Highlights

- The stratigraphic architecture of the last 130 ky in the Po Basin was reconstructed
- Along-strike and along-dip facies changes are emphasized through transects
- Detailed facies mapping of the MIS 5e maximum marine ingression has been provided
- MIS 5e-MIS 1 facies architecture clearly denotes a main glacio-eustatic control
- Detailed stratigraphic correlations reveal a structural control on sedimentation

Abstract

Eight stratigraphic transects, 40 to 140 km long reveal, for the first time on a regional scale, a comprehensive picture of facies architecture of the highly preserved Late Pleistocene-Holocene sedimentary succession from the rapidly subsiding Po Basin. Facies analysis and pollen-based correlation, supported by radiocarbon, electron-spin resonance and optically stimulated luminescence dates, enabled the attribution of distinct stratigraphic intervals to Marine Isotope Stages (MIS) 6 to 1.

Basin-scale facies changes appear to have been driven mostly by glacio-eustatic oscillations falling in the Milankovitch band (~100 ky). The MIS 5e coastal wedge was tracked continuously beneath the modern shoreline, for over 110 km along strike. Along-dip (west-east) stratigraphic correlation over 140 km revealed

the characteristic landward transition from shallow-marine and coastal facies to lagoonal, swamp, and floodplain deposits.

The MIS 5d-MIS 2 stratigraphic succession, up to 95-m-thick, records the stepped, basinward shift of facies related to the post-MIS 5e sea-level fall. In particular, lagoon and swamp facies mark minor transgressions (Substages 5c and 5a), whereas thick floodplain deposits and laterally extensive (> 40 km) fluvial channel-belts, up to 30 m thick, characterized the glacial periods (MIS 4 and MIS 2).

The Holocene (MIS 1) coastal wedge shares many similarities in terms of facies architecture and geometry with its MIS 5e counterpart, though maximum landward marine incursion during the MIS 5e transgression was 10 km farther inland (35 km inland of modern shoreline). Organic-rich (freshwater swamp) environments developed > 100 km landwards of the present-day coastline.

The MIS 5e-MIS 1 succession of the Po Basin displays an exceptional thickness, up to 130 m. Minimum values (~20 m) are recorded close to the Apennine margin and above the buried actively growing anticlines. The spatial distribution and geometry of the MIS 5e-MIS 1 strata, as well as rapidly varying subsidence rates (from 0.2 to 1.0 mm/y) reflect the strong influence of the structural setting (location of major thrust fronts) over the creation/destruction of accommodation.

Keywords: Late Quaternary; Last Interglacial; MIS 5e coastal wedge; Maximum marine ingression; Po Basin.

1. Introduction

The Last Interglacial (LI) coincides with Marine Isotope Stage (MIS) 5e, which is a proxy record of low global ice volume and high sea-level (Kukla et al., 2002). MIS 5e is the lowest substage of MIS 5 (Shackleton, 1969), which spans the time interval between Termination II (end of MIS 6, ~135 ky BP) and the onset of MIS 5d (~116 ky BP; Murray-Wallace, 2013; Shackleton et al., 2003).

The MIS 5e interval was characterized by warmer climate conditions and higher global sea-level (up to 9 m) than the present interglacial (MIS 1; Antonioli, 2012; Dutton et al., 2015; Dutton and Lambeck, 2012; Kopp et al., 2009; Tzedakis et al., 2018; Waelbroeck et al., 2002). For this reason, the LI is generally considered a good analog, albeit imperfect, of possible scenarios resulting from the ongoing global warming (Antonioli et

56 al., 2017; Clark and Huybers, 2009; IPCC, 2018, 2007; Overpeck et al., 2006; Sánchez Goñi et al., 2012, 1999;
57 Tzedakis, 2013) and its near-future projections (Church et al., 2013; Horton et al., 2019; Rohling et al., 2008;
58 Stammer et al., 2019).

59 Climate and relative sea-level characteristics of MIS 5e have been typically reconstructed from ice and
60 marine cores (Bard et al., 1990; Chappell and Shackleton, 1986; Chappell et al., 1996; Shackleton, 2000, 1987;
61 Siddall et al., 2003; Waelbroeck et al., 2002). On the other hand, LI sea-level has been estimated through the
62 analysis of geomorphological and stratigraphical features, such as prominent tidal notches, lagoonal
63 sedimentary facies, fossil beaches and marine terraces (Lambeck et al., 2004; Murray-Wallace, 2013; Pirazzoli,
64 1993; Rovere et al., 2016) or submerged speleothems (Antonioli et al., 2004; Bard et al., 2002). These sea-
65 level indicators have also been used as a regional datum to quantify geodetic variations over the last 120 ky
66 (Bordoni and Valensise, 1998; Murray-Wallace, 2002). In general, MIS 5e deposits are worldwide considered
67 as important stratigraphic markers (Creveling et al., 2015; Murray-Wallace and Woodroffe, 2014) and have
68 been used to assess vertical displacements due to regional subsidence or uplift (Ferranti et al., 2010, 2006;
69 Galili et al., 2007; Guillaume et al., 2013; Lambeck et al., 2004; Matsu'ura et al., 2019; Rovere et al., 2016).
70 MIS 5e sea-level markers have been documented worldwide in sub-aerially exposed successions in stable or
71 uplifting areas (Amorosi et al., 2014; Bardají et al., 2009; Carr et al., 2010; Mauz et al., 2012; Murray-Wallace
72 et al., 2016; Oliver et al., 2018), or buried beneath subsiding coastal plains (Carboni et al., 2010; De Santis et
73 al., 2010; Otvos, 2015, 2013).

74 In spite of the huge number of studies that focused on the LI sedimentary record, scarce attention has
75 been paid, in general, to detailed stratigraphic reconstructions of facies architecture, nor accurate
76 sedimentological studies have been undertaken on buried late Pleistocene successions. In relatively proximal
77 (alluvial) settings, the post-MIS 5e stratigraphy is generally poorly preserved due to river incision driven by
78 sea-level fall (Blum et al., 2013; Milli et al., 2016, 2013; Otvos, 2005; Tropeano et al., 2013; Vis et al., 2008).
79 By contrast, detailed stratigraphic information is available for the Rhine-Meuse system (the Netherlands), a
80 low-gradient fluvial system developed in a slowly subsiding setting (Busschers et al., 2005, 2007; Peeters et
81 al., 2019, 2015; Sier et al., 2015). However, because of river avulsion and erosion during the last 130 ky, the
82 MIS 5-MIS 2 stratigraphic record (up to 40 m thick), has only locally been preserved (Peeters et al., 2016,

2015). Additional high-resolution studies carried out in the Kanto and Echigo coastal plains, in Japan, have been limited to the MIS 5e or MISs 3-1 intervals (Nakazawa et al., 2017; Tanabe et al., 2013, 2009).

In the Po Basin (Northern Italy, Fig. 1), high subsidence rates (up to 2.5 mm/y over the last 1.43 My; Carminati and Di Donato, 1999) have led to the deposition of a stratigraphically extensive late Quaternary succession (Regione Emilia-Romagna and Eni-Agip, 1998; Regione Lombardia and Eni Divisione Agip, 2002). Several studies, focusing on relatively small areas or even on single cores (Amorosi et al., 2004, 1999a; Castorina and Vaiani, 2018; Fiorini, 2004; Scarponi and Kowalewski, 2004), have documented an almost continuous and highly-resolved sedimentary record of the last 140 ky. These studies documented the presence of a thick coastal sediment wedge at depths of up to 100 m. Local studies from the central Po Plain, up to 140 km landwards of the modern shoreline, showed clear changes in pollen taxa and lithofacies within a fully alluvial succession (Amorosi et al., 2008, 2001; Geological Map of Italy at 1:50,000 scale, Sheets: 187, 200, 223, 240, 255), which are interpreted to represent the abrupt change from cold (MIS 6, 4, 3 and 2) to temperate (MIS 5e and 1) climatic conditions.

