary matrices respectively. From Eq.(14.20) we see that the masses of the heavier states are proportional to M_N while those of the lighter ones to M_N^{-1}, hence the name of *see-saw mechanism* [9–13]. Also, as seen from Eq.(14.21), the heavy states are mostly right-handed while the light ones are mostly left-handed. Both the light and the heavy neutrinos are Majorana particles. Two well-known examples of extensions of the SM leading to a see-saw mechanism for neutrino masses are SO(10) Grand Unified Theories [10, 11] and left-right symmetry [13].

In this case the SM is a good effective low energy theory. Indeed the see-saw mechanism is a particular example of a full theory whose low energy effective realization is the SM with three light Majorana neutrinos which we describe in Sec.14.2.4.

14.2.3 *Light Sterile Neutrinos*

If the scale of some $n_s \le m$ eigenvalues of M_N are not higher than the electroweak scale, the low energy spectrum contains n_s additional light states with large admixture of sterile component. As in the case with Dirac Neutrinos, the SM is not a good low energy effective theory: there are more than three (3+n_s) light neutrinos, and they are admixtures of doublet and singlet fields. As in the general case, both light and heavy neutrinos are Majorana particles.

14.2.4 *Neutrino Masses from Generic New Physics*

Under the generic hypothesis that new physics (NP) beyond the SM only manifests itself directly above some scale $\Lambda_{\rm NP}$, we can consider that the SM is an effective low energy theory which is valid to describe the physical world at energies well below $\Lambda_{\rm NP}$ with the same gauge group, fermionic spectrum, and the pattern of spontaneous symmetry breaking of the SM. However, this is an effective theory, holding only till energy below $\Lambda_{\rm NP}$, and consequently does not need to be renormalizable. In this case the low energy Lagrangian can contain non-renormalizable higher dimensional terms whose effect will be suppressed by powers $1/\Lambda_{\rm NP}^{\text{dim-4}}$.

In this approach, the least suppressed NP effects at low energy are expected to come from dim= 5 operators. With the SM fields an gauge symmetry one can only construct the following set of dimension-five terms

$$\mathcal{O}_5 = \frac{Z^\nu_{ij}}{\Lambda_{\rm NP}}\left(\bar{L}_{Li}\tilde{\phi}\right)\left(\tilde{\phi}^T L^C_{Lj}\right) + \text{h.c.}. \qquad (14.22)$$

This set violates (14.3) which poses no problem since in general there is no reason for the NP to respect the accidental symmetries of the SM. In particular it violates total lepton number by two units and after spontaneous symmetry breaking it generates a bilinear neutrino field term:

$$-\mathcal{L}_{M_\nu} = \frac{Z^\nu_{ij}}{2}\frac{v^2}{\Lambda_{\rm NP}}\bar{\nu}_{Li}\nu^c_{Lj} + \text{h.c.}. \qquad (14.23)$$

This is a Majorana mass term (see Eq.(14.8)). It is built with the left-handed neutrino fields and with mass matrix:

$$(M_\nu)_{ij} = Z^\nu_{ij}\frac{v^2}{\Lambda_{\rm NP}}. \qquad (14.24)$$

We conclude that Eq.(14.24) would arise in a generic extension of the SM and that neutrino masses are very likely to appear if there is NP. Comparing Eq.(14.24) and Eq.(14.5), we also find that the scale of neutrino masses is suppressed by $v/\Lambda_{\rm NP}$ when compared to the scale of charged fermion masses providing an explanation for their smallness. Furthermore, both total lepton number and the lepton flavour symmetry $U(1)_e\times U(1)_\mu\times U(1)_\tau$ are broken by Eq.(14.24) which means that, generically, in the absence of additional symmetries on the coefficients Z_{ij}, we can expect lepton flavour mixing and CP violation as we discuss in next section.

Finally, we notice that, as mentioned in Sec.14.2.2, a theory where the NP is composed of m heavy sterile neutrinos, provides an specific example of a theory which at low energy theory contains three light mass eigenstates with an effective dim-5 interaction of the form (14.22) with $\Lambda_{\rm NP} = M_N$. This is, in this case the NP scale is the characteristic mass scale of the heavy sterile neutrinos.

14.3 Lepton Mixing

Let us start by considering $n = 3+m$ massive neutrino states and denote the neutrino mass eigenstates by $(\nu_1,\nu_2,\nu_3,\ldots,\nu_n)$. The neutrino interaction eigenstates are denoted by $\vec{\nu} = (\nu_{Le},\nu_{L\mu},\nu_{L\tau},\nu_{s1},\ldots,\nu_{sm})$. We label the corresponding mass and interaction eigenstates for the charged leptons as (e,μ,τ) and (e^I,μ^I,τ^I) respectively. The Lagrangian for the leptonic charged current interactions in the mass basis takes the form:

$$-\mathcal{L}_{\rm CC} = \frac{g}{\sqrt{2}}(\bar{e}_L,\,\bar{\mu}_L,\,\bar{\tau}_L)\gamma^\mu U\begin{pmatrix}\nu_1\\ \nu_2\\ \nu_3\\ \vdots\\ \nu_n\end{pmatrix} W^+_\mu + \text{h.c.}, \qquad (14.25)$$

where U is a $3\times n$ matrix [14–16]. It satisfies the unitary condition

$$UU^\dagger = I_{3\times 3}. \qquad (14.26)$$

However, in general $U^\dagger U \neq I_{n\times n}$.

In the interaction basis, the mass terms for the leptons are:

$$-\mathcal{L}_M = [(\bar{e}^I_L,\,\bar{\mu}^I_L,\,\bar{\tau}^I_L)M_\ell\begin{pmatrix}e^I_R\\ \mu^I_R\\ \tau^I_R\end{pmatrix} + \text{h.c.}] - \mathcal{L}_{M_\nu}, \qquad (14.27)$$

with $\mathcal{L}_{M_\nu}$ given in Eq.(14.8). M_ℓ can be diagonalize with two 3×3 unitary matrices V^ℓ and V^ℓ_R which satisfy

$$V^{\ell\dagger} M_\ell V^\ell_R = \text{diag}(m_e, m_\mu, m_\tau). \qquad (14.28)$$

Then for the charged leptons we have

$$-\mathcal{L}_{M_\ell} = \sum_{k=1}^{3} m_{\ell_k}\bar{\ell}_k\ell_k, \qquad (14.29)$$

with

$$\ell_k = (V^{\ell\dagger}\ell^I_L)_k + (V_R^{\ell\dagger}\ell^I_R)_k. \qquad (14.30)$$

Inverting the equation above we find that the weak-doublet components of the charged lepton fields are

$$\ell^I_{Li} = P_L\sum_{j=1}^{3}V^\ell_{ij}\ell_j. \qquad i=1,2,3 \qquad (14.31)$$

From Eqs.(14.14), (14.18) and (14.31) we find that the mixing matrix U can be expressed as:

$$U_{ij} = \mathcal{P}_{\ell,ii}\,V^{\ell}_{ik}{}^\dagger\,V^\nu_{kj}\,(\mathcal{P}_{\nu,jj}). \qquad (14.32)$$

The matrix $V^{\ell\dagger}V^\nu$ contains a number of phases that are not physical. Three of them are eliminated by the diagonal 3×3 phase matrix $\mathcal{P}_\ell$ that absorbs them in the charged lepton mass eigenstates. If neutrinos are Dirac states, further $n-1$ are similarly eliminated by absorbing them in the neutrino mass eigenstates with the diagonal $n\times n$ phase matrix $\mathcal{P}_\nu$. For Majorana neutrinos, $\mathcal{P}_\nu = I_{n\times n}$ because one cannot rotate by an arbitrary phase a Majorana field without physical effects. If one rotates a Majorana neutrino by a phase, this phase will appear in its mass term which will no longer be real. Consequently the number of phases that can be absorbed by redefining the mass eigenstates depends on whether the neutrinos are Dirac or Majorana particles. Altogether for $n \geq 3$ Majorana [Dirac] neutrinos the U matrix contains a total of $6(n-2)$ $[5n-11]$ real parameters, of which $3(n-2)$ are angles and $3(n-2)$ $[2n-5]$ can be interpreted as physical phases.

The possibility of arbitrary mixing between massive neutrino states was first discussed in the context of two neutrinos introduced in Ref. [17] (the possibility of two mixed massless flavour neutrino states had been previously considered in the literature [18], and even before the possibility of mixing between neutrino and antineutrino states in the seminal paper of Pontecorvo [19]). For that case, in which only mixing between two generations is considered with $n = 2$ distinct neutrino masses, the U matrix is 2×2 and contains one mixing angle if the neutrinos are Dirac and an additional physical phase if they are Majorana.

If there are only $n = 3$ Majorana neutrinos, U is a 3×3 matrix analogous to the CKM matrix for the quarks [20,21] but due to the Majorana nature of the neutrinos it depends on six independent parameters: three mixing angles and three phases. In this case the mixing matrix can be conveniently parametrized as:

$$U = \begin{pmatrix} 1 & 0 & 0 \\ 0 & c_{23} & s_{23} \\ 0 & -s_{23} & c_{23} \end{pmatrix} \cdot \begin{pmatrix} c_{13} & 0 & s_{13}e^{-i\delta_{\rm CP}} \\ 0 & 1 & 0 \\ -s_{13}e^{i\delta_{\rm CP}} & 0 & c_{13} \end{pmatrix} \cdot \begin{pmatrix} c_{21} & s_{12} & 0 \\ -s_{12} & c_{12} & 0 \\ 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} e^{i\eta_1} & 0 & 0 \\ 0 & e^{i\eta_2} & 0 \\ 0 & 0 & 1 \end{pmatrix}, \tag{14.33}$$

where $c_{ij} \equiv \cos\theta_{ij}$ and $s_{ij} \equiv \sin\theta_{ij}$. The angles θ_{ij} can be taken without loss of generality to lie in the first quadrant, $\theta_{ij} \in [0, \pi/2]$ and the phases $\delta_{\rm CP},\ \eta_i \in [0, 2\pi]$. This is to be compared to the case of three Dirac neutrinos. In this case the Majorana phases, η_1 and η_2, can be absorbed in the neutrino states so number of physical phases is one (similar to the CKM matrix). Thus we can write U as:

$$U = \begin{pmatrix} c_{12}\,c_{13} & s_{12}\,c_{13} & s_{13}\,e^{-i\delta_{\rm CP}} \\ -s_{12}\,c_{23} - c_{12}\,s_{13}\,s_{23}\,e^{i\delta_{\rm CP}} & c_{12}\,c_{23} - s_{12}\,s_{13}\,s_{23}\,e^{i\delta_{\rm CP}} & c_{13}\,s_{23} \\ s_{12}\,s_{23} - c_{12}\,s_{13}\,c_{23}\,e^{i\delta_{\rm CP}} & -c_{12}\,s_{23} - s_{12}\,s_{13}\,c_{23}\,e^{i\delta_{\rm CP}} & c_{13}\,c_{23} \end{pmatrix}. \tag{14.34}$$

This matrix is often called the Pontecorvo-Maki-Nakagawa-Sakata (PMNS) mixing matrix.

Notice that when the charged leptons have no other interactions that the SM ones, one can identify their interaction eigenstates with the corresponding mass eigenstates up to phase redefinition. This implies that, in this case, U is just a $3 \times n$ sub-matrix of the unitary neutrino mass diagonalizing matrix V^ν.

Finally, let us point out that for the case of 3 light Dirac neutrinos the procedure above leads to a unitary U matrix for the light states. But for three light Majorana neutrinos this is not the case when the full spectrum contains states which are heavy and are not in the low energy spectrum as seen, for example, in Eq.(14.21). This implies that, strictly speaking, the parametrization in Eq.(14.33) is not valid to describe the flavour mixing of the three light Majorana neutrinos in the see-saw mechanism. The violation of unitarity, however, is rather small, of the order $\mathcal{O}(M_D/M_N)$ as seen in Eq.(14.21). It is also severely constrained experimentally [22,23]. For all these reasons, for all practical purposes, we will consider the U matrix for the 3ν mixing case to be unitary independently of whether neutrinos are Dirac or Majorana particles.

14.4 Mass-Induced Flavour Oscillations in Vacuum

If neutrinos have masses and lepton flavours are mixed in the weak CC interactions, lepton flavour is not conserved in neutrino propagation [19, 24]. This phenomenon is usually referred to as *neutrino oscillations*. In brief, a weak eigenstates, ν_α, which by default is the state produced in the weak CC interaction of a charged lepton ℓ_α, is the linear combination determined by the mixing matrix U

$$|\nu_\alpha\rangle = \sum_{i=1}^{n} U^*_{\alpha i}|\nu_i\rangle\,, \tag{14.35}$$

where ν_i are the mass eigenstates and here n is the number of light neutrino species (implicit in our definition of the state $|\nu\rangle$ is its energy-momentum and space-time dependence). After travelling a distance L ($L \simeq ct$ for relativistic neutrinos), that state evolves as:

$$|\nu_\alpha(t)\rangle = \sum_{i=1}^{n} U^*_{\alpha i}|\nu_i(t)\rangle\,. \tag{14.36}$$

This neutrino can then undergo a charged-current (CC) interaction producing a charge lepton ℓ_β, $\nu_\alpha(t)N' \to \ell_\beta N$, with a probability

$$P_{\alpha\beta} = |\langle\nu_\beta|\nu_\alpha(t)\rangle|^2 = |\sum_{i=1}^{n}\sum_{j=1}^{n} U^*_{\alpha i}U_{\beta j}\langle\nu_j|\nu_i(t)\rangle|^2\,. \tag{14.37}$$

Assuming that $|\nu\rangle$ is a plane wave, $|\nu_i(t)\rangle = e^{-i\,E_i t}|\nu_i(0)\rangle$, [3] with $E_i = \sqrt{p_i^2 + m_i^2}$ and m_i being, respectively, the energy and the mass of the neutrino mass eigenstate ν_i. In all practical cases neutrinos are very relativistic ,so $p_i \simeq p_j \equiv p \simeq E$. We can then write

$$E_i = \sqrt{p_i^2 + m_i^2} \simeq p + \frac{m_i^2}{2E}\,, \tag{14.38}$$

and use the orthogonality of the mass eigenstates, $\langle\nu_j|\nu_i\rangle = \delta_{ij}$, to arrive to the following form for $P_{\alpha\beta}$:

$$P_{\alpha\beta} = \delta_{\alpha\beta} - 4\sum_{i<j}^{n} \mathrm{Re}[U_{\alpha i}U^*_{\beta i}U^*_{\alpha j}U_{\beta j}]\sin^2 X_{ij}$$
$$+ 2\sum_{i<j}^{n} \mathrm{Im}[U_{\alpha i}U^*_{\beta i}U^*_{\alpha j}U_{\beta j}]\sin 2X_{ij}\,, \tag{14.39}$$

where

$$X_{ij} = \frac{(m_i^2 - m_j^2)L}{4E} = 1.267\,\frac{\Delta m^2_{ij}}{\mathrm{eV}^2}\,\frac{L/E}{\mathrm{m/MeV}}\,. \tag{14.40}$$

If we had made the same derivation for antineutrino states we would have ended with a similar expression but with the exchange $U \to U^*$. Consequently we conclude that the first term in the right-hand-side of Eq.(14.39) is CP conserving since it is the same for neutrinos and antineutrinos, while the last one is CP violating because it has opposite sign for neutrinos and antineutrinos.

Equation (14.39) oscillatory in distance with oscillation lengths

$$L^{\rm osc}_{0,ij} = \frac{4\pi E}{|\Delta m^2_{ij}|}\,, \tag{14.41}$$

and with amplitudes proportional to products of elements in the mixing matrix. Thus, neutrinos must have different masses

[3] For a pedagogical discussion of the quantum mechanical description of flavour oscillations in the wave package approach see for example Ref. [3]. A recent review of the quantum mechanical aspects and subtleties on neutrino oscillations can be found in in Ref. [25].

($\Delta m^2_{ij} \neq 0$) and they must have not vanishing mixing ($U_{\alpha_i} U_{\beta i} \neq 0$) in order to undergo flavour oscillations. Also, from Eq.(14.39) we see that the Majorana phases cancel out in the oscillation probability. This is expected because flavour oscillation is a total lepton number conserving process.

Ideally, a neutrino oscillation experiment would like to measure an oscillation probability over a distance L between the source and the detector, for neutrinos of a definite energy E. In practice, neutrino beams, both from natural or artificial sources, are never monoenergetic, but have an energy spectrum $\Phi(E)$. In addition each detector has a finite energy resolution. Under these circumstances what is measured is an average probability

$$\begin{aligned}\langle P_{\alpha\beta}\rangle &= \frac{\int dE \frac{d\Phi}{dE}\sigma(E) P_{\alpha\beta}(E)\epsilon(E)}{\int dE \frac{d\Phi}{dE}\sigma_{CC}(E)\epsilon(E)} \\ &= \delta_{\alpha\beta} - 4\sum_{i<j}^{n} \mathrm{Re}[U_{\alpha i}U^*_{\beta i}U^*_{\alpha j}U_{\beta j}]\langle\sin^2 X_{ij}\rangle \\ &+ 2\sum_{i<j}^{n} \mathrm{Im}[U_{\alpha i}U^*_{\beta i}U^*_{\alpha j}U_{\beta j}]\langle\sin 2X_{ij}\rangle\,.\end{aligned} \tag{14.42}$$

σ is the cross section for the process in which the neutrino flavour is detected, and $\epsilon(E)$ is the detection efficiency. The minimal range of the energy integral is determined by the energy resolution of the experiment.

It is clear from the above expression that if $(E/L) \gg |\Delta m^2_{ij}|$ ($L \ll L^{\rm osc}_{0,ij}$) so $\sin^2 X_{ij} \ll 1$, the oscillation phase does not give any appreciable effect. Conversely if $L \gg L^{\rm osc}_{0,ij}$, many oscillation cycles occur between production and detection so the oscillating term is averaged to $\langle\sin^2 X_{ij}\rangle = 1/2$.

We summarize in Table 14.1. the typical values of L/E for different types of neutrino sources and experiments and the corresponding ranges of Δm^2 to which they can be most sensitive.

Table 14.1: Characteristic values of L and E for experiments performed using various neutrino sources and the corresponding ranges of $|\Delta m^2|$ to which they can be most sensitive to flavour oscillations in vacuum. SBL stands for Short Baseline and LBL for Long Baseline.

Experiment		L (m)	E (MeV)	$\lvert\Delta m^2\rvert$ (eV^2)
Solar		10^{10}	1	10^{-10}
Atmospheric		$10^4 - 10^7$	10^2–10^5	$10^{-1} - 10^{-4}$
Reactor	SBL	$10^2 - 10^3$	1	$10^{-2} - 10^{-3}$
	LBL	$10^4 - 10^5$		$10^{-4} - 10^{-5}$
Accelerator	SBL	10^2	10^3–10^4	> 0.1
	LBL	$10^5 - 10^6$	$10^3 - 10^4$	$10^{-2} - 10^{-3}$

Historically, the results of neutrino oscillation experiments were interpreted assuming two-neutrino states so there is only one oscillating phase, the mixing matrix depends on a single mixing angle θ and no CP violation effect in oscillations is possible. At present, as we will discuss in Sec.14.7, we need at least the mixing among three-neutrino states to fully describe the bulk of experimental results. However, in many cases, the observed results can be understood in terms of oscillations dominantly driven by one Δm^2. In this limit $P_{\alpha\beta}$ of Eq.(14.39) takes the form [24]

$$P_{\alpha\beta} = \delta_{\alpha\beta} - (2\delta_{\alpha\beta} - 1)\sin^2 2\theta \sin^2 X\,. \tag{14.43}$$

In this effective $2-\nu$ limit, changing the sign of the mass difference, $\Delta m^2 \to -\Delta m^2$, and changing the octant of the mixing angle, $\theta \to \frac{\pi}{2} - \theta$, is just redefining the mass eigenstates, $\nu_1 \leftrightarrow \nu_2$: $P_{\alpha\beta}$ must be invariant under such transformation. So the physical parameter space can be covered with either $\Delta m^2 \geq 0$ with $0 \leq \theta \leq \frac{\pi}{2}$, or, alternatively, $0 \leq \theta \leq \frac{\pi}{4}$ with either sign for Δm^2.

However, from Eq.(14.43) we see that $P_{\alpha\beta}$ is actually invariant under the change of sign of the mass splitting *and* the change of octact of the mixing angle separately. This implies that there is a two-fold discrete ambiguity since the two different sets of physical parameters, $(\Delta m^2, \theta)$ and $(\Delta m^2, \frac{\pi}{2} - \theta)$, give the same transition probability in vacuum. In other words, one could not tell from a measurement of, say, $P_{e\mu}$ in vacuum whether the larger component of ν_e resides in the heavier or in the lighter neutrino mass eigenstate. This symmetry is broken when one considers mixing of three or more neutrinos in the flavour evolution and/or when the neutrinos traverse regions of dense matter as we describe in Sec.14.7.1 and Sec.14.5 respectively.

14.5 Propagation of Massive Neutrinos in Matter

Neutrinos propagating in a dense medium can interact with the particles in the medium. The probability of an incoherent inelastic scattering is very small. For example the characteristic cross section for ν-proton scattering is of the order

$$\sigma \sim \frac{G_F^2 s}{\pi} \sim 10^{-43}\ \mathrm{cm}^2 \left(\frac{E}{\mathrm{MeV}}\right)^2, \tag{14.44}$$

where G_F is the Fermi constant and s is the square of the center of mass energy of the collision.