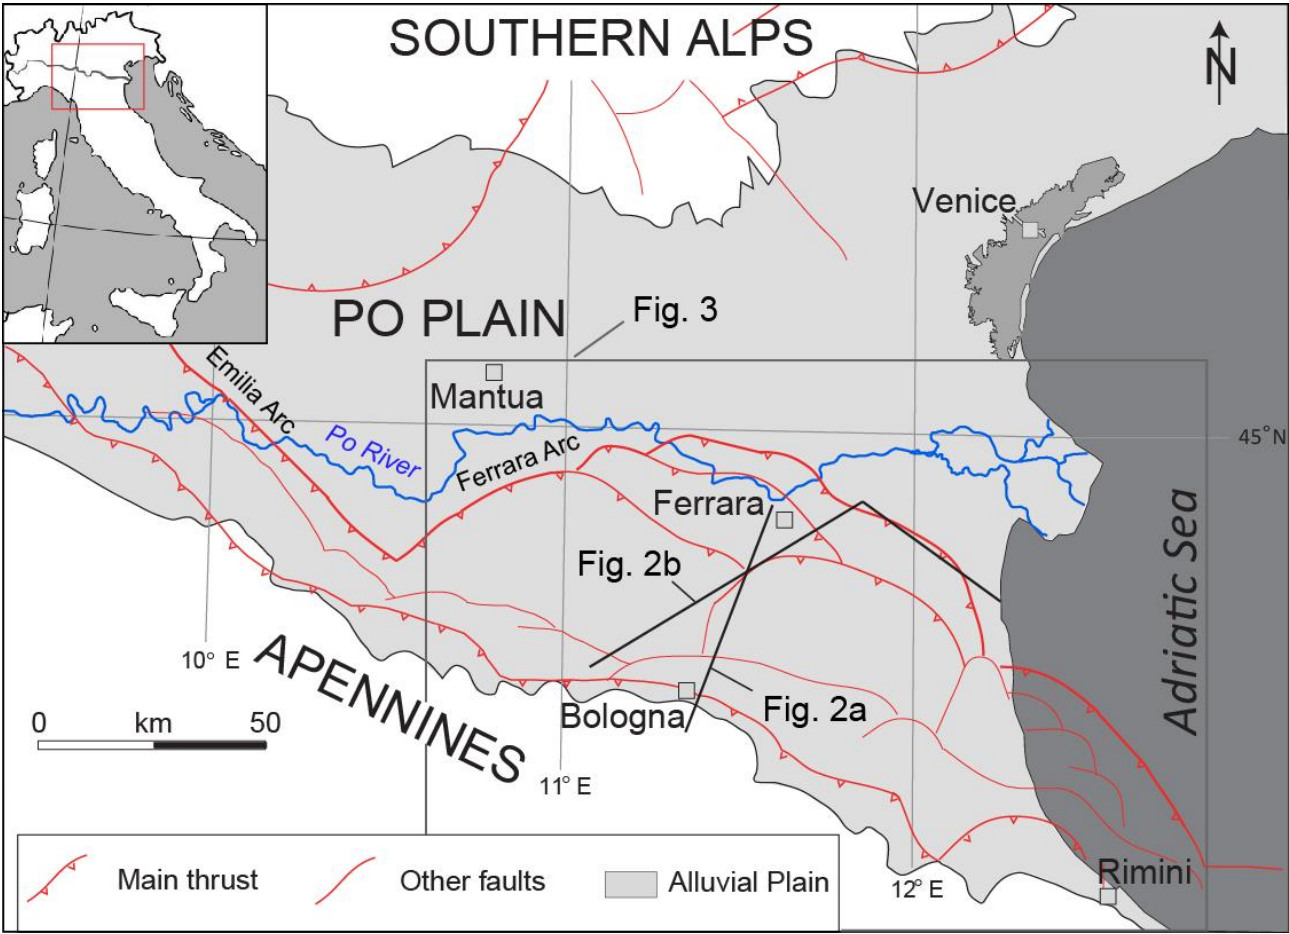

Fig. 1 – Structural map of the Po Plain, indicating the (i) buried Alpine and Apennine structures (modified from Burrato et al., 2003); (ii) study area (gray rectangle), and (iii) traces of seismic and stratigraphic profiles of Figure 2a, b.

Despite all these data, no stratigraphic reconstruction is currently available for the MIS 5e and post-MIS 5e sedimentary record at basin-scale. Whereas MIS 3-MIS 1 stratigraphy, and particularly the depositional architecture of the Holocene coastal wedge, have been studied in detail (Amorosi et al., 2019, 2017a; Bruno et al., 2017; Campo et al., in press, 2017), older Late Pleistocene strata are poorly known, especially in terms of lateral facies distribution and geometry of sedimentary bodies.

This work presents, for the first time, a high-resolution reconstruction of the stratigraphic architecture of the Po Basin succession of the last 130 ky. This study focusses on: (i) the basin-scale correlation of the MIS 5e coastal wedge and the identification of its landward equivalents; (ii) the reconstruction of its 3D geometries, with a specific focus on along-dip and along-strikes facies variations; (iii) the mapping of the maximum marine ingression during the MIS 5e highstand; (iv) the critical analysis of controlling-factors of facies distribution and thickness of MIS 5e deposits.

2. Geological setting

2.1 Structural setting

The Po Plain is the widest alluvial plain (~ 48,000 km²) of the Italian peninsula. It is the morphological expression of the Po Basin, a rapidly subsiding basin bounded by the south-verging Southern Alps and the north-verging Northern Apennines (Burrato et al., 2003; Fig. 1). These two orogens started to form in the Cretaceous, in response to the collision of the Adria microplate and the European Plate (Carminati and Doglioni, 2012). The Northern Apennines are a fold-and-thrust belt that formed mostly during the Neogene and the Quaternary (Basili and Barba, 2007; Malinverno and Ryan, 1986; Royden et al., 1987). The most external thrusts of the Apennines are buried beneath the Miocene to Quaternary sedimentary infill of the southern Po Basin (Pieri and Groppi, 1981; Figs. 1, 2a). In the central and eastern sectors of the Po Plain, the buried structures of the Northern Apennines consist of two arched thrust systems, with convexity towards the NNE (Fig. 1): the Emilia arc to the W and the Ferrara arc to the SE (Fig. 1). These thrust systems became

active in the Late Miocene (Boccaletti et al., 2011; Picotti and Pazzaglia, 2008; Scrocca et al., 2007) and, following the 2012 seismic events in the southern Po Plain (i.e. Emilia Earthquake, 2012; Caputo et al., 2015; Pondrelli et al., 2012) they are considered to be still active. Fault propagation and imbrication led to the formation of thrust-related anticlines (Maesano et al., 2015; Ori and Friend, 1984; Rossi et al., 2015; Toscani et al., 2014). Far away from anticline culminations, subsidence rates have been estimated to be as high as 2.5 mm/y over the last 1.43 My (Carminati et al., 2003; Carminati and Di Donato, 1999).

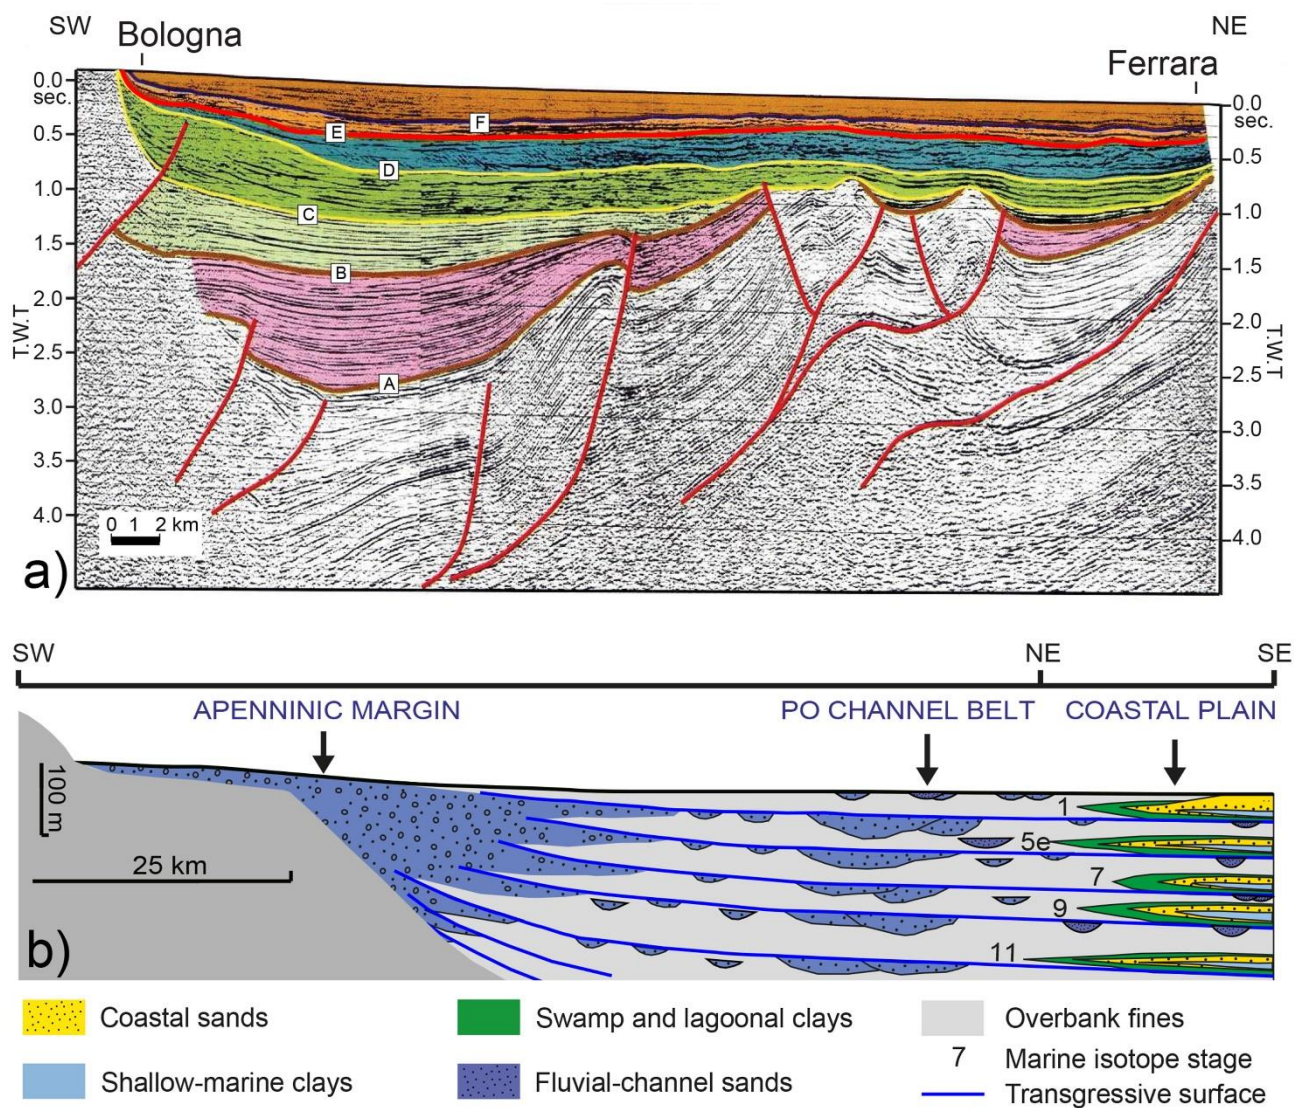

Fig. 2 – a) Interpreted seismic profile showing the Plio-Quaternary sedimentary infill of the Po Basin (colored area): depositional sequences (P2, Qm and Qc), major blind thrusts (red lines) and stratigraphic unconformities (A-F lines) are shown as interpreted by Regione Emilia-Romagna and ENI-Agip, (1998; location in Figure 1). T.W.T. – two-way travel time. For a depth-version of the same seismic profile, see Boccaletti et al. (2011), their Fig. 5, cross-section D-D'. b) Schematic illustration of the proximal-to-distal

137 stratigraphic architecture of the Middle-Late Pleistocene Po Plain succession, showing distinct cyclic changes
138 in facies and channel stacking in the Milankovitch band (~ 100 ky). Modified from Amorosi and Colalongo
139 (2005). Location can be found in Figure 1.

140 **2.2 Stratigraphic setting**

141 The sedimentary infill of the Po Basin has been investigated at basin-scale through the integration of
142 seismic and well data (Amadori et al., 2019; Ghielmi et al., 2013; Pieri and Groppi, 1981; Regione Emilia-
143 Romagna and Eni-Agip, 1998; Regione Lombardia and Eni Divisione Agip, 2002). The Plio-Quaternary
144 succession ranges in thickness between 8 km in the depocenters, to a few hundred meters atop the buried
145 anticlines (Mariotti and Doglioni, 2000; Pieri and Groppi, 1981). It is characterized by a shallowing-upward
146 trend, from Pliocene deep-marine to Quaternary shallow-marine and continental deposits (Ori, 1993; Ricci
147 Lucchi et al., 1982). Based on magnetostratigraphic data (Muttoni et al., 2003), the uppermost ~800 m of the
148 basin fill has been dated to the last 0.87 My. Throughout the basin, from proximal to distal locations, the late
149 Quaternary succession of the Po Basin fill is characterized by vertical cyclic changes in facies, with channel
150 stacking-patterns reflecting the Middle-Late Pleistocene alternation of glacial and interglacial periods
151 (Amorosi et al., 2008, 2004, 1999a). Beneath the coastal sector, two wedge-shaped, coastal to shallow-marine
152 sediment bodies, identified around ~100 m and 30 m depth (Fig. 2b) have been assigned to MIS 5e and MIS 1
153 respectively (Amorosi et al., 2004; Ferranti et al., 2006). Close to the Apennine margin and beneath the modern
154 Po River, sheet-like fluvial channel-bodies were formed during glacial periods, which alternate with mud-
155 dominated intervals assigned to the interglacials (Amorosi et al., 2008).

156

157 **3. Materials and methods**

158 **3.1 Stratigraphic dataset**

159 The study area is a ~8,500 km² wide sector of the Po Plain, framed between the cities of Mantova,
160 Ferrara, Reggio Emilia, Bologna, and Rimini (Fig. 3). The stratigraphic reconstruction of the Late Pleistocene-
161 Holocene succession – with a thickness of up to 150 m - has been carried out through the analysis and
162 interpretation of a large stratigraphic dataset (Fig. 3), mostly recovered as part of the geological mapping
163 (CARG) project of Italy (scale 1:50,000).

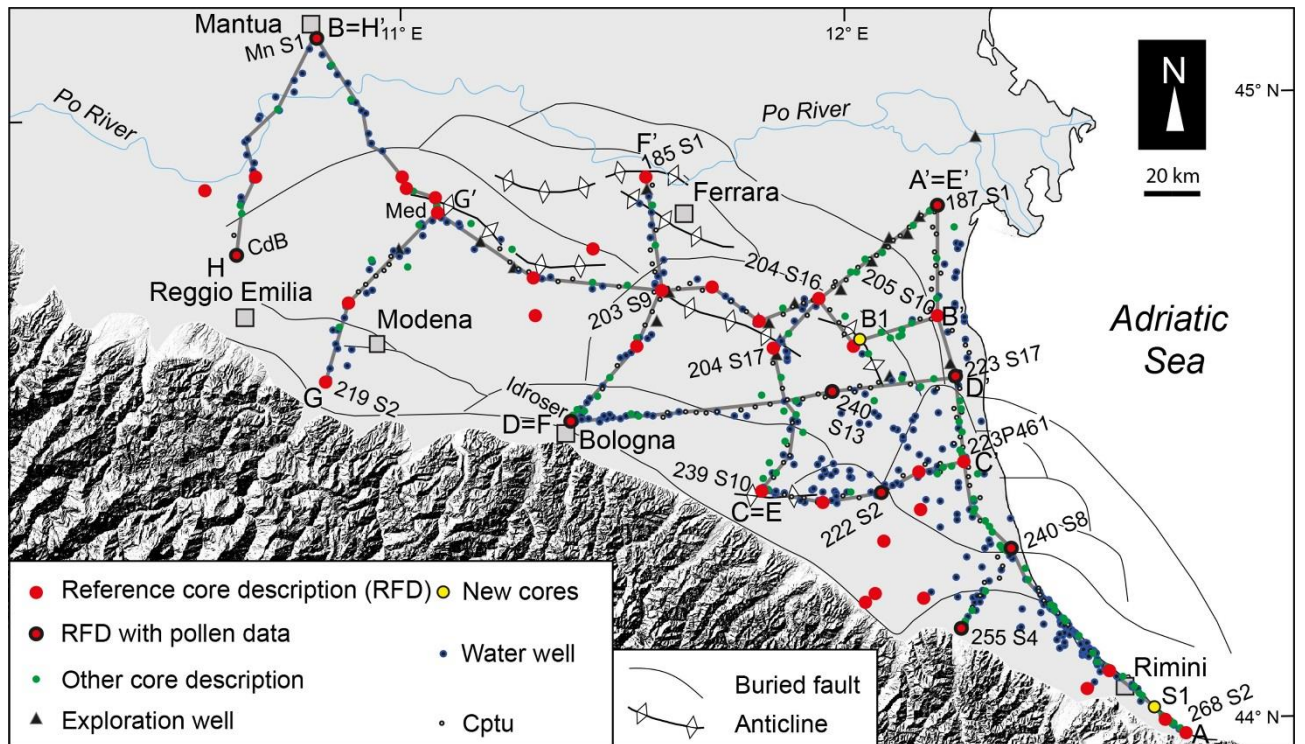

Fig. 3 – Study area, with indication of stratigraphic data used in this study and the main buried Apennine structures. Traces of cross sections of Figures 6-8 are represented by gray lines.