But when neutrinos propagate in dense matter, they can also interact coherently with the particles in the medium. By definition, in coherent interactions, the medium remains unchanged so it is possible to have interference of the forward scattered and the unscattered neutrino waves which enhances the effect of matter in the neutrino propagation. In this case the effect of the medium is not on the intensity of the propagating neutrino beam, which remains unchanged, but on the phase velocity of the neutrino wave, and for this reason the effect is proportional to G_F, instead of the G_F^2 dependence of the incoherent scattering. Coherence also allows decoupling the evolution equation of the neutrinos from those of the medium. In this limit the effect of the medium is introduced in the evolution equation for the neutrinos in the form of an effective potential which depends on the density and composition of the matter [26].

As an example, let us consider the evolution of ν_e in a medium with electrons, protons and neutrons with corresponding n_e, n_p and n_n number densities. The effective low-energy Hamiltonian describing the relevant neutrino interactions at point x is given by

$$H_W = \frac{G_F}{\sqrt{2}}\left[J^{(+)\alpha}(x)J^{(-)}_\alpha(x) + \frac{1}{4}J^{(N)\alpha}(x)J^{(N)}_\alpha(x)\right], \tag{14.45}$$

where the J_α's are the standard fermionic currents

$$J^{(+)}_\alpha(x) = \bar\nu_e(x)\gamma_\alpha(1-\gamma_5)e(x)\,, \tag{14.46}$$

$$J^{(-)}_\alpha(x) = \bar e(x)\gamma_\alpha(1-\gamma_5)\nu_e(x)\,, \tag{14.47}$$

$$\begin{aligned}J^{(N)}_\alpha(x) &= \bar\nu_e(x)\gamma_\alpha(1-\gamma_5)\nu_e(x) \\ &- \bar e(x)[\gamma_\alpha(1-\gamma_5) - 4\sin^2\theta_W\gamma_\alpha]e(x) \\ &+ \bar p(x)[\gamma_\alpha(1-g_A^{(p)}\gamma_5) - 4\sin^2\theta_W\gamma_\alpha]p(x) \\ &- \bar n(x)\gamma_\alpha(1-g_A^{(n)}\gamma_5)n(x)\,,\end{aligned} \tag{14.48}$$

and $g_A^{(n,p)}$ are the axial couplings for neutrons and protons, respectively.

Let as focus first on the the effect of the charged current interactions. The effective CC Hamiltonian due to electrons in the medium is

$$
\begin{aligned}
H_C^{(e)} &= \frac{G_F}{\sqrt{2}} \int d^3p_e f(E_e,T) \times \left\langle \langle e(s,p_e)\,|\,\bar{e}(x)\gamma^\alpha(1-\gamma_5)\nu_e(x)\bar{\nu}_e(x)\gamma_\alpha(1-\gamma_5)e(x)\,|\,e(s,p_e)\rangle \right\rangle \\
&= \frac{G_F}{\sqrt{2}}\bar{\nu}_e(x)\gamma_\alpha(1-\gamma_5)\nu_e(x) \int d^3p_e f(E_e,T)\left\langle \langle e(s,p_e)\,|\,\bar{e}(x)\gamma_\alpha(1-\gamma_5)e(x)\,|\,e(s,p_e)\rangle \right\rangle .
\end{aligned}
\tag{14.49}
$$

In the above equation we denote by s the electron spin, and by p_e its momentum and $f(E_e,T)$, is the energy distribution function of the electrons in the medium which is assumed to be homogeneous and isotropic and is normalized as

$$\int d^3p_e f(E_e,T) = 1\,. \tag{14.50}$$

We denote by $\left\langle \ldots \right\rangle$ the averaging over electron spinors and summing over all electrons in the medium. Coherence dictates that s, p_e are the same for initial and final electrons. The axial current reduces to the spin in the non-relativistic limit and therefore averages to zero for a background of non-relativistic electrons. The spatial components of the vector current cancel because of isotropy. Therefore the only non trivial average is

$$\int d^3p_e f(E_e,T)\left\langle \langle e(s,p_e)\,|\,\bar{e}(x)\gamma_0 e(x)\,|\,e(s,p_e)\rangle \right\rangle = n_e(x)\,, \tag{14.51}$$

which gives a contribution to the effective Hamiltonian

$$H_C^{(e)} = \sqrt{2}G_F n_e \bar{\nu}_{eL}(x)\gamma_0\nu_{eL}(x)\,. \tag{14.52}$$

This can be interpreted as a contribution to the ν_{eL} potential energy

$$V_C = \sqrt{2}G_F n_e\,. \tag{14.53}$$

Should we have considered antineutrino states we would have ended up with $V_C = -\sqrt{2}G_F n_e$ For a more detailed derivation of the matter potentials see, for example, Ref. [3].

With an equivalent derivation we find that for ν_μ and ν_τ, the potential due to its CC interactions is zero for most media since neither μ's nor $\tau's$ are present, while the effective potential for any active neutrino due to the neutral current interactions is found to be

$$V_{NC} = \frac{\sqrt{2}}{2}G_F\left[-n_e(1-4\sin^2\theta_w)+n_p(1-4\sin^2\theta_w)-n_n\right]. \tag{14.54}$$

In neutral matter $n_e = n_p$ and the contribution from electrons and protons cancel each other. So we are left only with the neutron contribution

$$V_{NC} = -1/\sqrt{2}G_F n_n\,. \tag{14.55}$$

After including these effects, the evolution equation for n ultra-relativistic neutrinos propagating in matter written in the mass basis is (see for instance Ref. [27–29] for the derivation):

$$i\frac{d\vec{\nu}}{dx} = H\,\vec{\nu}, \qquad H = H_m + U^{\nu\,\dagger}\,V\,U^\nu\,. \tag{14.56}$$

Here $\vec{\nu} \equiv (\nu_1,\, \nu_2,\, \ldots,\, \nu_n)^T$, H_m is the the kinetic Hamiltonian,

$$H_m = \frac{1}{2E}\,\mathrm{diag}(m_1^2,\, m_2^2,\, \ldots,\, m_n^2), \tag{14.57}$$

and V is the effective neutrino potential in the interaction basis. U^ν is the $n\times n$ submatrix of the unitary V^ν matrix corresponding to the n ultrarelativistic neutrino states. For the three SM active neutrinos with purely SM interactions crossing a neutral medium with electrons, protons and neutrons, the evolution equation takes the form (14.56) with $U^\nu \equiv U$, and the effective potential:

$$V = \mathrm{diag}\left(\pm\sqrt{2}G_F n_e(x),\, 0,\, 0\right) \equiv \mathrm{diag}\,(V_e,\, 0,\, 0)\,. \tag{14.58}$$

The sign $+$ $(-)$ in Eq.(14.58) applies to neutrinos (antineutrinos), and $n_e(x)$ is the electron number density in the medium, which in general is not constant along the neutrino trajectory so the potential is not constant. Characteristic value of the potential at the Earth core is $V_e \sim 10^{-13}$ eV while at the solar core $V_e \sim 10^{-12}$ eV. Since the neutral current potential Eq.(14.55) is flavour diagonal, it can be eliminated from the evolution equation as it only contributes to an overall unobservable phase.

The instantaneous mass eigenstates in matter, ν_i^m, are the eigenstates of the Hamiltonian H in (14.56) for a fixed value of x, and they are related to the interaction basis by

$$\vec{\nu} = \tilde{U}(x)\vec{\nu^m}\,. \tag{14.59}$$

The corresponding instantaneous eigenvalues of H are $\mu_i(x)^2/(2E)$ with $\mu_i(x)$ being the instantaneous effective neutrino masses.

Let us take for simplicity a neutrino state which is an admixture of only two neutrino species $|\nu_\alpha\rangle$ and $|\nu_\beta\rangle$, so the two instantaneous mass eigenstates in matter ν_1^m and ν_2^m have instantaneous effective neutrino masses

$$
\begin{aligned}
\mu_{1,2}^2(x) = {}& \frac{m_1^2+m_2^2}{2} + E[V_\alpha + V_\beta] \\
&\mp \frac{1}{2}\sqrt{[\Delta m^2\cos 2\theta - A]^2 + [\Delta m^2 \sin 2\theta]^2}\,,
\end{aligned}
\tag{14.60}
$$

and $\tilde{U}(x)$ is a 2x2 rotation matrix with the instantaneous mixing angle in matter given by

$$\tan 2\theta_m = \frac{\Delta m^2 \sin 2\theta}{\Delta m^2\cos 2\theta - A}\,. \tag{14.61}$$

In the Eqs.(14.60) and (14.61) A is

$$A \equiv 2E(V_\alpha - V_\beta)\,, \tag{14.62}$$

and its sign depends on depends on the composition of the medium and on the flavour composition of the neutrino state considered. From the expressions above we see that for a given sign of A the mixing angle in matter is larger(smaller) than in vacuum if this last one is in the first (second) octant. We see that the symmetry about 45 degrees which existing in vacuum oscillations between two neutrino states is broken by the matter potential in propagation in a medium. The expressions above show that very important effects are present when A, is close to $\Delta m^2\cos 2\theta$. In particular, as seen in Eq.(14.61), the tangent of the mixing angle changes sign if, along its path, the neutrino passes by some matter density region satisfying, for its energy, the *resonance condition*

$$A_R = \Delta m^2 \cos 2\theta\,. \tag{14.63}$$

This implies that if the neutrino is created in a region where the relevant potential satisfies $A_0 > A_R$ (A_0 here is the value of the relevant potential at the production point), then the effective mixing angle in matter at the production point is such that $\mathrm{sgn}(\cos 2\theta_{m,0}) = -\,\mathrm{sgn}(\cos 2\theta)$. So the flavour component of the mass eigenstates is inverted as compared to their composition in vacuum. In particular, if at production point we have $A_0 = 2A_R$, then $\theta_{m,0} = \frac{\pi}{2} - \theta$. Asymptotically, for $A_0 \gg A_R$, $\theta_{m,0} \to \frac{\pi}{2}$. In other words, if in vacuum the lightest (heaviest) mass eigenstate has a larger projection on the flavour α (β), inside a matter with density and composition such that $A > A_R$, the opposite holds. So if the neutrino system is travelling across a monotonically varying matter potential, the dominant flavour component of a given mass eigenstate changes when crossing the region with $A = A_R$. This phenomenon is known as *level crossing*.

Taking the derivative of Eq.(14.59) with respect to x and using Eq.(14.56), we find that in the instantaneous mass basis the evolution equation reads:

$$i\frac{d\vec{\nu}^m}{dx} = \\ = \left[\frac{1}{2E}\,\mathrm{diag}\left(\mu_1^2(x),\,\mu_2^2(x),\,\ldots,\,\mu_n^2(x)\right) - i\,\tilde{U}^\dagger(x)\,\frac{d\tilde{U}(x)}{dx}\right]\vec{\nu}^m\,. \tag{14.64}$$

The presence of the last term, Eq.(14.64) implies that this is a system of coupled equations. So in general, the instantaneous mass eigenstates, ν_i^m are not energy eigenstates. For constant or slowly enough varying matter potential this last term can be neglected and the instantaneous mass eigenstates, ν_i^m, behave approximately as energy eigenstates and they do not mix in the evolution. This is the *adiabatic* transition approximation. On the contrary, when the last term in Eq.(14.64) cannot be neglected, the instantaneous mass eigenstates mix along the neutrino path. This implies there can be *level-jumping* [30–33] and the evolution is *non-adiabatic*.

For adiabatic evolution in matter the oscillation probability take a form very similar to the vacuum oscillation expression, Eq.(14.39). For example, neglecting CP violation:

$$P_{\alpha\beta} = \left|\sum_i \tilde{U}_{\alpha i}(0)\tilde{U}_{\beta i}(L)\exp\left(-\frac{i}{2E}\int_0^L \mu_i^2(x')dx'\right)\right|^2 . \tag{14.65}$$

To compute $P_{\alpha\beta}$ in a varying potential one can always solve the evolution equation numerically. Also several analytic approximations for specific profiles of the matter potential can be found in the literature [34].

14.5.1 *The Mihheev-Smirnov-Wolfenstein Effect for Solar Neutrinos*

The matter effects discussed in the previous section are of special relevance for solar neutrinos. As the Sun produces ν_e's in its core, here we shall consider the propagation of a $\nu_e - \nu_X$ neutrino system (X is some superposition of μ and τ, which is arbitrary because ν_μ and ν_τ have only and equal neutral current interactions) in the matter density of the Sun.

The density of solar matter is a monotonically decreasing function of the distance R from the center of the Sun, and it can be approximated by an exponential for $R < 0.9R_\odot$

$$n_e(R) = n_e(0)\exp\left(-R/r_0\right)\ , \tag{14.66}$$

with $r_0 = R_\odot/10.54 = 6.6\times10^7$ m $= 3.3\times10^{14}$ eV^{-1}.

As mentioned above, the nuclear reactions in the Sun produce electron neutrinos. After crossing the Sun, the composition of the neutrino state exiting the Sun will depend on the relative size of $\Delta m^2\cos 2\theta$ versus $A_0 = 2\,E\,G_F\,n_{e,0}$ (here 0 refers to the neutrino production point which is near but no exactly at the center of the Sun, $R=0$).

If the relevant matter potential at production is well below the resonant value, $A_R = \Delta m^2\cos 2\theta \gg A_0$, matter effects are negligible. With the characteristic matter density and energy of the solar neutrinos, this condition is fulfilled for values of Δm^2 such that $\Delta m^2/E \gg L_{\mathrm{Sun-Earth}}$. So the propagation occurs as in vacuum with the oscillating phase averaged to 1/2 and the survival probability at the exposed surface of the Earth is

$$P_{ee}(\Delta m^2\cos 2\theta \gg A_0) = 1 - \frac{1}{2}\sin^2 2\theta > \frac{1}{2}\,. \tag{14.67}$$

If the relevant matter potential at production is only slightly below the resonant value, $A_R = \Delta m^2\cos 2\theta \gtrsim A_0$, the neutrino does not cross a region with resonant density, but matter effects are sizable enough to modify the mixing. The oscillating phase is averaged in the propagation between the Sun and the Earth. This regime is well described by an adiabatic propagation, Eq.(14.65). Using that $\tilde{U}(0)$ is a 2x2 rotation of angle $\theta_{m,0}$ – the mixing angle in matter at the neutrino production point–, and $\tilde{U}(L)$ is the corresponding rotation with vacuum mixing angle θ, we get

$$\begin{aligned} P_{ee}(\Delta m^2\cos 2\theta \ge A_0) &= \cos^2\theta_{m,0}\cos^2\theta + \sin^2\theta_{m,0}\sin^2\theta \\ &= \frac{1}{2}\left[1+\cos 2\theta_{m,0}\cos 2\theta\right]\,. \end{aligned} \tag{14.68}$$

This expression reflects that an electron neutrino produced at A_0 is an admixture of ν_1 with fraction $P_{e1,0} = \cos^2\theta_{m,0}$ and ν_2 with fraction $P_{e2,0} = \sin^2\theta_{m,0}$. On exiting the Sun, ν_1 consists of ν_e with fraction $P_{1e} = \cos^2\theta$, and ν_2 consists of ν_e with fraction $P_{2e} = \sin^2\theta$ so $P_{ee} = P_{e1,0}P_{1e} + P_{e2,0}P_{2e} = \cos^2\theta_{m,0}\cos^2\theta + \sin^2\theta_{m,0}\sin^2\theta$ [35–37], exactly as given in Eq.(14.68). Since $A_0 < A_R$ the resonance is not crossed so $\cos 2\theta_{m,0}$ has the same sign as $\cos 2\theta$ and still $P_{ee} \ge 1/2$.

Finally, in the case that $A_R = \Delta m^2\cos 2\theta < A_0$, the neutrino can cross the resonance on its way out. In the convention of $\Delta m^2 > 0$ this occurs if $\cos 2\theta > 0$ ($\theta < \pi/4$). which means that in vacuum ν_e is a combination of ν_1 and ν_2 with larger ν_1 component, while at the production point ν_e is a combination of ν_1^m and ν_2^m with larger ν_2^m component. In particular, if the density at the production point is much higher than the resonant density, $\Delta m^2\cos 2\theta \ll A_0$,

$$\theta_{m,0} = \frac{\pi}{2} \quad\Rightarrow\quad \cos 2\theta_{m,0} = -1\,, \tag{14.69}$$

and the produced ν_e is purely ν_2^m.

In this regime, the evolution of the neutrino ensemble can be adiabatic or non-adiabatic depending on the particular values of Δm^2 and the mixing angle. The oscillation parameters (see Secs.14.6.1 and 14.7) happen to be such that the transition is adiabatic in all ranges of solar neutrino energies. Thus the survival probability at the exposed surface of the Earth is given by Eq.(14.68) but now with mixing angle (14.69) so

$$P_{ee}(\Delta m^2\cos 2\theta < A_0) = \frac{1}{2}\left[1+\cos 2\theta_{m,0}\cos 2\theta\right] = \sin^2\theta\,. \tag{14.70}$$

So in this case P_{ee} can be much smaller than 1/2 because $\cos 2\theta_{m,0}$ and $\cos 2\theta$ have opposite signs. This is referred to as the Mihheev-Smirnov-Wolfenstein (MSW) effect [26, 38] which plays a fundamental role in the interpretation of the solar neutrino data.

The resulting energy dependence of the survival probability of solar neutrinos is shown in Fig.14.3 (together with a compilation of data from solar experiments). The plotted curve corresponds to $\Delta m^2 \sim 7.5\times10^{-5}$ eV^2 and $\sin^2\theta \sim 0.3$ (the so-called large mixing angle, LMA, solution). The figure illustrates the regimes described above. For these values of the oscillation parameters, neutrinos with $E \ll 1$ MeV are in the regime with $\Delta m^2\cos 2\theta \gg A_0$ so the curve represents the value of vacuum averaged survival probability, Eq.(14.67), and therefore $P_{ee} > 0.5$. For $E > 10$ MeV, on the contrary, $\Delta m^2\cos 2\theta \ll A_0$ and the survival probability is given by Eq.(14.70), so $P_{ee} = \sin^2\theta \sim 0.3$. In between, the survival probability is given by Eq.(14.68) with θ_0 changing rapidly from its vacuum value to the asymptotic matter value (14.69), 90°.

14.6 Experimental Study of Neutrino Oscillations

Neutrino flavour transitions, or neutrino oscillations, have been experimentally studied using various neutrino sources and detection techniques. Intense sources and large detectors are mandatory because of a large distance necessary for observable oscillation effects in addition to the small cross sections. Also, the relevant neutrino flux before oscillations should be known with sufficient precision for a definitive measurement. Here, the experimental status of neutrino oscillations with the different neutrino sources, the Sun, Earth's atmosphere, accelerators and nuclear reactors, are reviewed.

14.6.1 *Solar Neutrinos*

14.6.1.1 *Solar neutrino flux*

In the Sun, electron neutrinos are produced in the thermonuclear reactions which generate the solar energy. These reactions occur via two main chains, the pp chain and the CNO cycle. The pp chain includes reactions $p + p \to d + e^+ + \nu$ (pp), $p + e^- + p \to d + \nu$ (pep), ${}^3\mathrm{He} + p \to {}^4\mathrm{He} + e^+ + \nu$ (hep), ${}^7\mathrm{Be}+e^- \to {}^7\mathrm{Li}+\nu(+\gamma)$ (^{7}Be), and ${}^8\mathrm{B} \to {}^8\mathrm{Be}^*+e^++\nu$ (^{8}B). The CNO cycle involves ${}^{13}\mathrm{N} \to {}^{13}\mathrm{C}+e^++\nu$ (^{13}N), ${}^{15}\mathrm{O} \to {}^{15}\mathrm{N}+e^++\nu$ (^{15}O), and ${}^{17}\mathrm{F} \to {}^{17}\mathrm{O}+e^++\nu$ (^{17}F). Those reactions result in the overall fusion of protons into ^{4}He, $4p \to^4 \mathrm{He} + 2e^+ + 2\nu_e$, where the energy released in the reaction, $Q = 4m_p - m_{^4\mathrm{He}} - 2m_e \sim 26$ MeV, is mostly radiated through the photons and only a small fraction is carried by the neutrinos, $\langle E_{2\nu_e}\rangle = 0.59$ MeV. In addition, electron capture on ^{13}N, ^{15}O, and ^{17}F produces line spectra of neutrinos called ecCNO neutrinos. Dividing the solar luminosity by the energy released per neutrino production, the total neutrino flux can be estimated. At the Earth, the pp solar neutrino flux is about 6×10^{10} cm^{-2}s^{-1}.

The detailed calculation of the solar neutrino fluxes has been done based on the Standard Solar Model (SSM). The SSM describes the structure and evolution of the Sun based on a variety of inputs such as the mass, luminosity, radius, surface temperature, age, and surface elemental abundances. In addition, the knowledge of the absolute nuclear reaction cross sections for the relevant fusion reactions and the radiative opacities are necessary. John Bahcall and his collaborators continuously updated the SSM calculations over several decades [39, 40]. Figure 14.1 shows the solar neutrino fluxes predicted by the SSM calculation in [41] and ecCNO neutrinos in [42].