Stratigraphic data were provided by the geological surveys of Regione Emilia-Romagna and Regione Lombardia, and consist of 160 continuous-core descriptions, 554 water-well logs, 21 hydrocarbon exploration-well reports and 141 piezocone tests (see Data Availability).

Descriptions from cores reaching depths of 30-200 m (Fig. 3), provide high-quality information about lithology, grain size, color, pedogenic and other features such as peat layers, shell fragments, bioturbation, carbonate nodules, wood, and plant remains. Pocket penetration test values are frequently available. Selected core descriptions are part of published studies (Amorosi et al., 2008, 2004, 2001, 1999a; Bondesan et al., 2006; Castorina and Vaiani, 2018; Ferranti et al., 2006; Fiorini, 2004; Geological Map of Italy at 1:50,000 scale, Sheets: 256, 255, 241, 240, 223, 222, 221, 220, 205, 204, 187) and include sedimentological, micropaleontological, palynological and chronological data (i.e. ^{14}C and electron-spin resonance “ESR”; see Table 1 in Appendix and Data Availability). Among these, 44 cores with depths of > 100 m, have been used as reference (Fig. 3) for the identification of MIS 5e deposits and for detailed characterization of the post-MIS 5e succession.

181 Two continuously-cored boreholes (S1 and B1; see Fig. 3 for location), penetrating the entire MIS 5e-
182 MIS 1 succession, were recently recovered close to the Apennine margin (core S1) and above the crest of a
183 growing anticline in the Ferrara coastal plain (core B1; Fig. 3). Water wells (average depth~150 m; Fig. 3)
184 provided mostly basic lithological information (sand vs mud). Occasionally, the presence of marine shells is
185 reported.

186 Hydrocarbon-well reports (average depth~500 m; Fig. 3) provide the lowest-resolution stratigraphic
187 information. Nevertheless, they offer petrophysical data that can be useful for lithological distinctions and, in
188 a few cases, information about fossil and organic matter content is provided. Given their limited depth (< 35
189 m), piezocone tests (CPTU; Fig. 3) were utilized for stratigraphic correlation of the uppermost Pleistocene-
190 Holocene (MIS 3-MIS 1) deposits. The reader is referred to Amorosi and Marchi, (1999), Amorosi et al.,
191 (2015) and Campo et al. (in press) for stratigraphic interpretation of CPTU tests.

192

193 **3.2 Luminescence and radiometric dating**

194 One undisturbed sample was collected from core B1 and sent to the Oxford Luminescence Dating
195 Laboratory (University of Oxford, UK) for Optically Stimulated Luminescence (OSL) dating. This sample
196 was recovered during drilling operations with an Osterberg cell from a depth of 39.9-39.3 m. The 60 cm core
197 segment was removed and the exposed top and bottom parts were sealed with paraffin. Paraffin caps were
198 removed in a dark room and the upper and lowermost ~5 cm of the sample were discarded. The innermost part
199 of the core segment (39.85-39.5 m depth) was in turn split into four samples stored in lightproof containers
200 and sent to the laboratory. At the laboratory, the samples were given the following laboratory codes:

- 201 i) X7339 (OSL sample), from core B1 (39.60-39.50 m depth);
- 202 ii) X7340 (OSL spare sample), from core B1 (39.75 m depth);
- 203 iii) X7341 (dosimetry sample), from core B1 (39.80 m depth);
- 204 iv) X7342 (dosimetry sample), from core B1 (39.85 m depth).

205 The resulting age is based on luminescence measurements of sand-size quartz (150-255µm) extracted
206 from the samples using standard preparation techniques including, wet sieving, HCl (10%) treatment to remove
207 carbonates, HF treatment (48%) to dissolve feldspatic minerals and heavy mineral separation with sodium
208 polytungstate. Measurements were performed on small multigrain aliquots (n=30) with standard automated

luminescence readers made by Risø (Bøtter-Jensen, 1997, 1988; Bøtter-Jensen et al., 2000) and Freiberg Instruments (Richter et al., 2015) using a double SAR post-IR blue or post-IR green OSL measurement protocol (Banerjee et al., 2001; Murray and Wintle, 2000; Wintle and Murray, 2006). Dose rate calculations are based on Aitken (1985) and are derived from the concentration of radioactive elements (potassium, rubidium, thorium and uranium) within the sediment sample. These were derived from elemental analysis by ICP-MS/AES using a fusion sample preparation technique. The final OSL age estimate includes an additional 4% systematic error to account for uncertainties in source calibration and measurement reproducibility. Dose rate calculations were obtained using dose rate conversion factors of Guérin et al. (2011) and calculated using the DRAC software (v1.02) developed by Durcan et al. (2015). The contribution of cosmic radiation to the total dose rate was calculated as a function of latitude. Altitude, burial depth and an average over-burden density of 1.9 g/cm³ is based on data by Prescott and Hutton (1994).

Two organic-rich samples were collected from core B1 for radiocarbon analysis. Samples were dried at 40 °C and underwent to acid-alkali-acid pretreatment before AMS counting at KIGAM Laboratory (Korea Institute of Geoscience and Mineral Resources, Daejeon, Republic of Korea). OxCal 4.2 (Ramsey and Lee, 2013) with the IntCal 13 curve (Reimer et al., 2013) was used for radiocarbon age calibration.

224

225 **4. Depositional facies associations**

The complete MIS 6-MIS 1 succession of the southern Po alluvial and coastal plain was penetrated by cores S1 and B1, respectively 55 m and 39.9 m in length (Fig. 4). Lithofacies assemblages have been extensively described in previous studies and will not be reiterated here in detail. For detailed facies analysis of the MIS 6-MIS 3 interval, the reader is referred to Amorosi et al. (2008, 2004, 2001, 1999a) and Bondesan et al. (2006); whereas, for the MIS 2-MIS 1 interval, high-resolution facies descriptions have been reported by Amorosi et al. (2017a, 2017b), Bruno et al. (2017), and Campo et al. (2017). As documented by these studies, a large variety of facies associations typifies the MIS 6-MIS 1 Po Plain succession. For a complete overview of their major characteristics the reader may refer to the table in the Appendix. A generalized description of these deposits is given below. Twenty-one facies associations were grouped into five main depositional systems. Each group is briefly described from proximal to distal locations.

236 - Alluvial plain deposits. Three main facies associations form the alluvial plain depositional system: the
237 fluvial-channel facies association is 2-30 m thick, and consists of fine to coarse sand, up to gravel bodies with
238 fining-upwards (FU) trends (Fig. 4) and erosional lower boundaries. Crevasse and levee facies are made up of
239 < 2 m thick sand bodies and sand-silt alternations, respectively (Fig. 4), with scattered root fragments. FU
240 trends and sharp lower boundaries are characteristic of crevasse channels; in contrast, crevasse splays show
241 coarsening-upward (CU) grain-size trends and gradational lower boundaries. The well-drained floodplain
242 facies association is characterized by rooted and bioturbated clay and silty clay deposits with brownish mottles.
243 Pedogenic features typical of weakly developed paleosols (Inceptisols; Fig. 4) are common. The occurrence
244 of meiofauna commonly is rare, and includes fragments of freshwater (F) ostracods and poorly-preserved
245 marine foraminifers, mostly sparse in sandy deposits. Freshwater gastropods are locally encountered (Fig. 4).