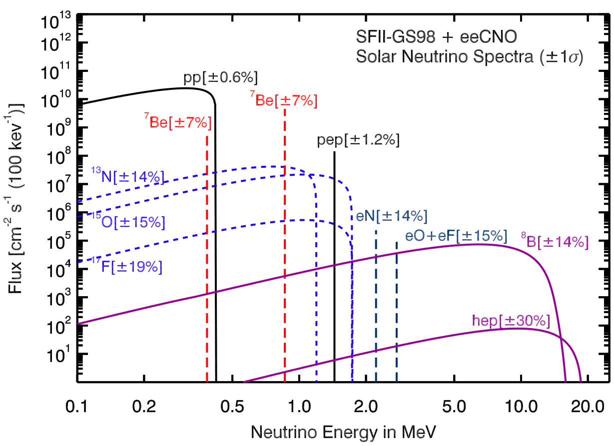

Figure 14.1: Spectrum of solar neutrino fluxes predicted by SSM calculation in [41]. In addition to standard fluxes, ecCNO neutrinos have been added based on [42]. Electron capture fluxes are given in cm^{-2}s^{-1}. Taken from [43]

14.6.1.2 *Detection of solar neutrinos and the solar neutrino problem*

Experiments which observed solar neutrinos are summarized in Table 14.2.

A pioneering solar neutrino experiment was carried out by R. Davis, Jr. and collaborators at Homestake starting in the late 1960s [44]. The Davis' experiment utilizes the reaction $\nu_e+{}^{37}\mathrm{Cl} \to e^-+{}^{37}\mathrm{Ar}$. Because this process has an energy threshold of 814 keV, the most relevant fluxes are the ^{7}Be and ^{8}B neutrinos. The detector contained $\sim$ 615 t of C_2Cl_4. The produced ^{37}Ar, which has a half life of 34.8 d, was chemically extracted and introduced into a low-background proportional chamber every few months. The Auger electrons from electron capture of ^{37}Ar were counted to determine the reaction rate.

From the beginning, the observed number of neutrinos in the Homestake mine experiment was significantly smaller than the prediction by SSM — it was almost one third. After thorough check of both experimental and theoretical work, the discrepancy remained. This became to be known as the solar neutrino problem. The final result from Homestake experiment is $2.56 \pm 0.16 \pm 0.16$ SNU [45], where SNU (solar neutrino unit) is a unit of event rate, 1 SNU $= 10^{-36}$ captures/(s atom). On the other hand, prediction based on SSM is $8.46^{+0.87}_{-0.88}$ SNU [46].

The detection of neutrinos from other production processes was recognized as an important input to investigate the origin of the solar neutrino problem. In particular, the pp neutrino is most abundant, and its flux prediction has the smallest uncertainty. Using the radiochemical technique with gallium, the reaction $\nu_e + {}^{71}\mathrm{Ga} \to e^- + {}^{71}\mathrm{Ge}$ has an energy threshold of 233 keV and can be used for the pp neutrino detection. According to the SSM, more than a half of the events on ^{71}Ga are due to the pp neutrinos, with the second dominant contribution coming from the ^{7}Be neutrinos. ^{71}Ge decays via electron capture with a half life of 11.4 d. The SAGE experiment in Baksan [47] used about 50 t of liquid metallic gallium as a target. The GALLEX experiment in LNGS [48] used 101 t of $GaCl_3$, containing 30.3 t of gallium. Both experiments used natural gallium, containing 39.9% of ^{71}Ga isotope. GALLEX was followed by its successor GNO experiment. The measured capture rate is $69.3 \pm 4.1 \pm 3.6$ SNU for GALLEX+GNO [49] and $65.4^{+3.1+2.6}_{-3.0-2.8}$ SNU for SAGE [50]. A SSM prediction is $127.9^{+8.1}_{-8.2}$ SNU [46].

The radiochemical detectors measure the reaction rate integrated between extractions. The real time measurement of solar neutrino was realized by the Kamiokande experiment [51]. The Kamiokande detector was a 3,000-t water-Cherenkov detector in the Kamioka mine. An array of 50 cm diameter PMTs were attached onto the inner wall of the detector to detect Cherenkov light. Although the original purpose of the Kamiokande detector was search for nucleon decays, with an upgrade of detector Kamiokande-II achieved an energy threshold sufficiently low to allow for the observation of solar neutrinos using ν-e elastic scattering (ES), $\nu_x + e^- \to \nu_x + e^-$. The signal and background from radioactivity can be statistically separated by using the directional correlation between the incoming neutrino and the recoil electron. The Super-Kamiokande, the successor of Kamiokande, started operation in April 1996. It is a large upright cylindrical water Cherenkov detectorcontaining 50 kt of pure water. An inner detector volume corresponding to 32 kt water mass is viewed by more than 11,000 inward-facing 50 cm diameter PMTs.

The ES reaction occurs via both charged and neutral current interactions. Consequently, it is sensitive to all active neutrino flavours, although the cross section for ν_e, which is the only flavour to interact via charged current, is about six times larger than that for ν_μ or ν_τ. Because the energy threshold is 6.5 MeV for Kamiokande and 3.5 MeV for the present Super-Kamiokande (for the kinetic energy of recoil electron), these experiments are sensitive to primarily to ^{8}B neutrinos.

The results from Kamiokande [52, 53] and Super-Kamiokande [54, 55] showed significantly smaller numbers of observed solar neutrinos compared to the prediction. The latest ^{8}B neutrino flux measured by Super-Kamiokainde is $(2.345{\pm}0.014{\pm}0.036){\times}10^6$ cm^{-2}s^{-1} [56], while a prediction based on the SSM is $(5.46 \pm 0.66) \times 10^6$ cm^{-2}s^{-1} [57]. In addition, no significant zenith angle variation nor spectrum distortion were observed in the initial phase of Super-Kamiokande, which placed strong constraints on the solution of the solar neutrino problem [58, 59].

14.6.1.3 *Solution of the solar neutrino problem*

SNO experiment in Canada used 1,000 t of heavy water (D_2O) contained in a spherical acrylic vessel which was surrounded by an H_2O shield. An array of PMTs installed on a stainless steel structure detected Cherenkov radiation produced in both the D_2O and H_2O. The SNO detector observed ^{8}B neutrinos via three different reactions. In addition to the ES scattering with an electron, with D_2O target the charged current (CC) $\nu_e + d \to e^- + p + p$ and the neutral current (NC) $\nu_x + d \to \nu_x + p + n$ interactions are possible. The CC reaction is sensitive to only ν_e, while NC reaction is sensitive to all active flavours of neutrinos with equal cross sections. Therefore, by comparing the measurements of different reactions, SNO could provide a model independent test of the neutrino flavour change.

In 2001, SNO reported the initial result of CC measurement [62]. Combined with the high statistics measurement of ν-e elastic scattering from Super-Kamiokande [58], it provided a direct evidence for existence of non-ν_e component in solar neutrino flux. The result of NC measurement in 2002 [63] established it

Table 14.2: List of solar neutrino experiments

Name	Target material	Energy threshold (MeV)	Mass (ton)	Years
Homestake	C_2Cl_4	0.814	615	1970–1994
SAGE	Ga	0.233	50	1989–
GALLEX	$GaCl_3$	0.233	100 [30.3 for Ga]	1991–1997
GNO	$GaCl_3$	0.233	100 [30.3 for Ga]	1998–2003
Kamiokande	H_2O	6.5	3,000	1987–1995
Super-Kamiokande	H_2O	3.5	50,000	1996–
SNO	D_2O	3.5	1,000	1999–2006
KamLAND	Liquid scintillator	0.5/5.5	1,000	2001–2007
Borexino	Liquid scintillator	0.19	300	2007–

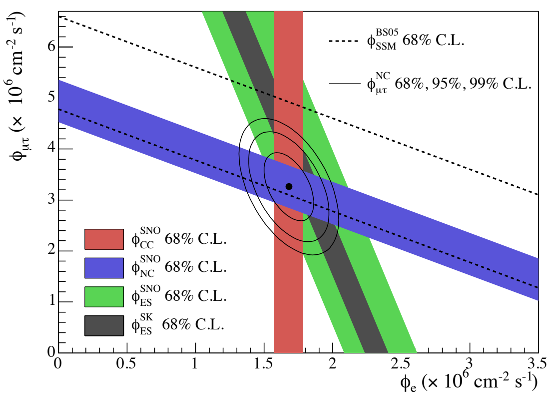

Figure 14.2: Fluxes of ^{8}B solar neutrinos, $\phi(\nu_e)$, and $\phi(\nu_{\mu,\tau})$, deduced from the SNO's CC, ES, and NC results [60]. The Super-Kamiokande ES flux is from [61]. The BS05(OP) standard solar model prediction [40] is also shown. The bands represent the 1σ error. The contours show the 68%, 95%, and 99% joint probability for $\phi(\nu_e)$ and $\phi(\nu_{\mu,\tau})$. The figure is from [60].

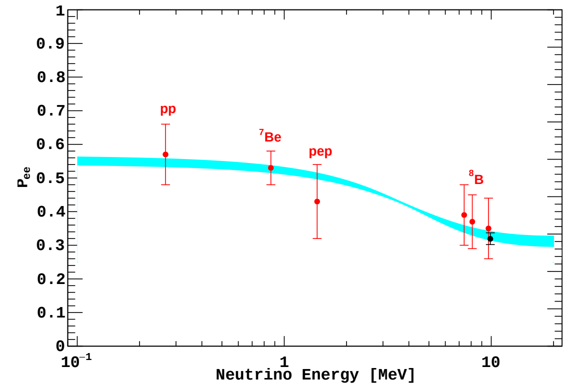

Figure 14.3: Electron neutrino survival probability as a function of neutrino energy. The points represent, from left to right, the Borexino pp, ^{7}Be, pep, and ^{8}B data (red points) and the SNO+SK ^{8}B data (black point). The three Borexino ^{8}B data points correspond, from left to right, to the low-energy (LE) range, LE+HE range, and the high-energy (HE) range. The electron neutrino survival probabilities from experimental points are determined using a high metallicity SSM from Ref. [57]. The error bars represent the $\pm 1\sigma$ experimental + theoretical uncertainties. The curve corresponds to the $\pm 1\sigma$ prediction of the MSW-LMA solution using the parameter values given in [65]. This figure is provided by A. Ianni.

with 5.3σ of statistical significance. Figure 14.2 shows the fluxes of electron neutrinos ($\phi(\nu_e)$) and muon and tau neutrinos ($\phi(\nu_{\mu,\tau})$) with the 68%, 95%, and 99% joint probability contours, obtained with the SNO data. Finally, together with the reactor neutrino experiment KamLAND (see Sec.14.6.4), the solution of solar neutrino problem was found to be the MSW adiabatic flavour transitions in the solar matter, the so-called large mixing angle (LMA) solution, with parameters $\Delta m^2 \sim 7.5\times 10^{-5}$ eV^2 and $\sin^2\theta \sim 0.3$.

From a combined result of three phases of SNO [64], the total flux of ^{8}B solar neutrino is found to be $(5.25\pm 0.16^{+0.11}_{-0.13})$ cm^{-2}s^{-1}, consistent with the SSM prediction. This consistency is one of major accomplishments of SSM.

In order to understand the SSM as well as to study the MSW effect for the solar neutrino, measurements of solar neutrinos other than ^{8}B are important. The Borexino experiment at Gran Sasso, Italy, detects solar neutrino via ν-e scattering in real time with a low energy threshold. The Borexino detector consists of 300 t of ultra-pure liquid scintillator, which achieved 0.19 MeV of energy threshold and 5% energy resolution at 1 MeV. Borexino reported the first real time detection of ^{7}Be solar neutrinos [66]. They also measured the fluxes of *pep* [67] and *pp* neutrino [68] for the first time. Together with ^{8}B [69] neutrino measurement, Borexino provides important data to study the MSW effect. The KamLAND experiment also measured ^{8}B [70] and ^{7}Be [71] solar neutrinos. Figure 14.3 shows the survival probability of solar ν_e as a function of neutrino energy. The data points are from the Borexino results [72, 73] except the SNO+SK ^{8}B data. The theoretical curve shows the prediction of the MSW-LMA solution. All the data shown in this plot are consistent with the theoretically calculated curve. This indicates that these solar neutrino measurements are consistent with the MSW-LMA solution of the solar neutrino problem.

The matter effects can also be relevant to the propagation of solar neutrinos through the Earth. Because solar neutrinos go through the Earth before interaction in the detector during the nighttime, a comparison of measured event rate between daytime and nighttime provides a clean and direct test of matter effects on neutrino oscillations. Super-Kamiokande reported the first indication of the day/night asymmetry in ^{8}B solar neutrinos [74]. The measured asymmetry, defined as the difference of the average day rate and average night rate divided by the average of those two rates, is $(-3.2\pm 1.1\pm 0.5)$%, corresponding to a statistical significance of 2.7σ. The measured value of the asymmetry is consistent with the LMA solution.

14.6.2 *Atmospheric Neutrinos*

14.6.2.1 *Atmospheric neutrino flux*

Atmospheric neutrinos are produced by the decays of pions and kaons generated in the interaction of cosmic rays and nucleons in the Earth's atmosphere. They have a broad range of energy ($\sim$0.1 GeV to >TeV) and long travel distances before detection ($\sim$10 to 1.3×10^4 km). As shown in Table 14.1, atmospheric neutrino oscillation experiments are most sensitive to flavour oscillations with $\Delta m^2 \sim 10^{-1}$ to 10^{-4} eV^2.

Considering their dominant production modes, some generic relations for flux ratios of different flavour of neutrinos can be derived without detailed calculations. From the decay chain of a charged pion $\pi^+ \to \mu^+\nu_\mu$ followed by $\mu^+ \to e^+\nu_e\bar{\nu}_\mu$ (and the charge conjugate for π^-), the ratio $(\nu_\mu+\bar{\nu}_\mu)/(\nu_e+\bar{\nu}_e)$ is expected to be around 2 at low energies ($\sim$ 1 GeV) where most muons decay in the atmosphere. For higher energies, some of muons reach the Earth before they decay and the ratio increases. One can also expect that the zenith angle distributions of atmospheric neutrinos are symmetric between upward-going and downward-going neutrinos. It is true for the energy above 1 GeV, but at lower energies, the Earth's geomagnetic field induces up-down asymmetries in the the primary cosmic ray. The zenith angle corresponds to the flight length of atmospheric neutrinos. Vertically upward-going neutrinos come from the other side of the Earth with flight lengths of $\sim 10^4$ km, while downward-going neutrinos produced just above the experimental site travel $\sim$10 km before detection.

The atmospheric neutrino fluxes are calculated in detail based on the energy spectrum and composition of primary cosmic rays and their hadronic interactions in the atmosphere. The effects of solar activity and geomagnetic field should be also taken into account. Results of calculations by several groups are available [75–78]. A typical uncertainty of the absolute flux is 10–20%, while the ratio of fluxes between different flavour has much smaller uncertainty ($< 5\%$).

14.6.2.2 *Observation of atmospheric neutrino oscillations*

The first detection of atmospheric neutrinos was reported in the 1960's by the underground experiments in the Kolar Gold Field experiment in India [79] and in South Africa [80]. In the 1980's, experiments searching for nucleon decays started operation. They used large underground detectors which could also observe atmospheric neutrinos. In these experiments, atmospheric neutrinos were studied as backgrounds to nucleon decays. Among the early experiments were Kamiokande [81] and IMB [82] using water Cherenkov detectors, and Frejus [83] and NUSEX [84] using iron tracking calorimeters.

The flavour of atmospheric neutrino can be identified in charged current interaction with nuclei, which produces the corresponding charged lepton. In order to study the neutrino oscillations, the identification of charged lepton is essential. Those detectors originally designed for nucleon decay search had capability to distinguish muons and electrons. For example, a water Cherenkov detector can utilize the information from Cherenkov ring patterns for particle identification; e-like particles ($e^{\pm}$, γ) produce more diffuse ring than μ-like particles ($\mu^{\pm}$, $\pi^{\pm}$) because of electromagnetic cascades and multiple Coulomb scattering effects.

To reduce the uncertainty, in early results the flux ratio $\nu_\mu/\nu_e \equiv (\nu_\mu + \bar{\nu}_\mu)/(\nu_e + \bar{\nu}_e)$ was measured, and the double ratio between observation and expectation $(\nu_\mu/\nu_e)_{\rm obs}/(\nu_\mu/\nu_e)_{\rm exp}$ was reported. The Kamiokande experiment reported an indication of a deficit of $(\nu_\mu + \bar{\nu}_\mu)$ flux [81]. IMB also observed similar deficit [82], but measurements by Frejus [83] and NUSEX [84] were consistent with the expectations. This was the original formulation of the atmospheric neutrino anomaly. Kamiokande reported studies with an increased data set of the sub-GeV (< 1.33 GeV) [85] as well as the multi-GeV (> 1.33 GeV) [86] samples. In the latter, they reported an analysis of zenith angle distributions, which showed an indication that the muon disappearance probability is dependent on the zenith angle, hence the travel length of neutrinos. However, the statistical significance was not sufficient to provide a conclusive interpretation.

The solution to the atmospheric neutrino anomaly was brought by Super-Kamiokande, which reported compelling evidence for neutrino oscillations in atmospheric neutrinos in 1998 [87]. The zenith angle (θ_z, with $\theta_z = 0$ for vertically downward-going) distributions of μ-like events showed a clear deficit of upward-going events, while no significant asymmetry was observed for e-like events. The asymmetry is defined as $A = (U - D)/(U + D)$, where U is the number of upward-going ($-1 < \cos\theta_{\rm z} < -0.2$) events and D is the number of downward-going ($0.2 < \cos\theta_{\rm z} < 1.0$) events. With multi-GeV (visible energy > 1.33 GeV) μ-like events alone, the measured asymmetry was $A = -0.296 \pm 0.048 \pm 0.001$, deviating from zero by more than 6σ. The sub-GeV (< 1.33 GeV) μ-like, upward through going, and upward stopping μ samples, which correspond to different energy range of neutrino, show the consistent behaviour, strengthening the credibility of the observation. The corresponding oscillation parameters were found to be $\Delta m^2 \sim 2.5 \times 10^{-3}$ eV^2 and $\theta \sim 45°$. Super-Kamiokande's results were confirmed by other atmospheric neutrino observations MACRO [88] and Soudan2 [89].

Although the energy and zenith-angle dependent muon neutrino disappearance observed with atmospheric neutrinos could be consistently explained by the neutrino oscillations between ν_μ and ν_τ, other exotic explanations such as neutrino decay or decoherence were not initially ruled out. By using a selected sample from Super-Kamiokande's atmospheric data with good L/E resolution, the L/E dependence of the survival probability was measured [90]. The observed dip in the L/E distribution was consistent with the expectation from neutrino oscillation, while alternative models were strongly disfavored.

As an experimental proof of ν_μ-ν_τ oscillation, appearance signal of ν_τ was searched for in the atmospheric neutrino data. Because of the high energy threshold (> 3.5 GeV) of ν_τ CC interaction and the short lifetime of τ lepton (0.3 ps), the identification of ν_τ appearance is experimentally very difficult. Super-Kamiokande reported evidence of tau neutrino appearance using atmospheric neutrino data with 4.6σ significance [91]. The definitive observation of ν_τ appearance was made by the long-baseline experiment, OPERA [92] (See Sec.14.6.3.3), and recently IceCube also reported the ν_τ appearance analysis [93] using atmospheric neutrinos.

14.6.2.3 *Neutrino oscillation measurements using atmospheric neutrinos*

Figure 14.4 shows the zenith angle distributions of atmospheric neutrino data from Super-Kamiokande. For wide range of neutrino energy and path length, the observed distributions are consistent with the expectation from neutrino oscillation. Atmospheric neutrinos in the energy region of a few to $\sim$10 GeV provide information for the determination of the neutrino mass ordering [94].

The neutrino telescopes primarily built for the high energy neutrino astronomy such as ANTARES [95] and IceCube [96] can also measure neutrino oscillations with atmospheric neutrinos. ANTARES consists of a sparse array of PMTs deployed under the Mediterranean Sea at a depth of about 2.5 km to to instrument a 10^5 m^3 volume. IceCube is a detector deployed in ice in Antarctica at the South Pole, at depth between 1.45 and 2.45 km. In the bottom center of IceCube there is a region of $\sim 10^7$ m^3 volume with denser PMT spacing called DeepCore to extend the observable energies to lower energy region. By observing the charged current interaction of up-going ν_μ, they measure the ν_μ disappearance. ANTARES reported a measurement of ν_μ disappearance with 20 GeV threshold [97]. With analysis of events with 6–56 GeV energy range, the results on ν_μ disappearance measurements from IceCube DeepCore [98] provided a precision comparable to the measurements by Super-Kamiokande and long-baseline experiments.

There are several projects for atmospheric neutrino observations either proposed or under preparation. The atmospheric neutrino observation program is included in the plans for future neutrino telescopes, ORCA in the second phase of KM3NeT project [99] in the Mediterranean Sea, and PINGU in the upgrade of IceCube [100]. In India, a 50 kt magnetized iron tracking calorimeter ICAL is planned at the INO [101]. Future large underground detectors, Hyper-Kamiokande in Japan [102] and DUNE in US [103] can also study the atmospheric neutrinos.

14.6.3 *Accelerator Neutrinos*

14.6.3.1 *Accelerator neutrino beams*

A comprehensive description of the accelerator neutrino beams is found in [104]. Conventional neutrino beams from accelerators are produced by colliding high energy protons onto a target, producing π and K which then decay into neutrinos, and stopping undecayed mesons and muons in the beam dump and soil. Because pions are the most abundant product in the high energy collisions, a conventional neutrino beam contains dominantly muon-type neutrinos (or antineutrinos).