246 - Freshwater and organic-rich inner/wave-dominated estuarine deposits. This depositional system
247 includes five freshwater (F), hypoaline and locally organic-rich facies associations (Fig. 4). Distributary-
248 channel (Fig. 4) and related crevasse/levee facies associations share several characteristics with their alluvial
249 counterparts: i.e. lithology, grain-size trends and erosional to transitional lower boundaries. However,
250 distributary-channel deposits are thinner and generally finer-grained than fluvial-channel sand bodies. The
251 bay-head delta facies association resembles distributary-channel sands in terms of lithology and sedimentary
252 structures, but the abundance of plant debris, the local development of CU trends, and the association between
253 freshwater and brackish fossils may represent diagnostic features. The poorly-drained floodplain facies
254 association consists of gray clay and silty clay, with no pedogenic features (Fig. 4) and rare carbonate
255 concretions. The swamp facies association is characterized by dark to brown clay, with abundant peat, wood
256 fragments, and vegetal remains (Fig. 4). Pedogenic features are almost absent, with the only exception of
257 histosols. The concentration of freshwater ostracods progressively increases from poorly-drained floodplain to
258 swamp facies. Pocket penetrometer values (Fig. 4) have commonly been used for the differentiation of fine-
259 grained deposits within the MIS 2-MIS 1 succession (e.g. well-drained floodplain, poorly-drained floodplain,
260 and swamp clays, see Amorosi et al., 2015). This approach, however, can locally be adopted even for their
261 older (MIS 6 to MIS 3, Fig. 4) counterparts, when they are not already overconsolidated.

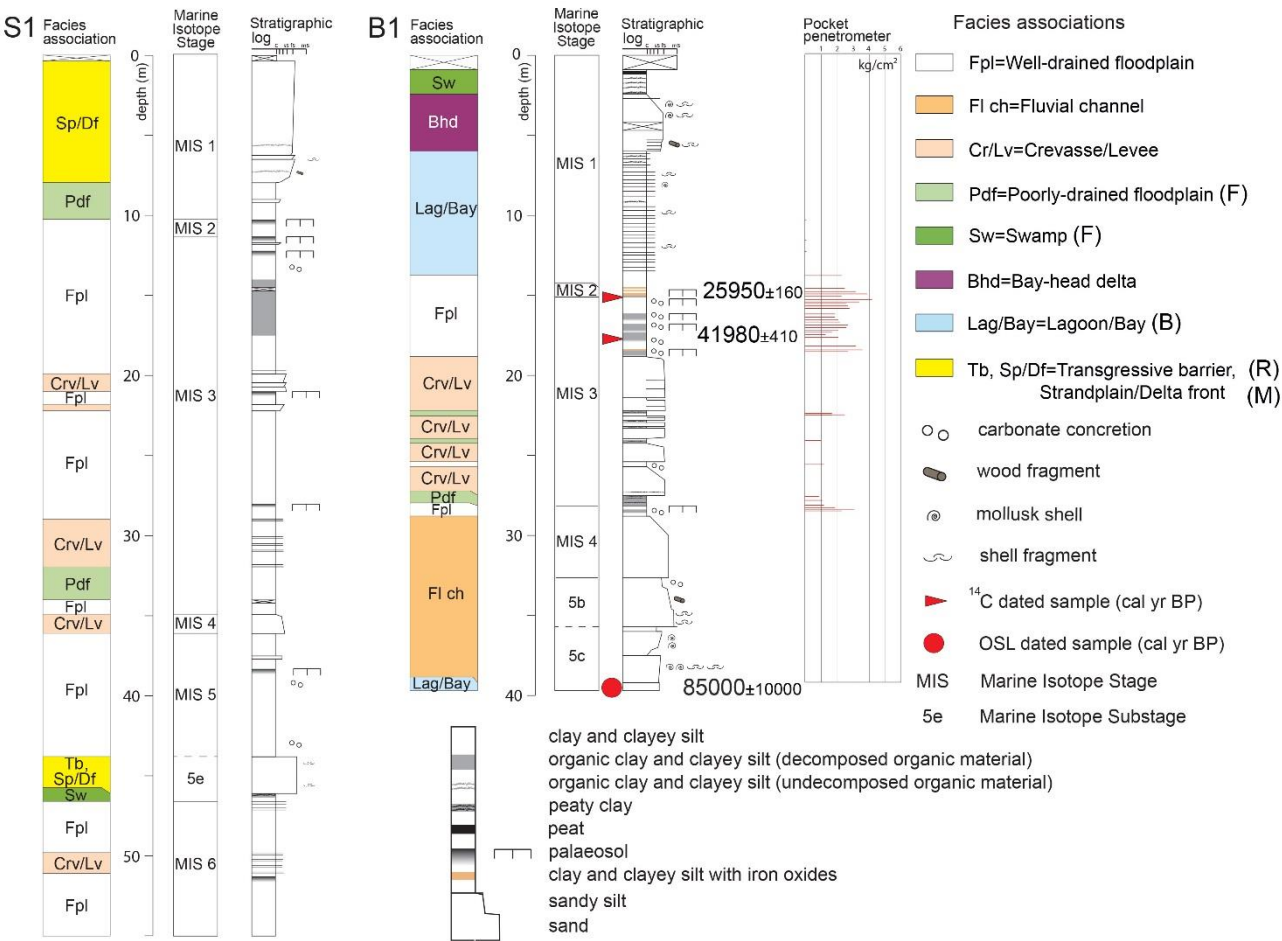

262 - Brackish outer wave-dominated estuarine deposits. This depositional system is composed of four mud-
263 dominated facies associations, with a diagnostic brackish fauna (B in Fig. 4), which is tolerant to sudden

264 changes in salinity and organic matter content. Facies subdivision is based on (i) the frequency and thickness
265 of sand intercalations, both increasing seawards; (ii) ostracod and foraminifer associations that reflect an
266 increasing marine water influence downstream; (iii) organic matter concentration that increases landwards.
267 From proximal to distal locations, brackish facies associations correspond to the following sub-environments:
268 salt-marsh, mud-flat, central lagoon/bay and outer lagoon/bay.

269 - Transgressive barrier, strandplain, and delta front deposits. This depositional system includes four
270 facies associations characterized by a generally high sand content. Grain size, ~~set~~ ⁽²⁾ thickness range, facies
271 boundaries, and fossil content are the main diagnostic features: the transgressive sand-sheet facies association
272 is the result of the shoreface retreat during MIS 5e-MIS 1 transgressions, and consists of shell-rich, medium-
273 to-silty sands with a maximum thickness of 2 m, an erosional lower boundary and FU trends; the upper
274 shoreface/foreshore facies association includes medium to coarse sand-bodies (1-5 m thick), with a gradational
275 lower boundary; the lower shoreface facies association also shows transitional lower boundaries to the
276 underlying prodelta facies and is composed of fine to very fine sand-bodies, 1-5 m thick; the mouth bar facies
277 association, up to 10 m thick, includes medium to fine sand deposits, with an abundance of plant debris (Fig.
278 4). The transgressive sand-sheet facies includes reworked sediments, with a reworked microfauna and an
279 abundance of mixed marine and brackish mollusk species (R in Fig. 4). Within mouth-bar and upper
280 shoreface/foreshore facies, no foraminifers or ostracods are generally preserved and a paucity of shells is
281 recorded. On the contrary, an abundant and highly diverse marine fossil assemblage (M in Fig. 4) is typical of
282 nearshore facies: i.e. especially lower shoreface.

283 - Offshore/prodelta deposits. This mud-dominated depositional system represents the most distal portion
284 of the Po Basin succession recovered onshore. Five facies associations were grouped into this depositional
285 system. All these facies include marine (M) fossils assemblages. Fine sand-clay alternations are characteristic
286 of the most proximal facies associations, such as the delta-front transition and offshore transition deposits.
287 These facies associations accumulated in similar water depths but in different subenvironments characterized
288 by high (i.e., delta-front transition) vs low/none (i.e., offshore transition) river influence, as the distance from
289 the river mouth increases. Delta-front transition facies may include plant debris. Seawards, the sand/mud ratio
290 rapidly decreases and organic-matter content increases: proximal prodelta facies (silty clay) is progressively
291 replaced by distal prodelta facies (clay), up to 8 m thick. The offshore facies association is made up of

292 bioturbated clay deposits, up to 2 m thick. The highly diversified meiofauna, typical of open-marine conditions,
 293 and lithological characteristics are consistent with the relatively deep depositional environment. Offshore-
 294 transition deposits are characterized, instead, by less diversified assemblages; whereas, prodelta muds
 295 generally include opportunistic species able to tolerate stressed marine conditions (i.e. high freshwater and
 296 sediment inputs) related to river floods.

300

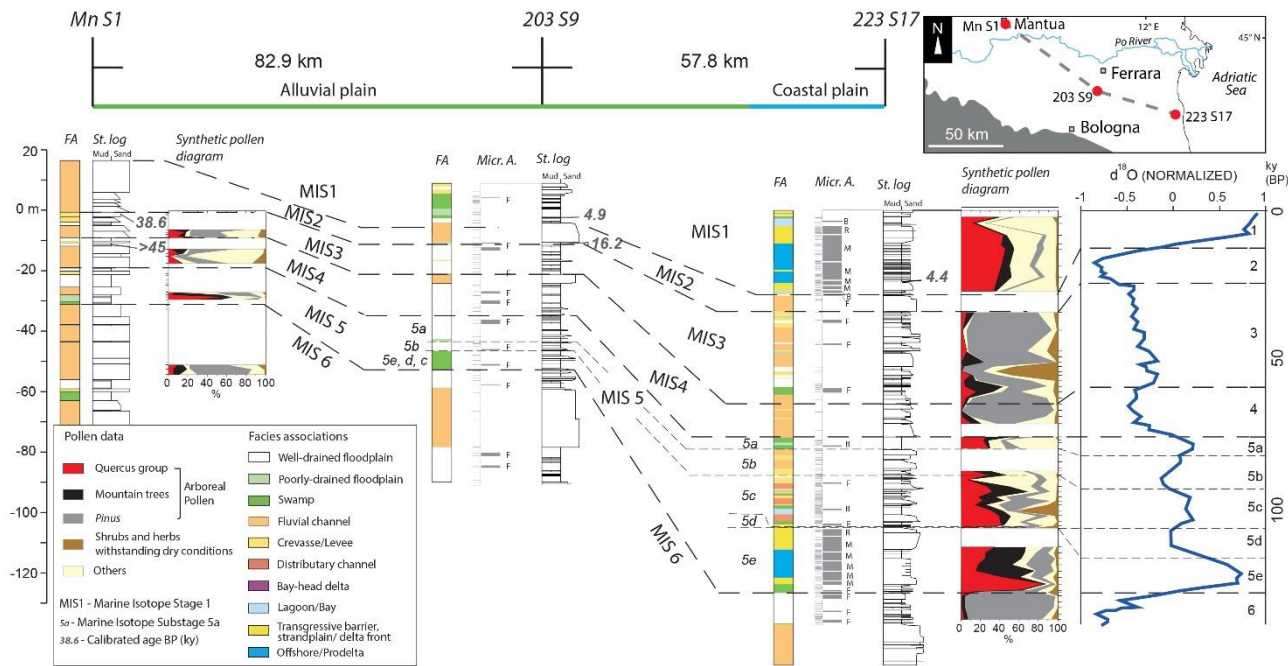

301 5. Pollen-based stratigraphic correlations

302 Stratigraphic correlations relied upon the combination of facies and pollen data available for 9 cores
 303 (Fig. 3). Particularly pollen data provided important information about climate-related vegetational and
 304 environmental changes.

305 Pollen taxa subdivision follows their ecological and climatic affinities (i.e. arboreal vs non arboreal and
 306 warmth- vs cold-loving taxa; see Zangheri, 1976; Pignatti, 1998, 2017), as previously done by Amorosi et al.

307 (2008, 2004, 2001,1999a). Two main groups have been distinguished: arboreal (AP) and non-arboreal pollen
308 (NAP). AP can be subdivided into three components: (i) *Quercus* group, representative of warm-temperate
309 phases (interglacials), which includes humidity- and warmth-loving species of deciduous broad-leaf forests
310 dominated by oaks; (ii) mountain trees and (iii) *Pinus* which are indicative of cool-wet and cold climate
311 conditions (glacials), respectively. NAP (i.e. shrubs and herbs), withstanding dry conditions, are indicators of
312 cold steppic environments.

313 Vertical changes in facies associations and pollen spectra led to high-resolution stratigraphic
314 correlations and subdivision into sediment units deposited during specific Marine Isotope Stages. Basin-scale
315 correlations between three reference cores, representative of proximal (core Mn S1), intermediate (core 203
316 S9), and distal (core 223 S17) locations of the Po Basin are shown in Figure 5. A schematic stratigraphic log
317 with facies interpretation is provided for each core. Detailed palaeontological analyses are available for cores
318 203 S9 and 223 S17 (Geological Map of Italy at 1:50,000 scale, Sheet: 203; Amorosi et al., 1999a), whereas
319 pollen data were obtained from cores Mn S1, Idroser (projected on core 203 S9) and 223 S17 (Amorosi et al.,
320 2008, 2001, 1999a).

322 **Fig. 5** –Basin-scale correlation from proximal (alluvial plain) to distal (coastal plain) locations of the Po
323 Basin. Facies associations and pollen signals recorded from cores were correlated with the oxygen-isotope
324 ($\delta^{18}\text{O}$) record of the last 150 ky (blue line; modified from Martinson et al., 1987). FA: facies association; St.
325 log: stratigraphic log; Micr. A.: Micropaleontological association (F: freshwater; B: brackish; R: reworked; M:

326 marine). See Figure 3 for location of the cores, and Table A1 (Appendix) for details on radiocarbon dates. For
327 the original pollen data the reader may refer to Data Availability.

328

329 As pollen concentration is very scarce in sandy deposits, the pollen curve from core Mn S1 is highly
330 discontinuous (Amorosi et al., 2008). However, pollen profiles from cores Mn S1, 203 S9 (i.e., Idroser) and
331 223 S17 show comparable pollen spectra at specific stratigraphic intervals (Fig. 5). Peaks in *Quercus* highlight
332 the onset of warmer/temperate periods on a basin scale. Two major warm phases were identified and linked to
333 the major peaks in $\delta^{18}\text{O}$ during MIS 5e and MIS 1 (Martinson et al., 1987, Fig. 5). The transition from glacial
334 to interglacial periods (e.g., MIS 6/5e) is characterized by sharp changes in pollen taxa (Fig. 5; Amorosi et al.,
335 2004) from high *Pinus* and mountain trees percentages (cold indicators) to high *Quercus* percentages (warm
336 indicators).

337 Pollen variations at glacial/interglacial transitions are paralleled by abrupt facies variations that reflect
338 rapid sea-level rise (Fig. 5). As an example, well-drained floodplain muds assigned to the MIS 6 glacial are
339 typically overlain by interglacial paralic and coastal facies associations attributed to MIS 5e (Fig. 5).
340 Landwards of the line of maximum marine ingression (core Mn S1, Fig. 5), the same pollen signal is associated
341 with the abrupt shift from barren fluvial sands to overlying (“transgressive”) swamp muds.

342 The correlation of stages and substages relies upon similar changes in pollen signals and on vertical
343 stacking patterns of facies, with an additional contribution by radiocarbon ages for the MIS 3-MIS 1 interval
344 (Fig. 5). Minor transgressions correlate with minor peaks in $\delta^{18}\text{O}$ (MIS 5c and 5a in Fig. 5). The thick alluvial
345 succession sandwiched between MIS 5e and MIS 1 deposits, and mostly characterized by cold pollen
346 signatures can be assigned to MIS 4-3-2 (Fig. 5). Poorly-drained and swamp deposits within this interval may
347 reflect lower magnitude transgressive pulsations mostly recorded at the onset of MIS 3 (Fig. 5).

348

349 **6. MIS 5e-MIS 1 stratigraphy in the southern Po Basin**

350 Basin-scale correlations along eight stratigraphic transects (Figs. 6-8) document the high-resolution,
351 Late Pleistocene-Holocene facies architecture of the Po Plain. Pollen data, coupled with ESR, OSL and
352 radiocarbon ages enable age attribution of the investigated strata, and their assignment to the MIS 5e-MIS 1
353 interval.

354 Two > 100 km-long stratigraphic transect were constructed: AA' (Fig. 6a) extends from the Apennine
355 margin to the modern Po Delta and is approximately parallel to the modern shoreline; and BB' (Fig. 6b) which
356 runs parallel to the Apennine margin, extends from the town of Mantua to the Adriatic coast (Figs. 3, 6). Figure
357 7 includes three stratigraphic cross-sections (i.e. CC', DD' and EE') that were traced in the distal sector of the
358 study area. The south-north oriented stratigraphic transects of Figure 8 (i.e. FF', GG', HH') were constructed
359 to explore along-strike changes in stratigraphy at proximal locations.