Focusing devices called magnetic horns are used to concentrate the neutrino beam flux towards the desired direction. A magnetic horn is a pulsed electromagnet with toroidal magnetic fields to focus charged particles that are parents of neutrinos. One can choose the dominant component of the beam to be either neutrinos or antineutrinos by selecting the direction of current in the magnetic horns. Even with the focusing with horns, *wrong sign* neutrinos contaminate in the beam. Also, there is small amount of contamination of ν_e and $\bar{\nu}_e$ coming primarily from kaon and

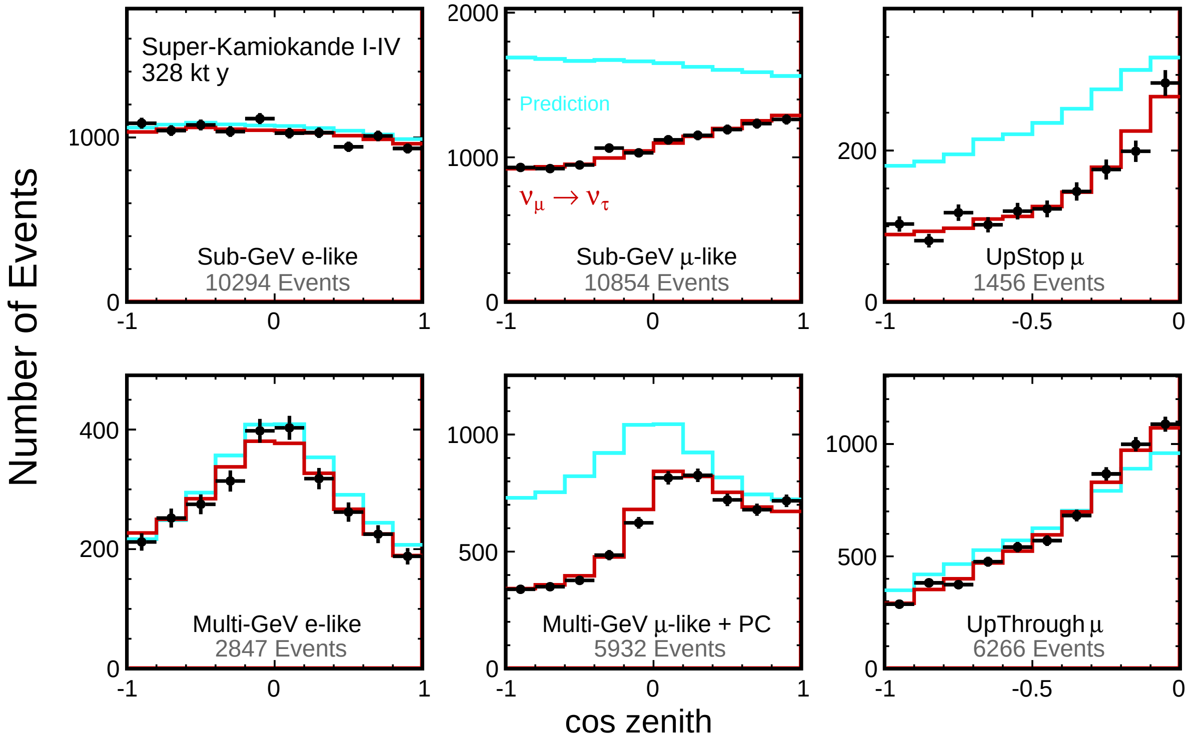

Figure 14.4: The zenith angle distributions of Super-Kamiokande atmospheric neutrino events. Fully contained 1-ring e-like and μ-like events with visible energy < 1.33 GeV (sub-GeV) and > 1.33 GeV (multi-GeV), as well as upward stopping and upward stopping μ samples are shown. Partially contained (PC) events are combined with multi-GeV μ-like events. The blue histograms show the non-oscillated Monte Carlo events, and the red histograms show the best-fit expectations for ν_μ-ν_τ oscillations. (This figure is provided by the Super-Kamiokande Collaboration)

Table 14.3: List of long-baseline neutrino oscillation experiments

Name	Beamline	Far Detector	L (km)	E_ν (GeV)	Year
K2K	KEK-PS	Water Cherenkov	250	1.3	1999–2004
MINOS	NuMI	Iron-scintillator	735	3	2005–2013
MINOS+	NuMI	Iron-scintillator	735	7	2013–2016
OPERA	CNGS	Emulsion	730	17	2008–2012
ICARUS	CNGS	Liquid argon TPC	730	17	2010–2012
T2K	J-PARC	Water Cherenkov	295	0.6	2010–
NOvA	NuMI	Liquid scint. tracking calorimeter	810	2	2014–

muon decays.

In order to maximize the sensitivity of the experiment, the ratio of baseline and neutrino energy (L/E) should be chosen to match the oscillation effects to be studied. In addition to maximizing the flux of neutrinos with relevant energy, neutrinos with irrelevant energy that result in unwanted background process should be suppressed. The energy of neutrino from a pion decay is

$$E_\nu = \frac{[1-(m_\mu/m_\pi)^2]E_\pi}{1+\gamma^2\theta^2}, \tag{14.71}$$

where E_ν and E_π are the energy of neutrino and pion, respectively, θ is the angle between the pion and neutrino direction, and $\gamma = E_\pi/m_\pi$. For $\theta = 0$, the energy of neutrino is linearly proportional to the energy of pion. In this case, a narrow band beam can be made by selecting the momentum of pions. On the other hand, for $\theta \neq 0$, the energy of neutrino is not strongly dependent on the parent energy for a wide range of pion energy, but dependent on the off-axis angle θ. Using this relation, a neutrino beam with narrow energy spectrum, around the energy determined by θ, can be produced. This off-axis beam method was first introduced for BNL E889 proposal [105] and adopted in T2K and NOvA experiments. For a list of neutrino beamlines, see also the review 32. Neutrino Beam Lines at High-Energy Proton Synchrotrons.

As indicated in Table 14.1, there are two different scales of baselines for accelerator-based experiments to study different ranges of Δm^2. The atmospheric mass splitting $\Delta m^2 \sim 2.5 \times 10^{-3}$ eV^2 gives rise to the first oscillation maximum at $L/E \sim 500$ GeV/km. In order to study this parameter region with ~ 1 GeV accelerator neutrino beam, a long baseline of a few hundreds to thousand km is necessary. On the other hand, there have been reports of possible neutrino oscillations at ~ 1 eV scale, which can be studied at ~ 1 km baseline with neutrinos from accelerators. These experiments are called short-baseline oscillation experiments.

The flux of a neutrino beam is calculated using Monte Carlo simulation based on the configuration of the beamline. An important ingredient of the neutrino flux prediction is the hadron production cross section. Data from dedicated hadron production experiments [106–108] are used to tune the beam simulation and constrain the uncertainty. The uncertainty of predicted neutrino flux for the most relevant energy region is ∼5–10% with the latest hadron production data.

14.6.3.2 *Near detectors and neutrino interaction cross sections*

Many long-baseline experiments use two detectors to reduce the systematic uncertainties arising from neutrino flux and neutrino-nucleus interactions. The near detectors either use the same technology as the far detector or consist of sub-detectors with complementary functions to obtain detailed information of the neutrino beam and interactions. The near detectors provide information for the neutrino flux, energy spectrum, and the interaction cross sections, which is used as an input to make predictions of observables at the far detector. However, even with the two-detector configuration, one should note that the neutrino flux is inevitably different between the near and the far detectors. In addition to the fact that the neutrino source looks like a line source for the near detector while it looks as a point source for the far detector, the neutrino oscillations alter the flavour composition of the neutrino beam quite significantly, as the design of a neutrino oscillation experiment requires.

For the precision measurements of neutrino oscillations with long-baseline experiments, the understanding of the neutrino-nucleus interaction becomes crucial. Because heavy nuclei are used as the interaction target, the nuclear effects complicate the understanding of the neutrino-nucleus interaction. For more information on the neutrino cross sections, see also the review 50. Neutrino Cross Section Measurements.

14.6.3.3 *Long-baseline experiments*

The first long-baseline experiment was the K2K experiment which used a neutrino beam from the KEK 12 GeV proton synchrotron directed towards Super-Kamiokande with a baseline of 250 km [109]. The beam had an average energy of 1.3 GeV. The K2K near detectors, located 300 m downstream of the production target, consisted of a combination of a 1 kt water Cherenkov detector and a set of fine grained detectors. K2K reported the confirmation of muon neutrino disappearance originally reported by Super-Kamiokande atmospheric neutrino observation [110].

The MINOS experiment used a beam from Fermilab and a detector in Soudan mine 735 km away [111]. The neutrino beam is produced in NuMI beamline [112] with 120 GeV proton beam from the Main Injector. The MINOS detectors are both iron-scintillator tracking calorimeters with toroidal magnetic fields. The far detector was 5.4 kt, while the near detector had a total mass of 0.98 kt and was located 1 km downstream of the production target. The NuMI beamline can vary the neutrino energy spectrum by changing the relative position of target and horns. Most of MINOS data were taken with the "low energy" configuration with the peak energy of around 3 GeV. MINOS combined accelerator and atmospheric neutrino data in both disappearance and appearance modes to measure oscillation parameters [113, 114]. Utilizing the separation of μ^- and μ^+ with the magnetic field in the far detector, MINOS also reported separate measurements of atmospheric neutrinos and antineutrinos [115].

When the NuMI beamline started operation for the NOvA experiment in 2013, it was set to the "medium energy" configuration which provided a beam with the peak neutrino energy of around 7 GeV to the MINOS+ experiment, which used the same MINOS near and far detectors. MINOS+ verified the energy dependence of ν_μ disappearance at energies above the first oscillation maximum. Utilizing the wide neutrino energy spectrum and high intensity in the medium energy configuration, limits on sterile neutrinos is reported [116].

In Europe, the CNGS neutrino beamline provided a beam with mean energy of 17 GeV from CERN to LNGS for long-baseline experiments with 732 km of baseline. The beam energy was chosen so that charged current (CC) interaction of ν_τ can occur for direct confirmation of ν_τ appearance. There was no near detector in CNGS because it was not necessary for the ν_τ appearance search. The OPERA experiment used a detector consisted of an emulsion/lead target with about 1.25 kt total mass complemented by electronic detectors. The excellent spatial resolution of emulsion enabled the event-by-event identification of τ leptons. OPERA observed ten ν_τ CC candidate events with 2.0±0.4 expected background [92] and confirmed $\nu_\mu \to \nu_\tau$ oscillation in appearance mode with a statistical significance of 6.1σ. Another neutrino experiment, ICARUS [117], which used 600 t liquid argon time projection chambers, was operated in Gran Sasso from 2010 to 2012.

The first generation of long-baseline experiments confirmed the existence of neutrino oscillation. The major initial goal of second generation experiments was the observation of $\nu_\mu \to \nu_e$ oscillation. Using this appearance mode, by comparison of neutrino and antineutrino oscillation probabilities, search for CP violation in the neutrino mixing becomes possible.

The T2K experiment started in 2010 using a newly constructed high-intensity proton synchrotron J-PARC and the Super-Kamiokande detector. It is the first long-baseline experiment to employ the off-axis neutrino beam. The off-axis angle of 2.5° was chosen to set the peak of neutrino energy spectrum at 0.6 GeV, matching the first maximum of oscillation probability at the 295 km baseline for $\Delta m^2 \sim 2.5 \times 10^{-3}$ eV^2. T2K employs a set of near detectors at about 280 m from the production target. The on-axis detector, called INGRID, is an array of iron-scintillator sandwich trackers to monitor the beam intensity, direction and profile. The off-axis detector ND280, consisting of several sub-detectors inside a magnet, is placed in the direction of far detector to measure the neutrino beam properties and to study neutrino interactions.

In 2011, T2K reported the first indication of $\nu_\mu \to \nu_e$ oscillation with a statistical significance of 2.5σ [118]. In the framework of 3ν mixing, it corresponds to detecting non-zero amplitude generated by the mixing angle θ_{13} (see Eq.14.33). Later $\nu_\mu \to \nu_e$ oscillation was established by T2K with more than 7σ in 2014 [119]. Figure 14.5 shows the reconstructed energy distributions from T2K, for neutrino and anti-neutrino beam mode and also for muon and electron candidates. The muon type events show clear deficit in both neutrino and antineutrino mode, consistent with the energy-dependent disappearance probability expected from neutrino oscillations. By a combined analysis of the neutrino and antineutrino data, T2K reported a hint of CP violation with more than 2σ [120, 121].

The NOvA experiment uses the NuMI beamline with an off-axis configuration. The 14 kt NOvA far detector is located near Ash River, Minnesota, 810 km away from the source. At 14.6 mrad off-axis from the central axis of the NuMI beam, the neutrino energy spectrum at the far detector has a peak around 2 GeV, corresponding to the first oscillation maximum at 810 km baseline. The near detector, located around 1 km from the source, has a functionally identical design to the far detector with a total active mass of 193 t. Both detectors are tracking calorimeters consisting of planes of polyvinyl chloride cells alternating in vertical and horizontal orientation filled with liquid scintillator.

The physics run of NOvA was started in 2014. Although the initial data indicated non-maximal mixing [122], later analysis with increased data and improved analysis resulted in the allowed region consistent with maximal mixing [123]. After confirmation of ν_e appearance from ν_μ beam [124, 125], NOvA started data taking with antineutrino beam in 2016. Using the antineutrino beam data, NOvA has sreported the observation of $\bar{\nu}_e$ appearance from $\bar{\nu}_\mu$ beam with 4.4σ significance [126]. Figure 14.6 shows the reconstructed neutrino energy distributions from NOvA. Some values of the CP-violating phase $\delta_{\rm CP}$ (see Eq.14.33) have been excluded for the inverted mass ordering ($m_3 < m_2 < m_1$, see Sec.14.7 for definitions), while no significant limit has been set for the case of normal mass ordering ($m_1 < m_2 < m_3$, see Sec.14.7 for definitions).

Two large-scale long-baseline experiments are under preparation or proposed in future. DUNE [103] will be a 1,300 km long-baseline experiment based in US. The DUNE far detector will consist of four modules of at least 10 kt fiducial mass liquid argon time projection chambers, located 1.5 km underground at the Sanford Underground Research Facility in South Dakota. The beamline for DUNE, 1.2 MW at start and upgradable to 2.4 MW, as well as the facility for near detectors will be newly constructed at Fermilab. In Japan, Hyper-Kamiokande [102] is proposed as the successor of the Super-Kamiokande detector. It will be a water Cherenkov detector with 260 (190) kt total (fiducial) mass. With upgrade of existing accelerator and beamline, J-PARC will provide a 1.3 MW neutrino beam to Hyper-Kamiokande. Both DUNE and Hyper-Kamiokande will have a rich physics program besides the long-baseline experiment, such as searches for nucleon decays and study of supernova neutrinos.

14.6.3.4 *Short-baseline experiments*

The LSND experiment searched for neutrino oscillation using neutrinos from stopped pions at Los Alamos. A 800 MeV linac was used to produce pions which stopped in the target. Most of

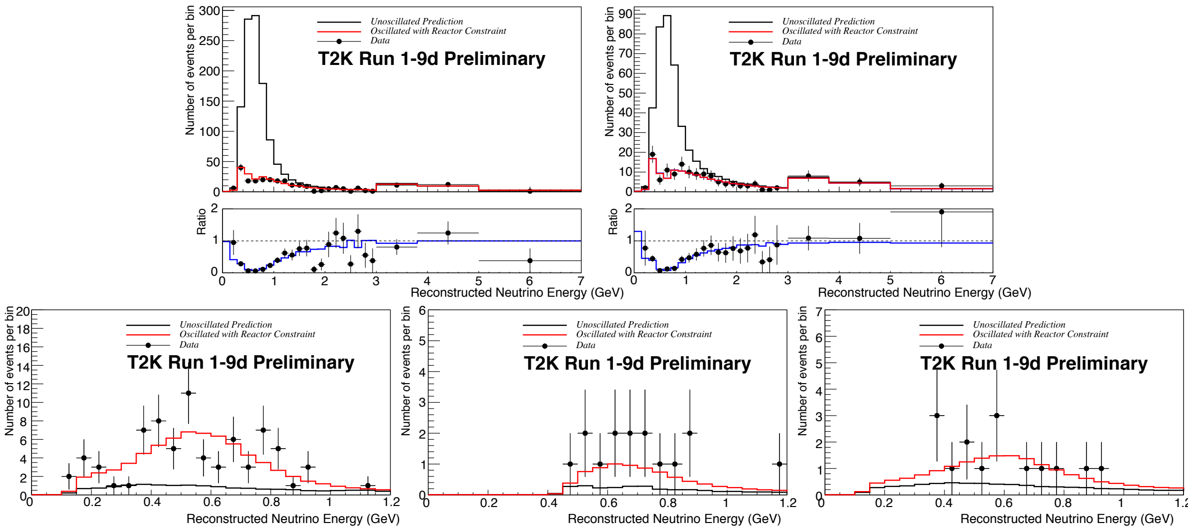

Figure 14.5: Reconstructed neutrino energy distributions from T2K. Data points with statistical error bars are shown together with the prediction without (black line) and including (red line) neutrino oscillation. Top: Single ring μ-like events. The left and right plot is for neutrino and antineutrino beam mode, respectively. Below each plot, the ratio to the prediction without oscillation is also shown. Bottom: Single ring e-like events. From left to right, 0 decay electron sample for neutrino beam, 1 decay electron sample for neutrino beam, and 0 decay electron sample for antineutrino beam. (This figure is provided by the T2K Collaboration)

π^-s are absorbed by the nuclei inside the target, while π^+s and their daughter μ^+s decay and produce neutrinos. Therefore, the produced neutrinos are mostly ν_μ, $\bar{\nu}_\mu$, and ν_e with very small contamination of $\bar{\nu}_e$. The detector was a tank filled with 167 t of diluted liquid scintillator, located about 30 m from the neutrino source. LSND searched for $\bar{\nu}_\mu \to \bar{\nu}_e$ appearance using the inverse beta decay process, $\bar{\nu}_e + p \to e^+ + n$, and found an excess of $87.9 \pm 22.4 \pm 6.0$ events over the expected background [127].

The KARMEN experiment was performed at the neutron spallation facility ISIS of the Rutherford Appleton Laboratory. The KARMEN 2 detector was a segmented liquid scintillation calorimeter with total volume of 65 m^3 located at a mean distance of 17.7 m from the ISIS target. KARMEN found a number of events consistent with the total background expectation, showing no signal for $\bar{\nu}_\mu \to \bar{\nu}_e$ oscillations [128]. The resulting limits exclude large regions of the parameter area favored by LSND.

The MiniBooNE experiment at Fermilab used a conventional neutrino beam to search for ν_e and $\bar{\nu}_e$ appearance in the same parameter region as LSND. The booster neutrino beamline (BNB) with a single magnetic horn uses a 8 GeV proton beam from the Fermilab booster to produce a neutrino (antineutrino) beam with energy spectrum peak of 600 (400) MeV. The MiniBooNE detector consists of a 12.2 m diameter sphere filled with 818 t of mineral and oil located 541 m from the target. MiniBooNE reported ν_e and $\bar{\nu}_e$ event excess in both neutrino and antineutrino running modes. In total, 460.5 ± 99.0 excess events are observed over the expected backgrounds, corresponding to 4.7σ significance [129].

Both LSND and MiniBooNE are single detector experiments. The reported excess will be further investigated with the multi-detector short-baseline neutrino (SBN) program at Fermilab BNB [130]. The SBN program comprises three liquid argon time projection chambers at different baselines in the same neutrino beamline. The 112 t Short-Baseline Near Detector will be located at 110 m from the target. The 85 t MicroBooNE detector has been operated at 470 m from the target. The ICARUS detector has been transported from Europe after refurbishment at CERN and is located at a baseline of 600 m.

JSNS^2 experiment at J-PARC will search for neutrino oscillations with $\Delta m^2 \sim 1$ eV^2 [131]. 1MW proton beam from the 3 GeV Rapid Cycling Synchrotron of J-PARC will produce neutrinos from muon decay at rest. With a detector filled with gadolinium loaded liquid scintillator of 17 t fiducial mass at 24 m from the target, JSNS^2 is aiming to provide a direct test of the LSND anomaly.

14.6.4 *Reactor Antineutrinos*

14.6.4.1 *Reactor antineutrino flux*

Nuclear reactors are very intense sources of $\bar{\nu}_e$'s in the MeV energy region, which are generated in nuclear fission of heavy isotopes (mainly ^{235}U, ^{238}U, ^{239}Pu, and ^{241}Pu). The $\bar{\nu}_e$ flux from a reactor can be estimated based on the thermal power output and fuel composition as a function of time. On average, about six $\bar{\nu}_e$'s are emitted and about 200 MeV of energy is released per fission. Therefore, a 1 GW$_{\rm th}$ (thermal power) reactor produces about 2×10^{20} $\bar{\nu}_e$'s per second.

The detailed estimate of $\bar{\nu}_e$ flux and energy spectrum can be obtained by either summing up the spectra of beta decays involved using available nuclear data information of each fission fragment and its decays, or using measurements of cumulative electron spectra associated with the beta decays of fission fragments. Because the fission of four main fuel isotopes involves thousands of beta-decay branches, a completely *ab initio* calculation is challenging. The cumulative electron spectra for ^{235}U, ^{239}Pu, and ^{241}Pu were measured at the Institut Laue-Langevin (ILL) reactor in Grenoble, France in the 1980s [132–134]. For the prediction of $\bar{\nu}_e$ flux from ^{238}U, a summation calculation in [135] was often used together with the ILL results.