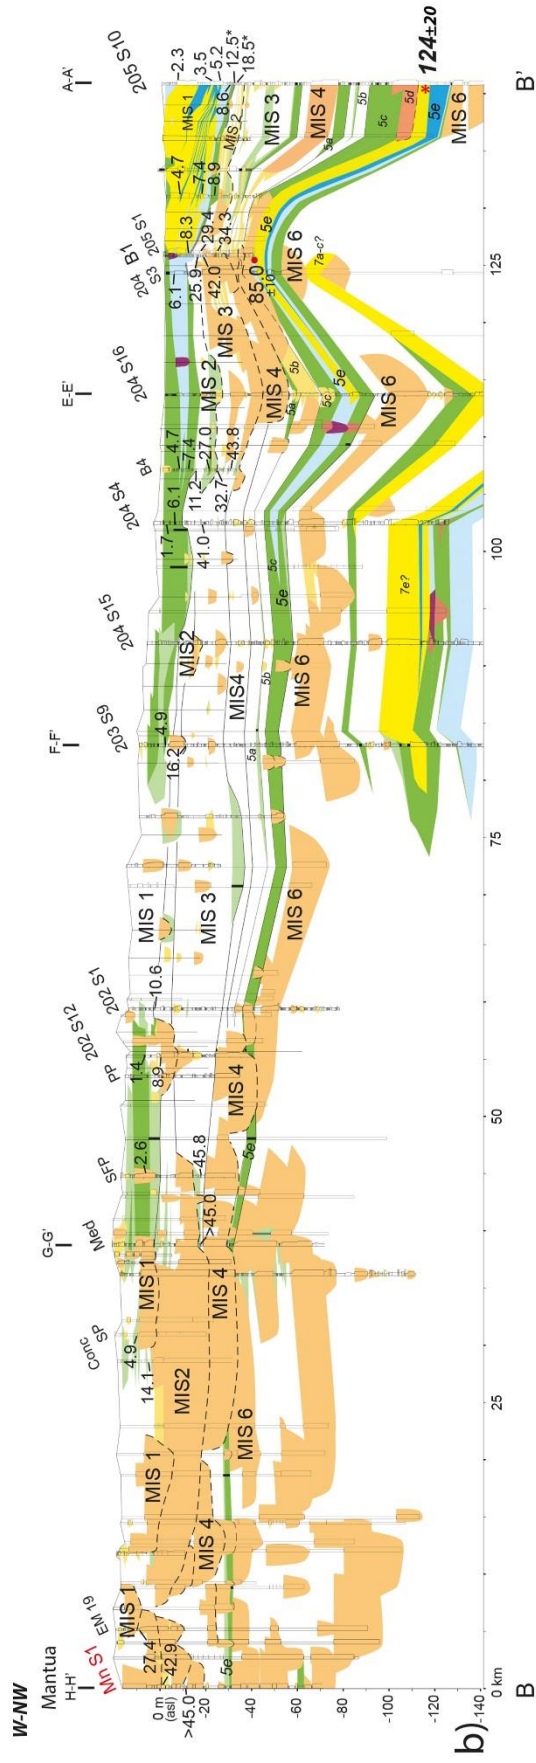

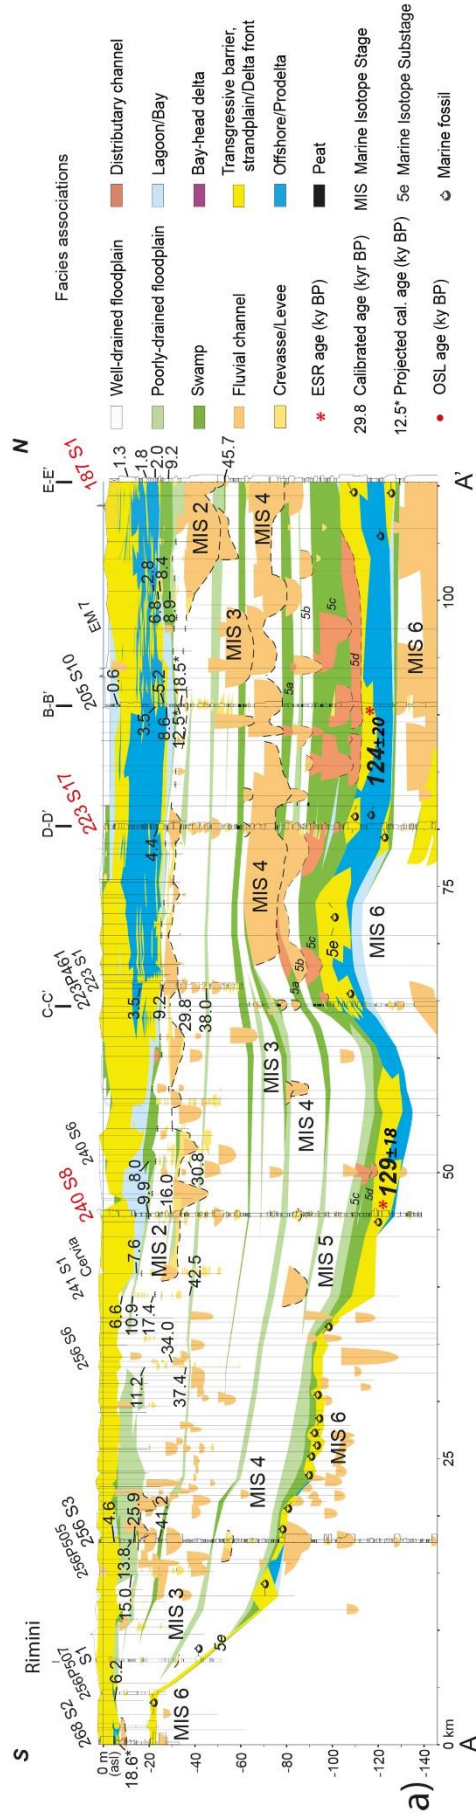

Fig. 6 – Basin-scale stratigraphic architecture of the MIS 5e-MIS 1 succession of the Po Basin along

two stratigraphic panels oriented parallel to the modern shoreline (a) and to the Apennine margin (b), respectively. See Figure 3 for location and Table A1 (Appendix) for details on radiocarbon dates. In red, reference cores with pollen data (see Data Availability).

The Last Interglacial (MIS 5e) coastal wedge, encountered at depths between 130 and 20 m, represents a prominent stratigraphic marker in the late Quaternary succession (Fig. 6). It is marked at the base by a characteristic deepening-upward trend, with transition from swamp to lagoon/estuary and transgressive-barrier facies (see cores 223 S17, 205 S10, 187 S1; Fig. 6a). In the distal sector, these deposits are overlain, in turn, by offshore and prodelta muds (Figs. 6 and 7). The prodelta facies association is overlain by a laterally extensive (> 100 km), ~ 10 m-thick, sand sheet made up of strandplain and delta front facies (Figs. 6 and 7). MIS 5e coastal deposits wedge-out southwards (Fig. 6a) and also towards the west (Fig. 6b), where coastal sands (cores 205 S10-204 S16) are progressively replaced by thin lagoon (core 204 S4) and swamp (cores 204 S15 and Mn S1) deposits. Close to the Apennine margin, where the MIS 5e succession is composed entirely of alluvial deposits (Figs. 7 and 8), lacking pollen data, the MIS 6-5e boundary has been tentatively placed in correspondence of a paleosol (core 239 S10; Fig. 7a, c) or atop laterally extensive fluvial-channel gravels, (core 219 S2; Fig. 8b). The top of MIS 5e deposits, generally ranging between 120 and 100 m depths, is only 60-40 meters deep at the top of the buried anticlines (Figs. 6b, 7b, c; Fig. 3 for location). Locally, MIS 5e deposits have been partially (Fig. 6a) or completely (Fig. 6b) eroded by younger fluvial/distributary-channel deposits. For example, in core B1, the OSL date from a distributary-channel deposit above MIS 5e marine sands yielded an age of 85 ± 10 ky BP (Figs. 4 and 6b), consistent with a MIS 5a to MIS 5c age attribution (Otvos, 2015).