A recent calculation of the reactor $\bar{\nu}_e$ flux [136] uses an improved *ab initio* approach for ^{238}U and combined information from nuclear databases and electron spectra measured at ILL for ^{235}U, ^{239}Pu, and ^{241}Pu. Another calculation [137] is provided for ^{235}U, ^{239}Pu, and ^{241}Pu based on the ILL measurement of electron spectra, taking into account higher order corrections and minimizing the use of nuclear databases. Both calculations predict about 3% higher normalization for the energy-averaged antineutrino fluxes of ^{235}U, ^{239}Pu, and ^{241}Pu compared to the original analyses of ILL data. However, the reactor antineutrino flux measurement at Daya Bay [138] is consistent with the old flux predictions and the flux measurement results. Also, an excess of $\bar{\nu}_e$ flux around 5 MeV, compared to the prediction, has been observed by recent reactor experiments [139–142]. Measurements of a fuel-dependent reactor $\bar{\nu}_e$ rate by Daya Bay [143] and RENO [144], and individual antineutrino spectra from ^{235}U and ^{239}Pu by Daya Bay [145] showed a discrepancy between the observed and predicted rate and spectrum from ^{235}U.

14.6.4.2 *Reactor antineutrino oscillation experiments*

Charged current interaction cannot happen if a reactor $\bar{\nu}_e$ changes its flavour to $\bar{\nu}_\mu$ or $\bar{\nu}_\tau$, because its energy is not sufficient to produce heavier charged leptons. Thus, $\bar{\nu}_e$ disappearance is the

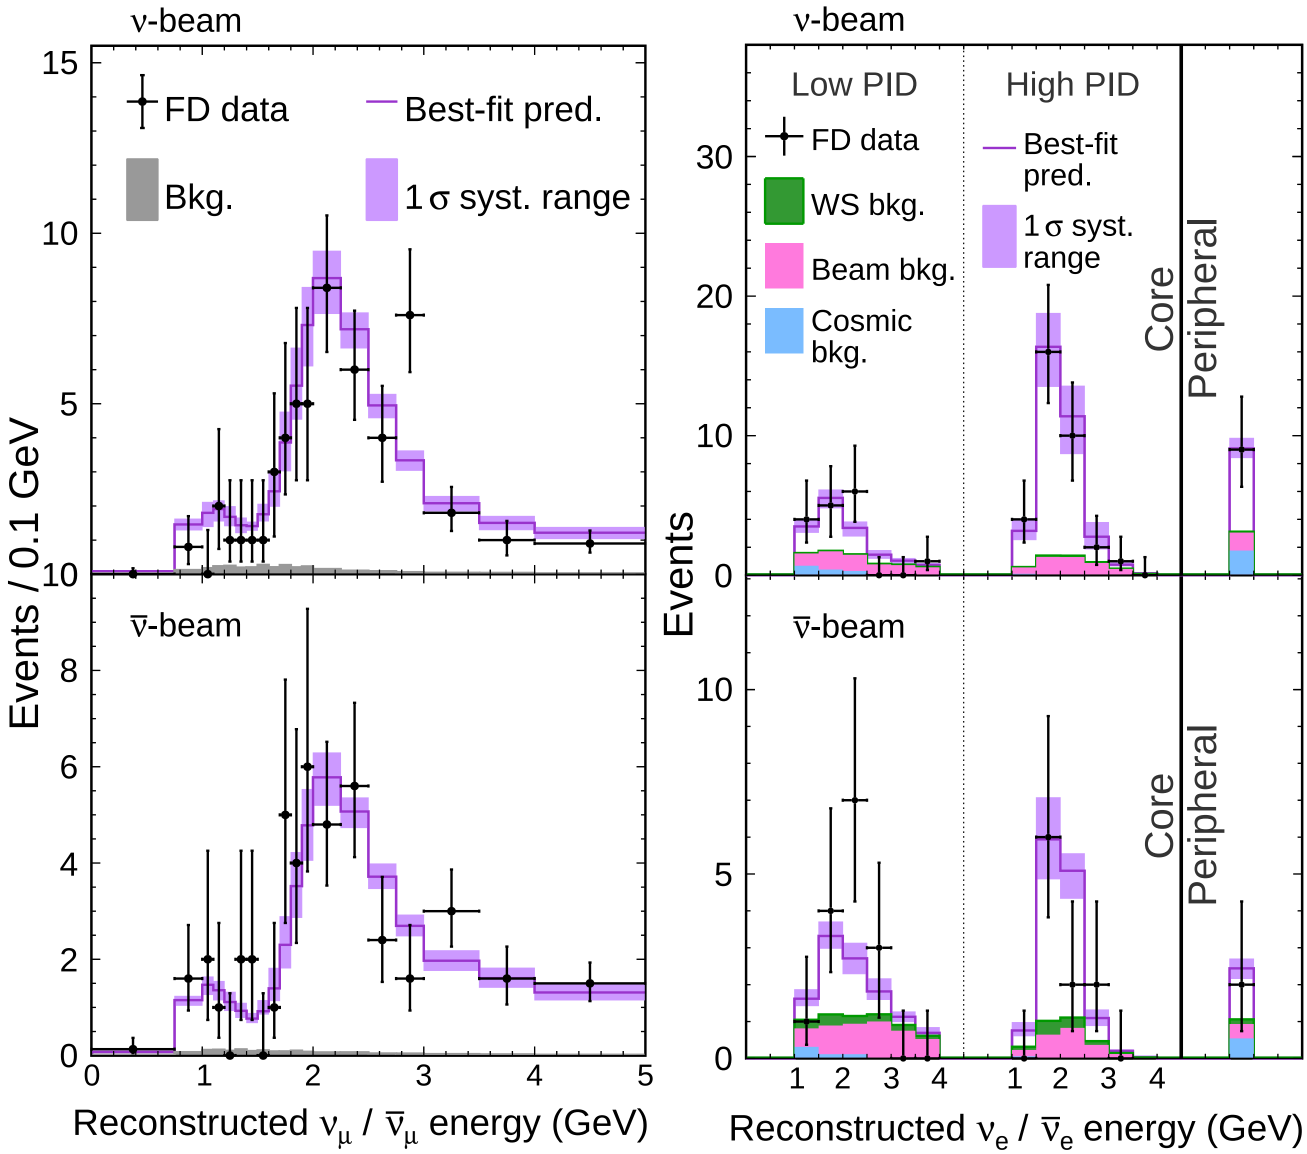

Figure 14.6: Reconstructed neutrino energy distributions from the NOvA far detector [126]. Top plots are for neutrino beam mode and bottom plots are for antineutrino beam mode. Left: muon-type candidates. Right: electron-type candidates, split into a low and high purity sample as well as the event counts in the peripheral sample which occurred near the edge of the detector.

Table 14.4: List of reactor antineutrino oscillation experiments

Name	Reactor power ($\mathrm{GW_{th}}$)	Baseline (km)	Detector mass (t)	Year
KamLAND	various	180 (ave.)	1,000	2001–
Double Chooz	4.25×2	1.05	8.3	2011–2018
Daya Bay	2.9×6	1.65	20×4	2011–
RENO	2.8×6	1.38	16	2011–
JUNO	26.6 (total)	53	20,000	

only channel to study neutrino flavour change with reactor experiments. The inverse beta decay $\bar{\nu}_e + p \to e^+ + n$ provides a way to detect $\bar{\nu}_e$ in the relevant energy region. The energy of prompt signal from e^+, E_p, is related to the energy of $\bar{\nu}_e$, $E_{\bar{\nu}} \sim E_p + 0.8$ MeV. The delayed coincidence with the signal from γ ray emitted by neutron capture on nucleus after thermalization very efficiently suppresses the backgrounds. Liquid scintillator is often used to realize large detectors containing hydrogen as the target of inverse beta decay. In order to increase the neutron detection efficiency, liquid scintillator is sometimes loaded with gadolinium because of large neutron capture cross section and higher energy of emitted γ rays, the total energy of about 8 MeV, by gadolinium, in contrast to 2.2 MeV for the capture by hydrogen.

Early reactor experiments that searched for neutrino oscillations at short or intermediate baselines reported negative results. The CHOOZ [146] and Palo Verde [147] experiments in 1990's searched for neutrino oscillations in the $\Delta m^2 \sim 10^{-2}$–10^{-3} eV^2 range and set a limit on the corresponding mixing angle $\sin^2 2\theta < 0.1$ at 90% CL.

Table 14.4 shows a list of reactor antineutrino experiments measuring neutrino oscillation. As was also shown in Table 14.1, experiments are designed with different baselines because of the different scale of mass splittings found by solar and atmospheric neutrino experiments. Experiments with O(100) km baseline are sensitive to Δm^2 of 10^{-4}–10^{-5} eV^2, while $\sim$ 1 km of baseline results in a sensitivity in a range of 10^{-2}–10^{-3} eV^2.

The KamLAND detector consists of 1,000 t of ultra-pure liquid scintillator contained in a 13-m diameter spherical balloon [148]. The detector is located in the original Kamiokande cavern, where the $\bar{\nu}_e$ flux was dominated by a few reactors at an average distance of $\sim$180 km until 2011. KamLAND reported the first results in 2002 showing that the ratio of the observed number of $\bar{\nu}_e$ events and expectation without disappearance is $0.611 \pm 0.085 \pm 0.041$, evidence for reactor $\bar{\nu}_e$ disappearance at the 99.95% confidence level [148]. It confirmed a large value of the mixing angle corresponding to the LMA solution, which was reported by solar neutrino experiments. It is noted that there is a $\sim 2\sigma$ level tension between the global solar neutrino data and KamLAND reactor data regarding the best-fit value of Δm^2, while the mixing angle is consistent. KamLAND also showed the evidence of $\bar{\nu}_e$ spectrum distortion consistent with the expectation from neutrino oscillations [149]. Figure 14.7 shows the ratio of observed $\bar{\nu}_e$ spectrum to the expectation for no-oscillation as a function of L_0/E ($L_0 =$ 180 km) for the KamLAND data. A clear oscillatory signature can be seen.

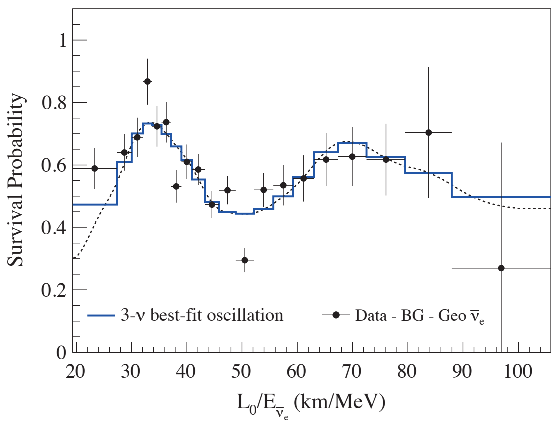

Figure 14.7: Ratio of the observed $\bar{\nu}_e$ spectrum to the expectation for no-oscillation versus L_0/E for the KamLAND data. L_0 = 180 km is the flux-weighted average reactor baseline. The 3-ν histogram is the best-fit survival probability curve from the three-flavour unbinned maximum-likelihood analysis using only the KamLAND data. This figure is taken from [150].

Following the establishment of neutrino oscillations with atmospheric, solar, accelerator, and reactor experiments, the measurement of the remaining mixing angle θ_{13} was recognized as the next major milestone. A reactor neutrino experiment with a baseline of $\sim$1 km can make an almost pure measurement of $\sin^2 2\theta_{13}$ from disappearance of $\bar{\nu}_e$. To be sensitive to a small value below the limit set by CHOOZ and Palo Verde, experiments with two detectors were proposed. Among several proposals, three experiments have been realized: Double Chooz in France [151], Daya Bay in China [152], and RENO in Korea [153].

These three experiments employ similar detector design optimized for the precise measurement of reactor antineutrino. An antineutrino detector consists of a cylindrical stainless steel vessel that houses two nested acrylic cylindrical vessels. The innermost vessel is filled with gadolinium-doped liquid scintillator as the primary antineutrino target. It is surrounded by a liquid scintillator layer to contain γ rays from the target volume. A buffer layer of mineral oil is placed an outside to shield inner volumes from radioactivity of PMTs and surrounding rock. The light from liquid scintillator is detected by an array of PMTs mounted on the stainless steel vessel. Optically separated by the stainless steel vessel, outside region is instrumented as a veto detector with either liquid scintillator (Double Chooz) or water Cherenkov (Daya Bay and RENO) detector.

The Double Chooz detector has gadolinium-doped liquid scintillator with mass of 8.3 t. The far detector at a baseline of $\sim$1050 m from the two 4.25 GW$_{\rm th}$ reactors started physics data taking in

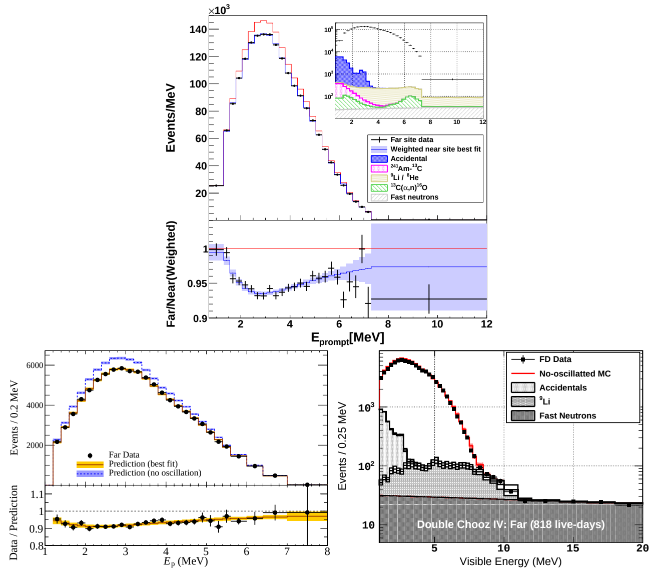

Figure 14.8: Energy spectra for prompt events at the far detectors for Daya Bay [139], RENO [140], and Double Chooz [141].

2011. The near detector, located at $\sim$400 m from the reactors, was completed in the end of 2014. Double Chooz finished data taking in early 2018. Daya Bay has two near (flux-weighted baseline 470 m and 576 m) and one far (1648 m) underground experimental halls near six reactors with 2.9 GW$_{\rm th}$ each. Daya Bay has eight antineutrino detectors in total; two detectors in each of the near detector halls, and four detectors in the far detector hall. Each detector contains 20 t of gadolinium-loaded liquid scintillator. RENO has two identical detectors located at 294 m and 1383 m from the center of an array of six 2.8 GW$_{\rm th}$ reactors. The mass of gadolinium-loaded liquid scintillator is 16 t per detector. RENO started data taking with both near and far detectors from August 2011.

All the three reactor neutrino experiments published first results in 2012. First, Double Chooz reported an indication of reactor electron antineutrino disappearance with the ratio of observed to expected events of $R = 0.944 \pm 0.016 \pm 0.04$, ruling out the no-oscillation hypothesis at the 94.6% CL [154]. Daya Bay observed $R = 0.940 \pm 0.011 \pm 0.004$, corresponding to 5.2$\sigma$ significance of non-zero value of θ_{13} [155]. RENO also reported $R = 0.920 \pm 0.009 \pm 0.014$, indicating a non-zero value of θ_{13} with a significance of 4.9σ [156]. These results established non-zero value of θ_{13}.

In the latest analysis, both Daya Bay [139] and RENO [140] report results constraining mass-squared difference as well as the mixing angle by using both relative $\bar{\nu}_e$ rate and energy spectra information. Double Chooz has reported the first analysis based on both far and near detectors [141] for the mixing angle, using neutron capture on any elements (primarily gadolinium and hydrogen) to increase the effective target mass. Figure 14.8 shows the energy spectra of the prompt signals observed in the far detector of three experiments.

In all three experiments as well as in the NEOS experiment [142], an excess of $\bar{\nu}_e$ events over expected energy spectrum have been observed around 5 MeV as mentioned earlier. This excess is observed in both near and far detectors and scales with the reactor power. Thanks to the cancellation between the near and far detectors, the neutrino oscillation measurements are not affected in multi-detector setup.

With a baseline of $\sim$50 km and an excellent energy measurement, reactor antineutrino experiments have significant sensitivity to the mass ordering. The JUNO experiment [157] aims to determine the mass ordering with this technique as its primary goal. It can also provide precision measurements of neutrino mixing parameters as well as a broad non-oscillation science program. The JUNO detector, which is under construction, will consist of 20 kt

Table 14.5: List of reactor antineutrino experiments for O(eV^2) oscillations

Name	Reactor power ($\mathrm{MW_{th}}$)	Baseline (m)	Detector mass (t)	Detector technology	S/B
NEOS	2,800	24	1	Gd-LS	22
DANSS	3,100	10–12	0.9	Gd-PS	∼30
STEREO	57	9–11	1.7	Gd-LS	0.9
PROSPECT	85	7–9	4	^{6}Li-LS	1.3
NEUTRINO-4	100	6–12	1.5	Gd-LS	0.5
SoLid	80	6–9	1.6	^{6}Li-PS	

liquid scintillator and be located at 53 km from two nuclear power plants in China.

14.6.4.3 *New reactor experiments sensitive to O(1) eV^2 oscillations*

Possible hints of neutrino oscillation at a scale of $\Delta m^2 \sim 1$ eV^2 (see Sec.14.8) have motivated reactor experiments at a distance of ∼10 m from the core. Recent experiments searching for ∼1 eV^2 oscillation at reactors are summarized in Table 14.5.

As the antineutrino source, some use industrial reactors which can provide a large flux leading to a high statistical precision. On the other hand, though the flux is orders of magnitude smaller, a research reactor could have favorable conditions, such as relatively easier access to a short baseline, simpler fuel composition, and compact size of the core.

The detectors are based on organic scintillators, either liquid scintillator (LS) or solid plastic scintillator (PS), which contain hydrogen as the target for inverse beta decay ($\bar{\nu}_e + p \to e^+ + n$). To identify the signal, neutron capture on either gadolinium (Gd) or ^{6}Li is detected with delayed coincidence. When a neutron is captured by Gd, γ rays with a total energy of 8 MeV are emitted. After neutron capture, ^{6}Li decays into triton and α. The effect of neutrino oscillation appears as a distortion of energy spectrum. To be independent from the reactor neutrino spectrum uncertainties, some experiments compare the spectra at different baselines by using a segmented detector or moving the detector.

The NEOS [142] uses about 1 t of gadolinium-loaded liquid scintillator in an unsegmented detector. It is located at 23.7 m from the center of a commercial reactor and covered by an overburden of about 20 meters of water equivalent. Thanks to the high power reactor, NEOS observes antineutrino events at a rate of 1976 per day, with a signal to background ratio of about 22. The energy resolution is 5% at 1 MeV.

DANSS [158] is another experiment using a commercial reactor. The detector is highly segmented, consisting of 2,500 plastic scintillator strips, each with the size of $1\times4\times100$ cm^3 and coated with a thin gadolinium-loaded reflective layer. The detector is placed on a movable platform below the reactor core. The overburden of 50 m water-equivalent reduces the cosmic muon flux by a factor of six. Data are taken with three baselines, 10.7, 11.7, and 12.7 m for a comparison between different baselines. The energy resolution of $\sigma_E/E \sim 34\%$ at 1 MeV and the large size of the reactor core, 3.7 m in height and 3.2 m in diameter, somewhat smear the oscillation pattern. However it is compensated by high statistics due to the high power reactor. The observed event rate is 4899 events per day, with less than 3% cosmic background contamination, at 10.7 m position.

The STEREO detector [159] has six identical target cells of 37 cm length, ~ 2m^3 of volume in total, filled with gadolinium-loaded liquid scintillator. They are placed from 9.4 to 11.1 m from the compact (80 cm high, 40 cm diameter) core of the ILL research reactor. The reconstructed energy resolution (σ_E/E) is about 9% at 0.835 MeV. The antineutrino event rate is 396 events per day with a signal to background ratio of about 0.9.

The PROSPECT detector [160] consists of a segmented 4 t ^{6}Li-doped liquid scintillator detector covering a baseline range of 7–9 m from the reactor core. Thin reflecting panels divide the LS volume into an 11×14 two-dimensional array of 154 optically isolated rectangular segments ($14.5 \times 14.5 \times 117.6$ cm^3). The energy resolution is 4.5% at 1 MeV. The detector is placed on the ground floor with an overburden of less than 1 m water-equivalent. With efficient background suppression by using pulse shape discrimination and 3D position reconstruction, a signal to background ratio of 1.3 is achieved. The antineutrino rate is 771 events per day.

NEUTRINO-4 [161] uses a gadolinium-loaded liquid scintillator detector segmented in 10×5 sections with a total volume of 1.8 m^3. The detector is installed on a movable platform and moved to various positions with baselines of 6–12 m. With the detector location close to the surface and no pule shape discrimination capability, the signal to background ratio is about 0.5. The energy resolution is 16% at 1 MeV.

The SoLid detector [162] is a finely segmented detector made of $5\times5\times5$ cm^3 plastic scintillator cubes and ^{6}LiF:ZnS sheets. A detector with 1.6 t of active volume is installed at a distance of 6–9 m from the research reactor core with an overburden of 10 m water-equivalent. The triton and α from neutron capture by ^{6}Li are detected by scintillation of ZnS. A high n-γ separation capability is achieved using the difference of time constant of scintillation between ZnS and plastic scintillator. Very fine segmentation of the detector allows 3D reconstruction of events, which also provide effective background discrimination. The energy resolution (σ_E/E) is expected to be $\sim$ 14% at 1 MeV.

14.7 Combined Analysis of Experimental Results: The 3ν Paradigm

From the experimental situation described in Sec.14.6 we conclude that

- Atmospheric ν_μ and $\bar{\nu}_\mu$ disappear most likely converting to ν_τ and $\bar{\nu}_\tau$. The results show an energy and distance dependence perfectly described by mass-induced oscillations.
- Accelerator ν_μ and $\bar{\nu}_\mu$ disappear over distances of $\sim$ 200 to 800 km. The energy spectrum of the results show a clear oscillatory behaviour also in accordance with mass-induced oscillations with wavelength in agreement with the effect observed in atmospheric neutrinos.
- Accelerator ν_μ and $\bar{\nu}_\mu$ appear as ν_e and $\bar{\nu}_e$ at distances $\sim$ 200 to 800 km.
- Solar ν_e convert to ν_μ and/or ν_τ. The observed energy dependence of the effect is well described by massive neutrino conversion in the Sun matter according to the MSW effect
- Reactor $\bar{\nu}_e$ disappear over distances of $\sim$ 200 km and $\sim$ 1.5 km with different probabilities. The observed energy spectra show two different mass-induced oscillation wavelengths: at short distances in agreement with the one observed in accelerator ν_μ disappearance, and a long distance compatible with the required parameters for MSW conversion in the Sun.

The minimum scenario to describe these results requires the mixing between the three flavour neutrinos of the standard model in three distinct mass eigenstates. In this case U in Eq. (14.32) is a 3×3 matrix analogous to the CKM matrix for the quarks [21] but due to the possible Majorana nature of the neutrinos it can depend on six independent parameters: three mixing angles and three phases. There are several possible conventions for the ranges of the angles and ordering of the states. The community finally agreed to a parametrization of the leptonic mixing matrix as in Eq. (14.33). The angles θ_{ij} can be taken without loss of generality to lie in the first quadrant, $\theta_{ij} \in [0, \pi/2]$, and the phase $\delta_{\mathrm{CP}} \in [0, 2\pi]$. Values of δ_{CP} different from 0 and π imply CP violation in neutrino oscillations in vacuum [163–165]. The Majorana phases η_1 and η_2 play no role in neutrino oscillations [164, 166].

Hence for the study of neutrino oscillations in the 3ν mixing scenario one can use the parametrization in Eq. (14.34) irrespective of whether neutrinos are Dirac or Majorana particles. Indeed, Majorana phases are very hard to measure since they are only physical if neutrino mass is non-zero and therefore the amplitude of any process involving them is suppressed a factor m_ν/E to some power where E is the energy involved in the process which is typically much larger than the neutrino mass. The most sensitive experimental probe of Majorana phases is the rate of neutrinoless $\beta\beta$ decay as discussed in Secs. 14.9.3 and 14.9.2.

In this convention there are two non-equivalent orderings for the spectrum of neutrino masses:

– Spectrum with Normal Ordering (NO) with $m_1 < m_2 < m_3$
– Spectrum Inverted ordering (IO) with $m_3 < m_1 < m_2$.

Furthermore the data show a hierarchy between the mass splittings, $\Delta m^2_{21} \ll |\Delta m^2_{31}| \simeq |\Delta m^2_{32}|$ with $\Delta m^2_{ij} \equiv m^2_i - m^2_j$.

In this section we follow the convention used in the listing section of the PDG and discuss the results for both, NO and IO, using Δm^2_{21}, which is always the smallest mass splitting, and Δm^2_{32} which, up to a sign, is the largest mass splitting for IO, while for NO the largest mass splitting is $\Delta m^2_{31} = \Delta m^2_{32} + \Delta m^2_{21}$.

With what we know of the mass differences (see table 14.7) and the neutrino mass scale (see Sec. 14.9), depending on the value of the lightest neutrino mass, the neutrino mass spectrum can be further classified in:

– Normal Hierarchical Spectrum (NH): $m_1 \ll m_2 < m_3$,
$\Rightarrow m_2 \simeq \sqrt{\Delta m^2_{21}} \sim 8.6\times10^{-3}\text{eV}, m_3 \simeq \sqrt{\Delta m^2_{32} + \Delta m^2_{21}} \sim 0.05\text{eV}$,

– Inverted Hierarchical Spectrum (IH): $m_3 \ll m_1 < m_2$,
$\Rightarrow m_1 \simeq \sqrt{|\Delta m^2_{32} + \Delta m^2_{21}|} \sim 0.0492\text{eV}, m_2 \simeq \sqrt{|\Delta m^2_{32}|} \sim 0.05\text{eV}$,

– Quasidegenerate Spectrum (QD): $m_1 \simeq m_2 \simeq m_3 \gg \sqrt{|\Delta m^2_{32}|}$.

Sometimes in the literature the determination of the neutrino mass spectrum is refered to as determination of the neutrino hierarchy. However, as described above, with what we know so far of the neutrino mass scale, the neutrino spectrum may or may not be hierarchical. Therefore determination of neutrino mass ordering is a more precise expression and it is the one used in this review.

In total the 3-ν oscillation analysis of the existing data involves six parameters: 2 mass differences (one of which can be positive or negative), 3 mixing angles, and the CP phase. The different experiments described in Sec.14.6 provide information on different subsets of these parameters. The precise statistical analysis of the data requires the numerical evaluation of the corresponding oscillation probabilities by solving the evolution equation of the neutrino ensemble from their source to the experiment. Nevertheless the dominant effects in the different experiments can be qualitatively understood in terms of approximate expressions for the oscillation probabilities which, for convenience, we briefly summarize here.

14.7.1 *3ν Oscillation Probabilities*

The relevant survival probabilities for solar and KamLAND experiments in the framework of three neutrino oscillations can be written as:

$$P^{3\nu}_{ee} = \sin^4\theta_{13} + \cos^4\theta_{13} P^{2\nu}_{ee}(\Delta m^2_{21}, \theta_{12}) , \tag{14.72}$$

where we have used the fact that $L^{\rm osc}_{0,32} = 4\pi E_\nu/\Delta m^2_{32}$ is much shorter than the distance travelled by both solar and KamLAND neutrinos, so that the oscillations related to $L^{\rm osc}_{0,32}$ are averaged. In presence of matter effects $P^{2\nu}_{ee}(\Delta m^2_{21}, \theta_{12})$ should be calculated taking into account the evolution in an effective matter density $n^{\rm eff}_e = n_e \cos^2\theta_{13}$. For $10^{-5} \lesssim \Delta m^2/\text{eV}^2 \lesssim 10^{-4}$, $P^{2\nu}_{ee}(\Delta m^2_{21}, \theta_{12})$ presents the following asymptotic behaviours [167]:

$$P^{2\nu,\rm sun}_{ee} \simeq 1 - \frac{1}{2}\sin^2(2\theta_{12}) \qquad \text{for } E_\nu \lesssim \text{few} \times 100 \text{ keV} , \tag{14.73}$$

$$P^{2\nu,\rm sun}_{ee} \simeq \sin^2(\theta_{12}) \qquad \text{for } E_\nu \gtrsim \text{few} \times 1 \text{ MeV} , \tag{14.74}$$

$$P^{2\nu,\rm kam}_{ee} = 1 - \frac{1}{2}\sin^2(2\theta_{12}) \sin^2\frac{\Delta m^2_{21} L}{2E_\nu} . \tag{14.75}$$

At present most of the precision of the solar analysis is provided by SNO and SK for which the relevant MSW survival probability provides a direct measurement of $\sin^2\theta_{12}$, as seen in Eq. (14.74). In the MSW regime the determination of Δm^2_{21} in solar experiments comes dominantly from the ratio between the solar potential and the Δm^2_{21} term required to simultaneously describe the CC/NC data at SNO and the undistorted spectra of ^{8}B neutrinos as measured in both SK and SNO. Conversely, KamLAND $\bar\nu_e$ survival probability proceeds dominantly as vacuum oscillations and provides a most precise determination of Δm^2_{21} via the strong effect of the oscillating phase in the distortion of the reactor energy spectrum. On the contrary it yields a weaker constraint on θ_{12} as the vacuum oscillation probability depends on the double-valued and "flatter" function $\sin^2(2\theta_{12})$.

In what respects the interpretation of ν_μ disappearance data at LBL experiments, the ν_μ survival probability can be expanded in the small parameters $\sin\theta_{13}$ and $\alpha \equiv \Delta m^2_{21}/\Delta m^2_{31}$ to good accuracy as [168, 169]

$$\begin{aligned} P_{\nu_\mu\to\nu_\mu} &\approx 1 - \sin^2 2\theta_{\mu\mu} \sin^2\frac{\Delta m^2_{\mu\mu} L}{4E_\nu} \\ &\approx 1 - \cos^2\theta_{13}\sin^2(2\theta_{23})\sin^2\frac{\Delta m^2_{32} L}{4E_\nu} + \mathcal{O}(\alpha, s^2_{13}) , \end{aligned} \tag{14.76}$$

with

$$\begin{aligned} \sin^2\theta_{\mu\mu} &= \cos^2\theta_{13}\sin^2\theta_{23} , \\ \Delta m^2_{\mu\mu} &= \sin^2\theta_{12}\Delta m^2_{31} + \cos^2\theta_{12}\Delta m^2_{32} \\ &\quad + \cos\delta_{\rm CP}\sin\theta_{13}\sin 2\theta_{12}\tan\theta_{23}\Delta m^2_{21} . \end{aligned}$$

At present ν_μ disappearance results at LBL provide the best determination of $|\Delta m^2_{32}|$ and θ_{23} but as seen above, the probability is symmetric with respect to the octant of $\theta_{\mu\mu}$ which implies symmetry around $s^2_{23} = 0.5/c^2_{13}$.

The relevant oscillation probability for ν_e appearance at LBL experiments can be expanded at the second order in the small parameters $\sin\theta_{13}$ and α, and assuming a constant matter density it takes the form [170–172]:

$$\begin{aligned} P_{\nu_\mu\to\nu_e,(\bar\nu_\mu\to\bar\nu_e)} &\approx 4\,\sin^2\theta_{13}\,\sin^2\theta_{23}\frac{\sin^2\Delta}{(1-A)^2} \\ &+ \alpha^2\sin^2 2\theta_{12}\,\cos^2\theta_{23}\frac{\sin^2 A\Delta}{A^2} \\ &+ 8\,\alpha\,J^{\rm max}_{\rm CP}\cos(\Delta \pm \delta_{\rm CP})\,\frac{\sin\Delta A}{A}\,\frac{\sin\Delta(1-A)}{1-A} , \end{aligned} \tag{14.77}$$

with

$$J^{\rm max}_{\rm CP} = \cos\theta_{12}\sin\theta_{12}\cos\theta_{23}\sin\theta_{23}\cos^2\theta_{13}\sin\theta_{13} , \tag{14.78}$$

and

$$\Delta \equiv \frac{\Delta m^2_{31} L}{4E_\nu} , \quad A \equiv \frac{2E_\nu V}{\Delta m^2_{31}} , \tag{14.79}$$

where V is the effective matter potential in the Earth crust. Results on ν_e appearance at LBL provide us with the dominant information on leptonic CP violation. Furthermore α, Δ, and A are sensitive to the sign of Δm^2_{32} (*i.e.*, the type of the neutrino mass ordering). The plus (minus) sign in Eq. (14.77) applies for neutrinos (antineutrinos), and for antineutrinos $V \to -V$, which implies $A \to -A$. Numerically one finds for a typical Earth crust matter density of 3 g/cm^3 that at T2K with $E \sim 0.7$ GeV, matter effects are of order few percent, whereas in NOvA with $E \sim 2$ GeV we can have $|A| \sim 0.2$. Also $\alpha^2 \approx 10^{-3}$, which implies that the second term in the first line of Eq. (14.77) gives a very small contribution compared to the other terms. Also, the first term in Eq. (14.77) (which dominates for large θ_{13}) depends on $\sin^2\theta_{23}$ and therefore is sensitive to the octant.

The ν_e survival probability relevant for reactor experiments with medium baseline (MBL), $L \sim 1$ km, can be approximated as [169, 173]:

$$P_{\nu_e\to\nu_e} = 1 - \sin^2 2\theta_{13}\sin^2\frac{\Delta m^2_{ee}L}{4E_\nu} + \mathcal{O}(\alpha^2)\,, \tag{14.80}$$

where

$$\Delta m^2_{ee} = \cos^2\theta_{12}\Delta m^2_{31} + \sin^2\theta_{12}\Delta m^2_{32}\,. \tag{14.81}$$

These MBL reactor experiments provide the most precise determination of θ_{13}. Furthermore there is an additional effect sensitive to the mass ordering when comparing the disappearance of ν_μ at LBL experiments – which is symmetric with respect to the sign of $\Delta m^2_{\mu\mu}$ given in Eq.(14.7.1)– , with that of ν_e disappearance at MBL reactors which is symmetric with respect to the slightly different effective mass-squared difference Δm^2_{ee} given in Eq. (14.81)

Finally for atmospheric neutrinos the fluxes contain ν_e, ν_μ, $\bar\nu_e$ and $\bar\nu_\mu$ and for a good fraction of the events, neutrinos travel through the Earth matter. In the context of 3ν mixing, the dominant oscillation channel of atmospheric neutrinos is $\nu_\mu \to \nu_\tau$ driven by $|\Delta m^2_{32}|$ with an amplitude controlled by θ_{23} with subleading oscillation modes, triggered by Δm^2_{21} and/or θ_{13}, which depend on the octant of θ_{23}, on the mass ordering and on $\delta_{\rm CP}$. In that respect an interesting observable is the deviation of e-like events relative to the no-oscillation prediction N_e^0, since in the two-flavour limit one expects $N_e = N_e^0$. Such deviation can be written in the following way (see, *e.g.*, [174]):

$$\begin{aligned}\frac{N_e}{N_e^0} - 1 &\approx (r\sin^2\theta_{23} - 1)P_{2\nu}(\Delta m^2_{32},\theta_{13})\\ &+ (r\cos^2\theta_{23} - 1)P_{2\nu}(\Delta m^2_{21},\theta_{12})\\ &- \sin\theta_{13}\sin 2\theta_{23}\, r\,\Re(A^*_{ee}A_{\mu e})\,.\end{aligned} \tag{14.82}$$

Here $r \equiv \Phi_\mu/\Phi_e$ is the flux ratio with $r \approx 2$ in the sub-GeV range and $r \approx 2.6 \to 4.5$ in the multi-GeV range. $P_{2\nu}(\Delta m^2,\theta)$ is an effective two-flavour oscillation probability and $A_{ee}, A_{\mu e}$ are elements of a transition amplitude matrix. The three terms appearing in Eq. (14.82) have a well defined physical interpretation. The first term is important in the multi-GeV range and is controlled by the mixing angle θ_{13} in $P_{2\nu}(\Delta m^2_{32},\theta_{13})$. This probability can be strongly affected by resonant matter effects [175–180]. Depending on the mass ordering the resonance will occur either for neutrinos or antineutrinos. The second term is important for sub-GeV events and it takes into account the effect of oscillations due to Δm^2_{21} and θ_{12} [181–184]. Via the pre-factor containing the flux ratio r both, the first and second terms in Eq. (14.82) depend on the octant of θ_{23}, though in opposite directions: the multi-GeV (sub-GeV) excess is suppressed (enhanced) for $\theta_{23} < 45°$. Finally, the last term in Eq. (14.82) is an interference term between θ_{13} and Δm^2_{21} amplitudes and this term shows also dependence on the CP phase $\delta_{\rm CP}$ [174, 184].

Subdominant three neutrino effects can also affect μ-like events. For example for multi-GeV muon events one can write the excess in μ-like events as [185, 186]

$$\begin{aligned}\frac{N_\mu}{N_\mu^0} - 1 &\approx \sin^2\theta_{23}\left(\frac{1}{r} - \sin^2\theta_{23}\right)P_{2\nu}(\Delta m^2_{32},\theta_{13})\\ &- \frac{1}{2}\sin^2 2\theta_{23}\left[1 - \Re(A_{33})\right]\,.\end{aligned} \tag{14.83}$$

The first term is controlled by θ_{13} and is subject to resonant matter effects, similar to the first term in Eq. (14.82), though with a different dependence on θ_{23} and the flux ratio. In the second term, A_{33} is a probability amplitude satisfying $P_{2\nu}(\Delta m^2_{32},\theta_{13}) = 1 - |A_{33}|^2$. In the limit $\theta_{13} = 0$ we have $\Re(A_{33}) = \cos(\Delta m^2_{32}L/2E)$, such that the second term in Eq. (14.83) just describes two-flavour $\nu_\mu \to \nu_\mu$ vacuum oscillations.

14.7.2 *3ν Oscillation Analysis*

We summarize in Table 14.6 the different experiments which dominantly contribute to the present determination of the different parameters in the chosen convention.

The table illustrates that the determination of the leptonic parameters requires global analysis of the data from the different experiments. Over the years these analyses have been in the hands of a few phenomenological groups. We show in Table 14.7 the results from the latest analyses in Refs. [187–190]. For the sake of comparison all results are presented in the convention of the listing section as described above.

The table illustrates the dependence of the present determination of the parameters on variations of the statistical analysis performed by the different groups and on the data samples included. In that last respect the main difference resides on the results from Super-Kamiokande atmospheric data [94] which, at present, can only be included in these analysis by directy adding the χ^2 tabulated χ^2 map provided by the experiment.

Altogether the different analysis find consistent results, in particular on the better known parameters, θ_{12}, θ_{13} and Δm^2_{21} and $|\Delta m^2_{32}|$. The issues which still require clarification are: the mass ordering discrimination, the determination of θ_{23} and the leptonic CP phase $\delta_{\rm CP}$:

- In all analyses the best fit is for the normal mass ordering. Inverted ordering is disfavoured with a $\Delta\chi^2$ which ranges from slightly above 2σ – driven by the interplay of long-baseline accelerator and short-baseline reactor data – to 3σ when adding the atmospheric χ^2 table from Ref. [94].
- All analyses find some preference for the second octant of θ_{23} but with statistical significance still well below 3σ.
- The best fit for the complex phase in NO is at $\delta_{\rm CP} \sim 120°$ but CP conservation (for $\delta_{\rm CP} \sim 180°$) is still allowed at a confidence level (CL) of 1-2σ. We notice that, at present, the significance of CP violation in the global analysis is reduced with respect to that reported by T2K [191] because NOvA data does not show a significant indication of CP violation.

14.7.3 *Convention-independent Measures of Leptonic CP Violation in 3ν Mixing*

In the framework of 3ν mixing leptonic CP violation can also be quantified in terms of the leptonic Jarlskog invariant [192], defined by:

$$\begin{aligned}\Im\left[U_{\alpha i}U^*_{\alpha j}U^*_{\beta i}U_{\beta j}\right] &\equiv \sum_{\gamma=e,\mu,\tau}\sum_{k=1,2,3} J_{\rm CP}\,\epsilon_{\alpha\beta\gamma}\,\epsilon_{ijk}\\ &\equiv J^{\rm max}_{\rm CP}\sin\delta_{\rm CP}\,.\end{aligned} \tag{14.84}$$

With the convention in Eq. (14.33) $J^{\rm max}_{\rm CP}$ is the combination of mixing angles in Eq. (14.78). For example from the analysis in Ref. [187, 188]

$$J^{\rm max}_{\rm CP} = 0.03359 \pm 0.0006\,(\pm 0.0019)\,, \tag{14.85}$$

at 1σ (3σ) for both orderings, and the preference of the present data for non-zero $\delta_{\rm CP}$ implies a non-zero best fit value $J^{\rm best}_{\rm CP} = -0.019$.

The status of the determination of leptonic CP violation can also be graphically displayed by projecting the results of the global analysis in terms of leptonic unitarity triangles [193–195]. Since in the analysis U is unitary by construction, any given pair of rows or columns can be used to define a triangle in the complex plane. There a total of six possible triangles corresponding to the unitary conditions

$$\sum_{i=1,2,3} U_{\alpha i}U^*_{\beta i} = 0 \text{ with } \alpha \neq \beta\,, \qquad \sum_{\alpha=e,\mu,\tau} U_{\alpha i}U^*_{\alpha j} = 0 \text{ with } i \neq j\,. \tag{14.86}$$

Table 14.6: Experiments contributing to the present determination of the oscillation parameters.

Experiment	Dominant	Important
Solar Experiments	θ_{12}	Δm^2_{21} , θ_{13}
Reactor LBL (KamLAND)	Δm^2_{21}	θ_{12} , θ_{13}
Reactor MBL (Daya-Bay, Reno, D-Chooz)	θ_{13}, $\lvert\Delta m^2_{31,32}\rvert$	
Atmospheric Experiments (SK, IC-DC)		θ_{23},$\lvert\Delta m^2_{31,32}\rvert$, θ_{13},$\delta_{\rm CP}$
Accel LBL ν_μ,$\bar\nu_\mu$, Disapp (K2K, MINOS, T2K, NOνA)	$\lvert\Delta m^2_{31,32}\rvert$, θ_{23}	
Accel LBL ν_e,$\bar\nu_e$ App (MINOS, T2K, NOνA)	$\delta_{\rm CP}$	θ_{13} , θ_{23}

Table 14.7: 3ν oscillation parameters obtained from different global analysis of neutrino data. In all cases the numbers labeled as NO (IO) are obtained assuming NO (IO), *i.e.*, relative to the respective local minimum. SK-ATM makes reference to the tabulated χ^2 map from the Super-Kamiokande analysis of their data in Ref. [94].

As illustration we show in Fig. 14.9 the recasting of the allowed regions of the analysis in Ref. [187, 188] in terms of one leptonic unitarity triangle. We show the triangle corresponding to the unitarity conditions on the first and third columns (after the shown rescaling) which is the equivalent to the one usually shown for the quark sector. In this figure the absence of CP violation would imply a flat triangle, *i.e.*, $\Im(z) = 0$. So the CL at which leptonic CP violation is being observed would be given by the CL at which the region crosses the horizontal axis. Notice however, that this representation is made *under the assumption of a unitary U matrix* and therefore does not provide any test of unitarity in the leptonic sector.

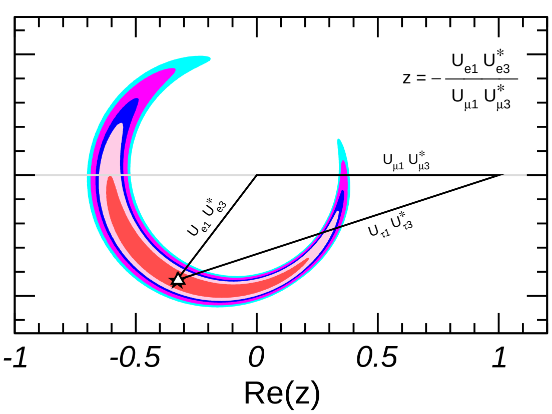

Figure 14.9: Leptonic unitarity triangle for the first and third columns of the mixing matrix. After scaling and rotating the triangle so that two of its vertices always coincide with $(0, 0)$ and $(1, 0)$ the figure shows the 1σ, 90%, 2σ, 99%, 3σ CL (2 dof) allowed regions of the third vertex for the NO from the analysis in Ref. [187, 188].

14.8 Beyond 3ν: Additional Neutrinos at the eV Scale

Besides the huge success of three-flavour oscillations described in Sec.14.7, as mentioned in Secs.14.6.3 and 14.6.4, there are some anomalies which cannot be explained within the 3ν framework and which might point towards the existence of additional neutrino states with masses at the eV scale. In brief:

- the LSND experiment [127] reports evidence for $\bar{\nu}_\mu \to \bar{\nu}_e$ transitions with $E/L \sim 1$ eV^2, where E and L are the neutrino energy and the distance between source and detector, respectively (see *Short Baseline Experiments* subsection of Sec.14.6.3).
- this effect has also been searched for by the MiniBooNE experiment [196], which reports a yet unexplained event excess in the low-energy region of the electron neutrino and anti-neutrino event spectra. No significant excess is found at higher neutrino energies. Interpreting the data in terms of oscillations, parameter values consistent with the ones from LSND are obtained, but the test is not definitive;
- radioactive source experiments at the Gallium solar neutrino experiments both in SAGE and GALLEX/GNO have obtained an event rate which is somewhat lower than expected. If not due to uncertainties in the interaction cross section, this effect can be explained by the hypothesis of ν_e disappearance due to oscillations with $\Delta m^2 \gtrsim 1$ eV^2 ("Gallium anomaly") [197, 198];
- new calculations of the neutrino flux emitted by nuclear reactors [136, 137] predict a neutrino rate which is a few percent higher than observed in short-baseline ($L \lesssim 100$ m) reactor experiments [4]. If not due to systematic or theoretical uncertainties, a decrease rate at those distances can be explained by assuming $\bar{\nu}_e$ disappearance due to oscillations with $\Delta m^2 \sim 1$ eV^2 ("reactor anomaly") [200]. This reactor anomaly is under study both by the experimental community – with a set of follow-up measurements performed at SBL both at reactors and accelerators (see the corresponding subsections in Sec.14.6.4 and Sec.14.6.3)– , and by the theory community for improvements of the reactor flux calculations.

As mentioned in Sec.14.1 whatever the extension of the SM we want to consider it must contain only three light active neutrinos. Therefore if we need more than three light massive neutrinos we must add sterile neutrinos to the particle content of the model.

The most immediate question as these anomalies were reported was whether they could all be consistently described in combination with the rest of the neutrino data – in particular with the negative results on disappearance of ν_μ at short distances – if one adds those additional sterile states. Quantitatively one can start by adding a fourth massive neutrino state to the spectrum, and perform a global data analysis to answer this question. Although the answer is always the same the physical reason behind it depends on ordering assumed for the states. In brief, there are six possible four-neutrino schemes which can in principle accommodate the results of solar+KamLAND and atmospheric+LBL neutrino experiments as well as the SBL result. They can be divided in two classes: (2+2) and (3+1). In the (3+1) schemes, there is a group of three close-by neutrino masses (as on the 3ν schemes described in the previous section) that is separated from the fourth one by a gap of the order of 1 eV, which is responsible for the SBL oscillations. In (2+2) schemes, there are two pairs of close masses (one pair responsible for solar results and the other for atmospheric [201]) separated by the $\mathcal{O}$(eV) gap. The main difference between these two classes is the following: if a (2+2)-spectrum is realized in nature, the transition into the sterile neutrino is a solution of either the solar or the atmospheric neutrino problem, or the sterile neutrino takes part in both. Consequently a (2+2)-spectrum is easier to test because the required mixing of sterile neutrinos in either solar and/or atmospheric oscillations would modify their effective matter potential in the Sun and in the Earth and giving distinctive effects in the solar and/or atmospheric neutrino observables. Those distinctive effects were not observed so oscillations into sterile neutrinos did not describe well either solar or atmospheric data. Consequently as soon as the early 2000's 2+2 spectra could be ruled out already beyond 3-4 σ as seen in the left panel in Fig.14.10 taken from Ref. [202].

On the contrary, for a (3+1)-spectrum (and more generally for a $3+N$-spectrum with an arbitrary N number of sterile states), the sterile neutrino(s) could be only slightly mixed with the active ones and mainly provide a description of the SBL results. In this case the oscillation probabilities for experiments working at $E/L \sim 1$ eV^2 take a simple form:

$$P_{\alpha\alpha} = 1 - \sin^2 2\theta_{\alpha\alpha} \sin^2 \Delta\,, \qquad P_{\mu e} = \sin^2 2\theta_{\mu e} \sin^2 \Delta\,, \tag{14.87}$$

where $\Delta \equiv \Delta m^2_{41} L/4E$ and one can define effective mixing angles

$$\sin^2 2\theta_{\alpha\alpha} \equiv 4|U_{\alpha 4}|^2 (1 - |U_{\alpha 4}|^2)\,, \qquad \sin^2 2\theta_{\mu e} \equiv 4|U_{\mu 4}|^2 |U_{e4}|^2\,. \tag{14.88}$$

In here $\alpha = e, \mu$ and $U_{\alpha 4}$ are the elements of the lepton mixing matrix describing the mixing of the 4th neutrino mass state with the electron and muon flavour. In this scenario there is no sensitivity to CP violation in the the Δ driven oscillations, so the relations above are valid for both neutrinos and antineutrinos. At linear order in the mixing elements one can derive a relation between the amplitudes of appearance and disappearance probabilities:

$$4 \sin^2 2\theta_{\mu e} \approx \sin^2 2\theta_{ee} \sin^2 2\theta_{\mu\mu}\,. \tag{14.89}$$

This relation implies a constraint between the possible results in disappearance and appearance experiments. Consequently it is not trivial to find a consistent description to all the SBL anomalies. Over the years, different groups have performed a variety of such global analysis leading to quantitative different conclusions on the statistical quality of the global fit (see for example [203–208], see also Refs. [209, 210] for recent reviews on the subject). Generically the results of the global analysis show that there is significant tension between groups of different data sets – in particular between appearance and disappearance results – and Eq.(14.89) makes it difficult to obtain a good global fit as illustrated in the right panel in Fig.14.10 taken from Ref. [203] which concluded that 3+1 scenario is excluded at 4.7σ level.

A straightforward question to ask is whether the situation improves if more neutrino states at the eV scale are introduced. Simplest extension is the introduction of 2 states with eV scale mass splittings, ν_4 and ν_5. The ordering of the states can be such that Δm^2_{41} and Δm^2_{51} are both positive ("3+2") or one of them is negative ("1+3+1"). From the point of view of the description of the data the most important new qualitative feature in that now non-zero CP violation at $E/L \sim$ eV^2 is possibly observable [206, 211–213]. This allows some additional freedom in fitting neutrino versus anti-neutrino data from LSND and MiniBooNE together. However, it still holds that a non-zero $\nu_\mu \to \nu_e$ appearance at SBL necessarily predicts SBL disappearance for both ν_e and ν_μ. So, generically, the tension between appearance and disappearance results remains, thought differences in the methodology of statistical quantification of the degree of agreement/disagreement in these scenarios can lead to different conclusions on whether they can provide a successful description of all the data [203,209,210]. Cosmological observations can provide complementary information on the number of relativistic neutrino states in thermal equilibrium in the early Universe and on the sum of their masses which sets further constrains on light sterile neutrino scenarios (see Section 26, Neutrinos in cosmology).

[4] However, as discussed in Sec.14.6.4, the reactor antineutrino flux measurement at Daya Bay [143, 199] is consistent with the old flux predictions and the flux measurement results in the previous short-baseline reactor neutrino oscillation experiments.

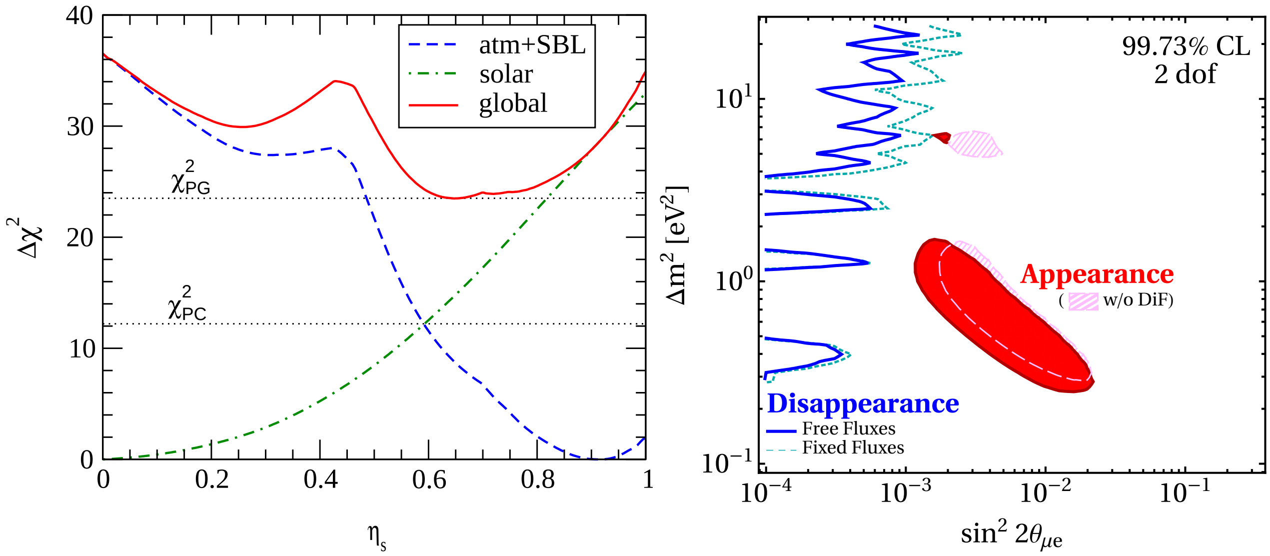

Figure 14.10: *Left*: Status of the 2+2 oscillation scenarios from Ref. [202] ($\eta_S = \sum_i |U_{is}|^2$ where i runs over the two massive states mostly relevant for solar neutrino oscillations). In the figure also shown are the values of $\chi^2_{\rm PC}$ and $\chi^2_{\rm PG}$ relevant for parameter consistency test and parameter goodness of fit respectively. *Right*: Present status of 3+1 oscillation scenarios from Ref. [203].

14.9 Laboratory Probes of ν Mass Scale and its Nature

As described in Secs.14.4 and 14.5 neutrino flavour oscillations in vacuum and flavour transitions in matter only depend on the differences between the neutrino masses-squared, Δm^2_{ij}, and on the mixing matrix elements, U_{ij}. But they are insensitive to the absolute mass scale for the neutrinos, m_i. They also give us no information on whether they are Dirac or Majorana particles.

Clearly the observation of flavour oscillations imply a lower bound on the mass of the heavier neutrino in Δm^2_{ij}, $|m_i| \geq \sqrt{\Delta m^2_{ij}}$ for $\Delta m^2_{ij} > 0$. But there is no upper bound on m_i. In particular, oscillation results allow neutrino spectrum to be approximately degenerate at a mass scale that is much higher than the $\sqrt{\Delta m^2_{ij}}$ that they determine. Information of the mass scale of the neutrino is provided by other type of experiments. In here we briefly summarize the most sensitive laboratory probes of the neutrino mass scale and on whether they are Dirac or Majorana particles. Cosmological observations provide, albeit indirectly, complementary information on the neutrino mass scale as it is reviewed in Section 26, Neutrinos in cosmology.

14.9.1 *Constraints from Kinematics of Weak Decays*

The only model independent information on the neutrino masses, rather than mass differences, can be extracted from energy-momentum conservation relation in reactions in which a neutrino or an anti-neutrino is involved.

Historically these bounds were labeled as limits on the mass of the flavour neutrino states corresponding to the charged flavour involved in the decay. Fermi proposed in 1933 such a kinematic search for the ν_e neutrino mass (which we will label here as $m^{\rm eff}_{\nu_e}$) in the end part of the beta spectra in ^{3}H beta decay $^3\text{H} \rightarrow {}^3\text{He} + e^- + \bar{\nu}_e$.

Because ^{3}H beta decay is a superallowed transition, the nuclear matrix elements are energy independent so the electron spectrum is determined exclusively by the phase space

$$\begin{aligned} \frac{dN}{dE} &= C\, p\, E\, (Q-T)\sqrt{(Q-T)^2 - (m^{\rm eff}_{\nu_e})^2}\, F(E) \\ &\equiv R(E)\, \sqrt{(E_0-E)^2 - (m^{\rm eff}_{\nu_e})^2}\,. \end{aligned} \tag{14.90}$$

E_0 is the mass difference between the inital and final nucleus, $E = T + m_e$ is the total electron energy, p its momentum, $Q \equiv E_0 - m_e$ is the maximum kinetic energy of the electron and Final state Coulomb interactions are contained in the Fermi function $F(E)$. $R(E)$ in the second equality contains all the m_ν-independent factors.

The Kurie function is defined as $K(T) \equiv \sqrt{\frac{dN}{dE}\frac{1}{pEF(E)}}$. From Eq.(14.90) we see that if $m^{\rm eff}_{\nu_e}$=0 $K(T)$ would depend linearly on T. A non-vanishing neutrino mass then provokes a distortion from the straight-line T-dependence at the end point, So for $m^{\rm eff}_{\nu_e} = 0$, $T_{\rm max} = Q$, while for $m^{\rm eff}_{\nu_e} \neq 0$, $T_{\rm max} = Q - m^{\rm eff}_{\nu_e}$. In ^{3}H beta decay $Q = 18.6$ KeV is very small and therefore this decay is more sensitive to this $m^{\rm eff}_{\nu_e}$-induced distorsion.

The most recent result on the kinematic search for neutrino mass in tritium decay is from KATRIN [214], experiment which has found so far no indication of $m_{\nu_e} \neq 0$ and sets an upper limit

$$m^{\rm eff}_{\nu_e} < 1.1 \text{ eV}\,, \tag{14.91}$$

at 90% CL improving over the previous bound from the Mainz [215] and Troitsk [216] experiments which constrained $m^{\rm eff}_{\nu_e} < 2.2$ eV at 95% CL. KATRIN continues running with an estimated sensitivity limit of $m^{\rm eff}_{\nu_e} \sim 0.2$ eV. Project 8 is exploring a new technique for β-spectrometry based on cyclotron radiation [217].

An alternative isotope to Tritium is ^{163}Ho [218] which presents the advantage of a smaller $Q = 2.8$ KeV. It decays via electron-capture to ^{163}Dy. Currently, there are three experiments exploring this decay to probe the neutrino mass: ECHo [219], HOLMES [220], and NuMECS [221]. These experiments are complementary to tritium-based searches from a technical point-of-view. Also the decay of ^{163}Ho determines the effective electron neutrino mass as opposed to anti-neutrino in Tritium.

For the other flavours the present limits compiled in the listing section of the PDG read

$$m^{\rm eff}_{\nu_\mu} < 190 \text{ keV (90\% CL)} \qquad \text{from} \qquad \pi^- \rightarrow \mu^- + \bar{\nu}_\mu\,, \tag{14.92}$$

$$m^{\rm eff}_{\nu_\tau} < 18.2 \text{ MeV (95\% CL)} \qquad \text{from} \qquad \tau^- \rightarrow n\pi + \nu_\tau\,. \tag{14.93}$$

In the presence of mixing and for neutrinos with small mass differences the distortion of the beta spectrum is given by the sum of the individual spectra generated incoherently by each neutrino massive state weighted with the relevant mixing matrix element squared [222]:

$$\frac{dN}{dE} = R(E)\sum_i |U_{ei}|^2 \sqrt{(E_0-E)^2 - m_i^2}\,\Theta(E_0 - E - m_i)\,. \tag{14.94}$$

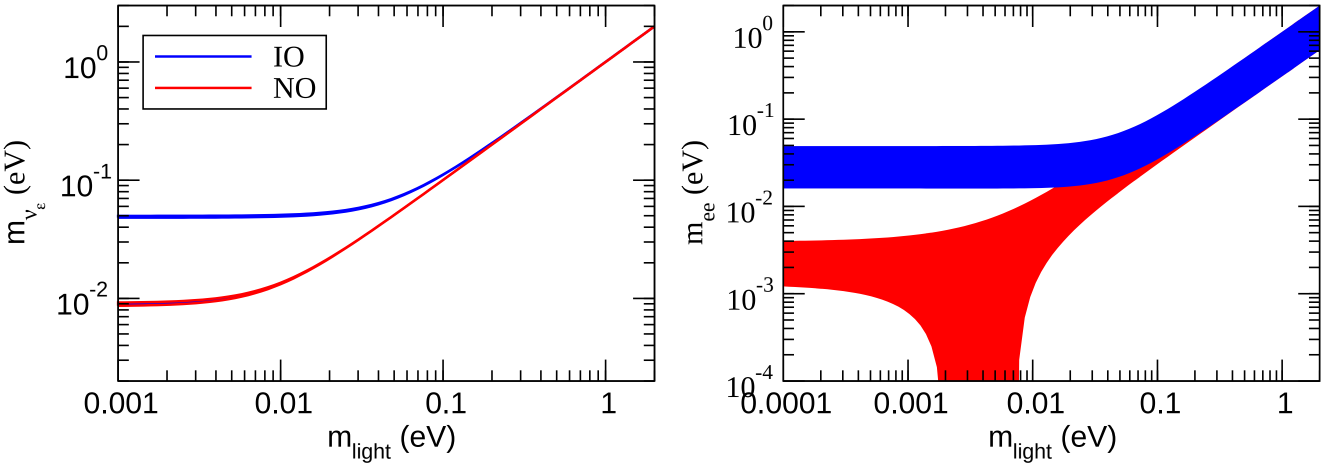

Figure 14.11: Allowed 95% CL ranges (1 dof) for the neutrino mass observable determined in ^{3}H beta decay (left panel) and in $0\nu\beta\beta$ (right panel) in the framework of 3ν mixing as a function of the lightest neutrino mass. The ranges are obtained by projecting the results of the global analysis of oscillation data (w/o SK-atm) in Ref. [187]. The region for each ordering is defined with respect to its local minimum.

The step function, $\Theta(E_0 - E - m_i)$ arises because a neutrino with a given mass m_i can only be produced if the available energy is larger than its mass. Equation (14.94) shows the two main effects of the neutrino masses and mixings on the electron energy spectrum: First kinks appear at the electron energies $E_e^{(i)} = E \sim E_0 - m_i$ with sizes that are determined by $|U_{ei}|^2$. Second the end point shifts to $E_{\rm ep} = E_0 - m_0$, where m_0 is the lightest neutrino mass. Corrections are induced once the the energy resolution of the experiment is considered [223, 224]

In the 3-ν mixing scenario the distortion of the spectrum can still be effectively described by a single parameter – which we will still denote as m_{ν_e} – if for all neutrino states $E_0 - E = Q - T \gg m_i$. In this case one can expand Eq.(14.94) as:

$$\frac{dN}{dE} \simeq R(E) \sum_i |U_{ei}|^2 \sqrt{(E_0 - E)^2 - (m_{\nu_e}^{\rm eff})^2}\,, \tag{14.95}$$

with

$$(m_{\nu_e}^{\rm eff})^2 = \frac{\sum_i m_i^2 |U_{ei}|^2}{\sum_i |U_{ei}|^2} = \sum_i m_i^2 |U_{ei}|^2\,, \tag{14.96}$$

where unitarity is assumed in the second equality. In this approximation the distortion of the end point of the spectrum is described by a single parameter, and with the present results from KATRIN it is bounded to be

$$\begin{aligned} 1.1\ \text{eV} \geq m_{\nu_e}^{\rm eff} &= \sqrt{\sum_i m_i^2 |U_{ei}|^2} \\ &= \begin{cases} \sqrt{m_0^2 + \Delta m_{21}^2 (1 - c_{13}^2 c_{12}^2) + \Delta m_{32}^2 s_{13}^2} & \text{in NO}\,, \\ \sqrt{m_0^2 + \Delta m_{21}^2 c_{13}^2 c_{12}^2 - \Delta m_{32}^2 c_{13}^2} & \text{in IO}\,, \end{cases} \end{aligned} \tag{14.97}$$

where $m_0 = m_1$ (m_3) is the lightest neutrino mass in NO (IO) spectrum. Correspondingly the bounds in Eqs.(14.92) and (14.93) apply to the combinations $\sum_i m_i^2 |U_{\alpha i}|^2$ for $\alpha = \mu$ and τ respectively. So with the values known of the mixing matrix elements the strongest constraint on the absolute value of the neutrino mass comes from Tritium beta decay.

From Eq.(14.97) we see that, given the present knowledge of the neutrino mass differences and their mixing from oscillation experiments, it is possible to translate the experimental information of m_{ν_e} on a corresponding range for the lightest neutrino mass and that such relation depends on the ordering of the states. We plot in Fig.14.11 the recasting of the allowed regions of the analysis in Ref. [187] in terms of the allowed range m_{ν_e} as a function of $m_{\rm light} \equiv m_0$. In particular one finds that the results of oscillation experiments imply a lower bound on $m_{\nu_e} > 0.048$ (0.0085) eV for IO (NO) at 95% CL.

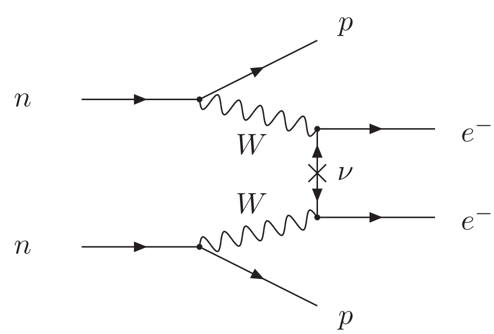

Figure 14.12: Feynman diagram for neutrinoless double-beta decay.

14.9.2 *Dirac vs Majorana: Neutrinoless Double-beta Decay*

The most sensitive probe to whether neutrinos are Dirac or Majorana states is the neutrinoless double beta decay ($0\nu\beta\beta$):

$$(A, Z) \to (A, Z+2) + e^- + e^-\,. \tag{14.98}$$

In the presence of neutrino masses and mixing the process in Eq.(14.98) can be generated at lower order in perturbation theory by the term represented in Fig.14.12. The corresponding amplitude is proportional to the product of the two leptonic currents

$$\begin{aligned} M_{\alpha\beta} &\propto [\bar{e}\gamma_\alpha(1-\gamma_5)\nu_e]\ \left[\bar{e}\gamma_\beta(1-\gamma_5)\nu_e\right] \\ &\propto \sum_i (U_{ei})^2\,[\bar{e}\gamma_\alpha(1-\gamma_5)\nu_i]\ \left[\bar{e}\gamma_\beta(1-\gamma_5)\nu_i\right]\,. \end{aligned} \tag{14.99}$$

The neutrino propagator in Fig.14.12 can only arise from the contraction $\langle 0\,|\,\nu_i(x)\nu_i(y)^T\,|\,0\rangle$. But if the neutrino is a Dirac particle ν_i field annihilates a neutrino states and creates an antineutrino state which are different, so the contraction $\langle 0\,|\,\nu_i(x)\nu_i(y)^T\,|\,0\rangle = 0$ and $M_{\alpha\beta} = 0$. On the other hand, if ν_i is a Majorana particle, neutrino and antineutrino are described by the same field and $\langle 0\,|\,\nu_i(x)\nu_i(y)^T\,|\,0\rangle \neq 0$.

The conclusion is that in order to induce the $0\nu\beta\beta$ decay, neutrinos must be Majorana particles. This is consistent with the fact that the process (14.98) violates total lepton number by two units. Conversely, if $0\nu\beta\beta$ decay is observed, massive neutrinos cannot be Dirac states [225].

It is important to stress that neutrinoless double beta decay could be dominantly induced by other new physics effects beyond that of Majorana neutrino masses, Consequently the connection between the observation or limitation of the neutrinoless double beta decay and the neutrino mass can only be made under some assumption about the source of total lepton number violation in the model.

The observable determined by the experiments is the half-life of the decay. Under the assuption that the Majorana neutrino mass is the only source of lepton number violation at low energies, the decay half-life is given by:

$$(T^{0\nu}_{1/2})^{-1} = G^{0\nu} \left| M^{0\nu} \right|^2 \left(\frac{m_{ee}}{m_e} \right)^2 , \tag{14.100}$$

where $G^{0\nu}$ is the phase space integral taking into account the final atomic state, $|M^{0\nu}\ |$ is the nuclear matrix element of the transition, and m_{ee} is the *effective Majorana mass of* ν_e,

$$\begin{aligned} m_{ee} &= \left| \sum_i m_i U^2_{ei} \right| \\ &= \begin{cases} \left| m_0 c^2_{12} c^2_{13} + \sqrt{\Delta m^2_{21} + m^2_0}\, s^2_{12} c^2_{13} e^{2i(\eta_2 - \eta_1)} + \sqrt{\Delta m^2_{32} + \Delta m^2_{21} + m^2_0}\, s^2_{13} e^{-2i(\delta_{\rm CP} + \eta_1)} \right| & \text{in NO} , \\ \left| m_0 s^2_{13} + \sqrt{m^2_0 - \Delta m^2_{32}}\, s^2_{12} c^2_{13} e^{2i(\eta_2 + \delta_{\rm CP})} + \sqrt{m^2_0 - \Delta m^2_{32} - \Delta m^2_{21}}\, c^2_{12} c^2_{13} e^{2i(\eta_1 + \delta_{\rm CP})} \right| & \text{in IO} , \end{cases} \end{aligned}$$

which, in addition to the masses and mixing parameters that affect the tritium beta decay spectrum, depends also on the leptonic CP violating phases. We plot in Fig.14.11 the the recasting of the allowed regions of the analysis in Ref. [187] in terms of the allowed range m_{ee} as a function of $m_{\rm light} \equiv m_0$ for the two orderings. As a consquence of the dependence on the unknown Majorana phases, the allowed range of m_{ee} for a given value of $m_{\rm light}$ and ordering is substantially broader than that of m_{ν_e}. Nevertheless, the results of oscillation experiments imply a lower bound on the effective Majorana mass for the IO, which at 95%CL reads $m_{ee} > 0.016$ eV.

From Eq.(14.100) we see that nuclear structure details enter relation between the decay rate (or lifetime) and the effective Majorana mass. As a consequence uncertainties in the nuclear structure calculations result in a spread of m_{ee} values for a given $T^{0\nu}_{1/2}$ by a factor of 2–3 [226].

We present in Sec.14.9.3 a brief description of the experimental searches for neutrinoless double-beta decay. At the time of writing of this review the strongest bound on $0\nu\beta\beta$ decay lifetime comes from the search in KamLAND-Zen experiment [227] (see Sec.14.9.3) which uses 13 Tons of Xe-loaded liquid scintillator to search for the decay $0\nu\beta\beta$ of ^{136}Xe and has set a bound on the half-life of $T^{0\nu}_{1/2} > 1.07 \times 10^{26}$ yr at 90% CL. Using a variety of nuclear matrix element calculations, the corresponding upper bound on the effective Majorana mass is

$$m_{ee} < 61 - 165 \text{ meV} . \tag{14.101}$$

14.9.3 *Experimental Search for Neutrinoless Double-beta Decay*

The signature of $0\nu\beta\beta$ is that the sum of energy of two electrons is equal to the Q-value of the nuclear transition. Various requirements must be met to achieve high sensitivity such as a large source mass with isotopic enrichment, underground location to shield cosmic-ray induced background, and ultra-low background techniques to reduce radioactive background. The sensitivity to the half-life is proportional to $\varepsilon M t$ in the case of a background-free measurement and $\varepsilon\sqrt{\frac{Mt}{b\Delta E}}$ for the case background exists, where ε is the detection efficiency of the signal, M is the source mass, t is the measurement time, b is the background rate, and ΔE is the energy resolution.

There are 35 candidate nuclei for double-beta decay. Currently, experiments using ^{136}Xe and ^{76}Ge have reported the most sensitive results of $0\nu\beta\beta$ search. Because of the uncertainties related to the nuclear matrix element, complementarity of technologies, different background, and the investigation of the mechanism behind the $0\nu\beta\beta$ in case of a positive signal, it is important to pursue the searches with various isotopes.

The energy from electrons is measured with either ionization, scintillation, or through phonons. In some experiments a combination of two techniques is used. Among those using ionization detection, ultra-high-purity germanium detector provides the best sensitivity thanks to high energy resolution and low background. GERDA uses total 20.0 kg of broad energy germanium (BEGe) and 15.6 kg of coaxial detectors, both enriched in ^{76}Ge, for the second phase. Background levels of $(5.6^{+3.4}_{-2.4}) \times 10^{-4}$ counts/(keV·kg·year) for BEGe detectors and $(5.7^{+4.1}_{-2.6}) \times 10^{-4}$ counts/(keV·kg·year) for coaxial detectors have been achieved [228], which enable a background-free search. The Majorana-Demonstrator [229] consists of 44.1 kg of Ge (29.7 kg enriched to 88% in ^{76}Ge) detectors split between two modules. It has achieved energy resolution of 2.5 keV FWHM at the Q-value (2.039 MeV).

Liquid scintillator detectors have simple structure and can utilize existing large detectors with low background environments. By adding an inner balloon to contain xenon-loaded liquid scintillator to the KamLAND detector, KamLAND-Zen used 380 kg of xenon with 90.1% enrichment in ^{136}Xe. Reducing the background level by purification of scintillator, KamLAND-Zen reported the half-life limit above 10^{26} years at 90% CL [227]. The SNO detector has been also upgraded to be filled with liquid scintillator in SNO+ experiment [230]. The SNO+ detector will be loaded with 0.5% natural tellurium, corresponding to approximately 1330 kg of ^{130}Te to search for $0\nu\beta\beta$.

With a time projection chamber, one can utilize both ionization and scintillation. EXO-200 uses a liquid xenon time projection chamber with enrichment to 80.6%, corresponding to 74.7 kg of ^{136}Xe in the fiducial mass [231]. An energy resolution of 1.15% (σ/E) is achieved at the Q-value of ^{136}Xe $0\nu\beta\beta$. The NEXT collaboration has been developing a high-pressure xenon gas time projection chamber with electroluminescent amplification and optical readouts. An energy resolution of 1% FWHM at the Q-value of ^{136}Xe $0\nu\beta\beta$ is demonstrated with NEXT-White detector [232].

CUORE uses cryogenic bolometer to measure the energy in a calorimetric way. The detector is located in Gran Sasso and composed of 988 TeO_2 bolometers for a total mass of 742 kg, corresponding to 206 kg of ^{130}Te. An effective energy resolution of (7.7±0.5) keV FWHM is achieved for the first result [233]. For further reduction of background towards future search based on the CUORE technology, CUPID proposes to simultaneously measure the calorimetric signal and the scintillation light. Using the prototype CUPID-0, the technology is demonstrated and also $0\nu\beta\beta$ is searched for with ^{82}Se [234].

AMoRE also uses the simultaneous detection of heat and scintillation. Six ^{100}Mo-enriched and ^{48}Ca-depleted $CaMoO_4$ crystals with a total mass of 1.9 kg (AMoRE-Pilot) are operated in Yangyang underground laboratory located in South Korea, searching for $0\nu\beta\beta$ of ^{100}Mo [235].

A tracker-calorimeter technique is employed in NEMO. Source isotopes are hosted in thin foils surrounded by a tracking detector, which in turn is surrounded by a calorimeter. Full topological event reconstruction with this configuration enables background rejection and gives additional information after discovery. The

NEMO-3 experiment used 7 isotopes, with the largest mass comprised of ^{100}Mo (7 kg) [236]. NEMO-3 also reported a first search for neutrinoless quadruple-β decay of ^{150}Nd [237].

15. Quark Model

Revised August 2019 by C. Amsler (Stefan Meyer Inst.), T. DeGrand (Colorado U., Boulder) and B. Krusche (Basel U.).

15.1 Quantum numbers of the quarks

Quantum chromodynamics (QCD) is the theory of strong interactions. QCD is a quantum field theory and its constituents are a set of fermions, the quarks, and gauge bosons, the gluons. Strongly interacting particles, the hadrons, are bound states of quark and gluon fields. As gluons carry no intrinsic quantum numbers beyond color charge, and because color is believed to be permanently confined, most of the quantum numbers of strongly interacting particles are given by the quantum numbers of their constituent quarks and antiquarks. The description of hadronic properties which strongly emphasizes the role of the minimum-quark-content part of the wave function of a hadron is generically called the quark model. It exists on many levels: from the simple, almost dynamics-free picture of strongly interacting particles as bound states of quarks and antiquarks, to more detailed descriptions of dynamics, either through models or directly from QCD itself. The different sections of this review survey the many approaches to the spectroscopy of strongly interacting particles which fall under the umbrella of the quark model.

Quarks are strongly interacting fermions with spin 1/2 and, by convention, positive parity. Antiquarks have negative parity. Quarks have the additive baryon number 1/3, antiquarks -1/3. Table 15.1 gives the other additive quantum numbers (flavors) for the three generations of quarks. They are related to the charge Q (in units of the elementary charge e) through the generalized Gell-Mann-Nishijima formula

$$\mathsf{Q} = \mathsf{I}_z + \frac{\mathcal{B} + \mathsf{S} + \mathsf{C} + \mathsf{B} + \mathsf{T}}{2} , \tag{15.1}$$

where $\mathcal{B}$ is the baryon number. The convention is that the quark *flavor* (I_z, S, C, B, or T) has the same sign as its *charge* Q. With this convention, any flavor carried by a charged meson has the same sign as its charge, *e.g.*, the strangeness of the K^+ is +1, the bottomness of the B^+ is +1, and the charm and strangeness of the D_s^- are each −1. Antiquarks have the opposite flavor signs.

Table 15.1

	d	u	s	c	b	t
Q – electric charge	$-\frac{1}{3}$	$+\frac{2}{3}$	$-\frac{1}{3}$	$+\frac{2}{3}$	$-\frac{1}{3}$	$+\frac{2}{3}$
I – isospin	$\frac{1}{2}$	$\frac{1}{2}$	0	0	0	0
I_z – isospin z-component	$-\frac{1}{2}$	$+\frac{1}{2}$	0	0	0	0
S – strangeness	0	0	−1	0	0	0
C – charm	0	0	0	+1	0	0
B – bottomness	0	0	0	0	−1	0
T – topness	0	0	0	0	0	+1

The hypercharge is defined as

$$\mathsf{Y} = \mathcal{B} + \mathsf{S} - \frac{\mathsf{C} - \mathsf{B} + \mathsf{T}}{3} . \tag{15.2}$$

Thus Y is equal to $\frac{1}{3}$ for the u and d quarks, $-\frac{2}{3}$ for the s quark, and 0 for all other quarks. More details and derivations on the quark structure of mesons and baryons can be found in Ref. [1].

15.2 Mesons

Mesons have baryon number $\mathcal{B} = 0$. In the quark model, they are $q\bar{q}\,'$ bound states of quarks q and antiquarks $\bar{q}\,'$ (the flavors of q and q' may be different). If the orbital angular momentum of the $q\bar{q}\,'$ state is ℓ, then the parity P is $(-1)^{\ell+1}$. The meson spin J is given by the usual relation $|\ell - s| \leq J \leq |\ell + s|$, where s is 0 (antiparallel quark spins) or 1 (parallel quark spins). The charge conjugation, or C-parity $C = (-1)^{\ell+s}$, is defined only for the $q\bar{q}$ states made of quarks and their own antiquarks. The C-parity can be generalized to the G-parity $G = (-1)^{I+\ell+s}$ for mesons made of quarks and their own antiquarks (isospin $\mathsf{I}_z = 0$), and for the charged $u\bar{d}$ and $d\bar{u}$ states (isospin $\mathsf{I} = 1$).

The mesons are classified in J^{PC} multiplets. The $\ell = 0$ states are the pseudoscalars (0^{-+}) and the vectors (1^{--}). The orbital excitations $\ell = 1$ are the scalars (0^{++}), the axial vectors (1^{++}) and (1^{+-}), and the tensors (2^{++}). Assignments for many of the known mesons are given in Tables 15.2, 15.3 and 15.4. Radial excitations are denoted by the principal quantum number n. The very short lifetime of the t quark makes it likely that bound-state hadrons containing t quarks and/or antiquarks do not exist.

States in the natural spin-parity series $P = (-1)^J$ must, according to the above, have $s = 1$ and hence, $CP = +1$. Thus, mesons with natural spin-parity and $CP = -1$ (0^{+-}, 1^{-+}, 2^{+-}, 3^{-+}, *etc.*) are forbidden in the $q\bar{q}\,'$ model. The $J^{PC} = 0^{--}$ state is forbidden as well. Mesons with such *exotic* quantum numbers may exist, but would lie outside the $q\bar{q}\,'$ model (see section below on exotic mesons).

Following SU(3), the nine possible $q\bar{q}\,'$ combinations containing the light u, d, and s quarks are grouped into an octet and a singlet of light quark mesons:

$$\mathbf{3} \otimes \overline{\mathbf{3}} = \mathbf{8} \oplus \mathbf{1} . \tag{15.3}$$

A fourth quark such as charm c can be included by extending SU(3) to SU(4). However, SU(4) is badly broken owing to the much heavier c quark. Nevertheless, in an SU(4) classification, the sixteen mesons are grouped into a 15-plet and a singlet:

$$\mathbf{4} \otimes \overline{\mathbf{4}} = \mathbf{15} \oplus \mathbf{1} . \tag{15.4}$$

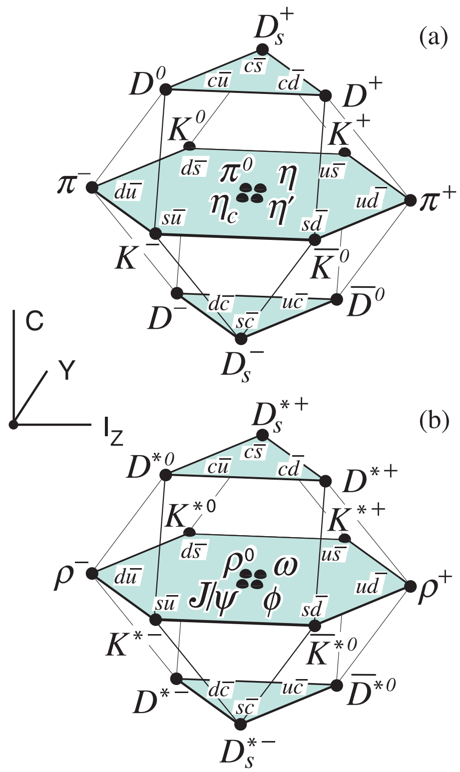

Figure 15.1: SU(4) weight diagram showing the 16-plets for the pseudoscalar (a) and vector mesons (b) made of the u, d, s, and c quarks as a function of isospin I_z, charm C, and hypercharge $\mathsf{Y} = \mathcal{B} + \mathsf{S} - \frac{\mathsf{C}}{3}$. The nonets of light mesons occupy the central planes to which the $c\bar{c}$ states have been added.

The *weight diagrams* for the ground-state pseudoscalar (0^{-+}) and vector (1^{--}) mesons are depicted in Fig. 15.1. The light quark mesons are members of nonets building the middle plane in Fig. 15.1(a) and (b).

Isoscalar states with the same J^{PC} mix, but mixing between the two light quark isoscalar mesons, and the much heavier charmonium or bottomonium states, are generally assumed to be negligible. In the following, we shall use the generic names a for the $\mathsf{I} = 1$, K for the $\mathsf{I} = 1/2$, and f and f' for the $\mathsf{I} = 0$ members of

Table 15.2: Suggested $q\bar{q}$ quark-model assignments for some of the observed light mesons. Mesons in bold face are included in the Meson Summary Table. The wave functions f and f' are given in the text (Eqn. 15.9). The singlet-octet mixing angles from the linear mass formula (15.12) and its quadratic version (in which the masses are squared) are also given for the well established nonets. The classification of the 0^{++} mesons is tentative: the light scalars $a_0(980)$, $f_0(980)$, $f_0(500)$ and $K_0^*(700)$ are often considered to be four-quark states, and are omitted from the table, see Eqn. (15.26) below. The isoscalar 0^{++} mesons $f_0(1370)$, $f_0(1500)$ (not shown) and $f_0(1710)$ are expected to mix, see the "Note on Non-$q\bar{q}$ mesons" and the "Note on Scalar Mesons below 2 GeV" in the Meson Listings for details. The isoscalar assignments in the 2^1S_0 (0^{-+}) nonet are also tentative. The $\eta(1405)$ (not shown) and $\eta(1475)$ may be manifestations of the same state, see the "Note on Pseudoscalar and Pseudovector Mesons in the 1400 MeV Region" in the Meson Listings.
† The $1^{+\pm}$ and $2^{-\pm}$ isospin $\frac{1}{2}$ states mix. In particular, the K_{1A} and K_{1B} are nearly equal (45°) mixtures of the $K_1(1270)$ and $K_1(1400)$ (see [2] and references therein).
‡ The physical vector mesons may be mixtures of 1^3D_1 and 2^3S_1 [3].

the light quark nonets. Thus, the physical isoscalars are mixtures of the SU(3) wave function ψ_8 and ψ_1:

$$f' = \psi_8\,\cos\theta - \psi_1\,\sin\theta\ , \tag{15.5}$$
$$f = \psi_8\,\sin\theta + \psi_1\,\cos\theta\ , \tag{15.6}$$

where θ is the nonet mixing angle and

$$\psi_8 = \frac{1}{\sqrt{6}}(u\bar{u} + d\bar{d} - 2s\bar{s})\ , \tag{15.7}$$

$$\psi_1 = \frac{1}{\sqrt{3}}(u\bar{u} + d\bar{d} + s\bar{s})\ . \tag{15.8}$$