A thick (up to 95 m) succession made up entirely of non-marine deposits overlies the MIS 5e coastal wedge (Fig. 6). It is characterized by a cyclic alternation of swamp and locally brackish (core 223 S17) deposits with alluvial facies, showing an overall shallowing-upward trend. Two thin lagoon horizons have been identified between 90-65 and 60 m depth (Fig. 7b). Paludal deposits can be tracked landwards for about 40 km (Fig. 6b). Their thickness and lateral extent decrease upsection and southwards (Fig. 6a). Similarly, poorly-drained floodplain intervals thin out upstream where they are progressively replaced by well-drained-

389 floodplain muds and fluvial-channel sands (Figs. 6b, 7a, b). Three laterally extensive (> 40 km) fluvial channel-
390 belt sand bodies, up to 20 m thick, are vertically stacked in the northern sector, between 80 and 30 m depths
391 (Fig. 6a). The deepest sand sheet has been tentatively assigned to MIS 4. The narrower (< 15 km, Fig. 6b) and
392 thinner (~ 5 m) fluvial-channel sand body accumulated between 45 and 30 ky BP (see radiocarbon dates in
393 Fig. 6 and Table 1). The deposition of the youngest fluvial channel-belt took place between ~ 30 and 12 ky BP
394 (Fig. 6).

395 The uppermost stratigraphic interval is the Holocene coastal wedge, that was deposited during the last
396 10 ky BP (radiometric ages of Figs. 6-8). It shares many characteristics in terms of facies distribution and
397 geometry of sediment bodies with its MIS 5e counterpart (Fig. 6). Similarly, it wedges out toward the west
398 (Fig. 6b), with a landward transition from marine to alluvial deposits. A comparable upward transition from
399 basal estuarine deposits to a laterally extensive (> 100 km) coastal sand-sheet (Fig. 6a) typifies the early
400 Holocene succession. Middle-late Holocene deposits, however, display thicker prodelta and strandplain/delta
401 front deposits. (Fig. 6a). The maximum upstream migration of swamp, lagoon and coastal facies associations
402 is less pronounced for the Holocene coastal wedge than for MIS 5e deposits (Figs. 6b, 7a, b, 8a).

7. Factors controlling sediment deposition and preservation

7.1 Eustatic control on MIS 5e-MIS 1 stratigraphy

Facies and vegetation changes at the MIS 6/5e transition clearly reflect post-glacial sea-level rise (Waelbroeck et al., 2002). Since global mean surface temperatures were at least 2° C warmer than at present, the mean MIS 5e sea-level stood 4-6 m higher than the modern sea-level (Rohling et al., 2008), with oscillations up to 9 m (Dutton and Lambeck, 2012; Kopp et al., 2013; Rovere et al., 2016). Consequently, many coastal areas worldwide experienced the effects of a severe marine ingression (Bardají et al., 2009; Mauz et al., 2012; Murray-Wallace et al., 2016; Otvos, 2015; Peeters et al., 2019; Törnqvist et al., 2000). In the southern part of the study area (south of Ravenna in Fig. 9), the MIS 5e and MIS 1 (i.e., modern) shoreline positions approximately coincide. This is possibly due to the high topographic gradient at the basin margin that likely hindered marine transgression. On the contrary, SE of Ferrara the MIS 5e shoreline backstepped up to 36.5 km landwards of the modern beach position (9.5 km west of its MIS 1-highstand analogue - Fig. 9). Brackish lagoonal and outer estuarine environments extended up to 47.5 km from the modern shoreline, whereas more or less continuous freshwater swamp, inner-estuary environments are recorded up to 140 km upstream of the present-day coastline (Fig. 9). Poorly-drained and well-drained floodplain facies associations characterize the more abrupt transition from coastal to alluvial settings towards the Apennine margin (Fig. 9). This reconstruction is consistent with the work of Fontana et al. (2010), who placed the inner margin of the MIS 5e lagoon 10-20 km landwards of the Holocene one, in the nearby Venetian-Friulian coastal Plain.

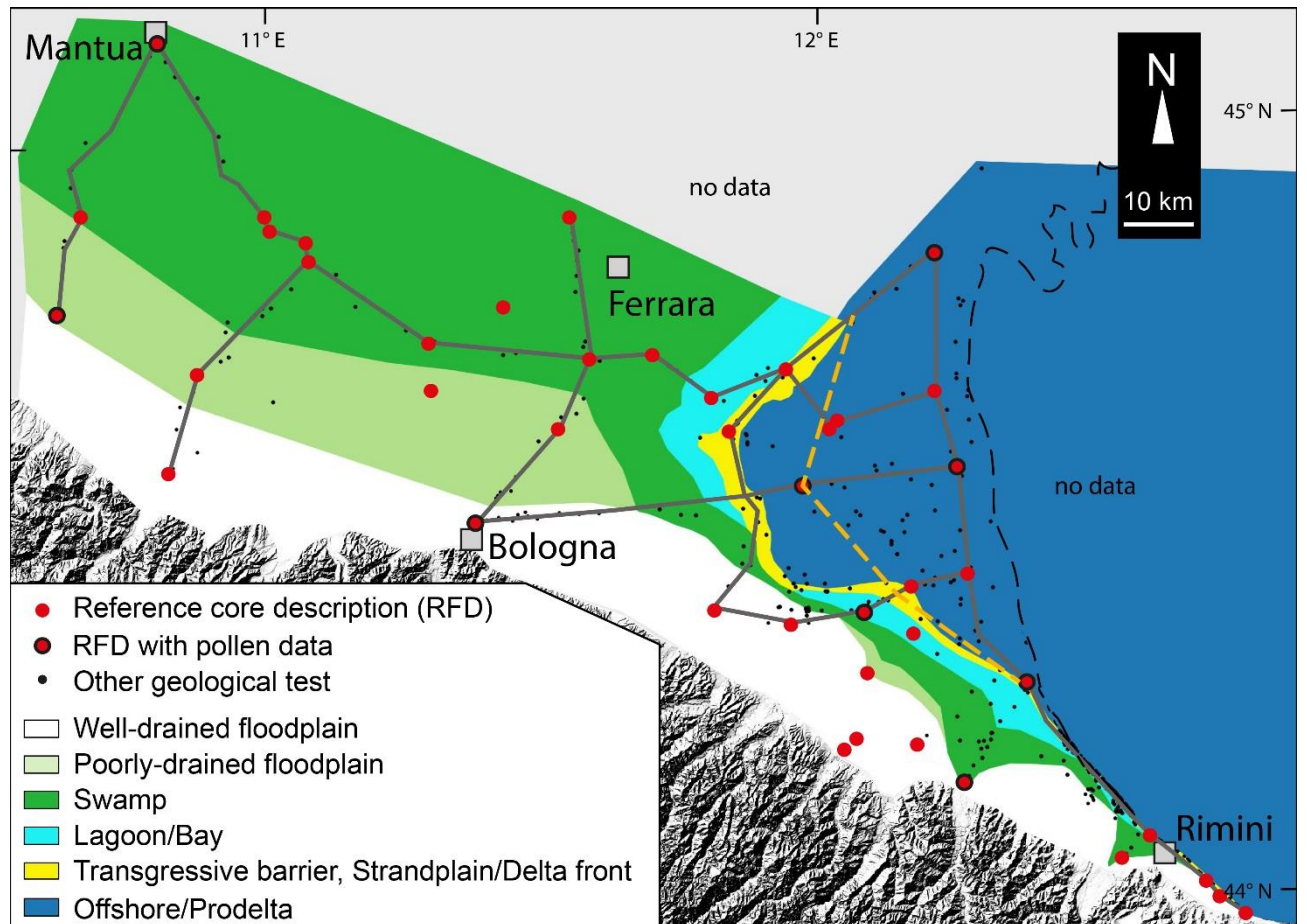

Fig. 9 – Paleogeography of the Po Plain during the MIS 5e maximum marine ingress. Gray lines indicate the traces of stratigraphic panels of Figures 6, 7, 8. The orange dashed line depicts the MIS 1 shoreline during the MIS 1 maximum marine ingress. The black dashed-line indicates the modern shoreline.

The correlation of cyclic facies patterns and pollen signals with the oxygen-isotope record of the last 150 ky (Fig. 5) testifies to a major glacio-eustatic control on MIS 6-MIS 1 stratigraphic architecture in the Po Basin. At the scale of the last interglacial-glacial cycle ($\sim 10^5$ years), in fact, the contribution of other allogenic (e.g., tectonics) or authogenic controlling factors on facies architecture is less clear and/or significant. Authogenic component, for example, seems to play a key-role at smaller (parasequence, 10^2 - 10^3 years) scale, as documented by Amorosi et al. (2017, 2019). On the other hand, the exceptional stratigraphic expansion of the Po sedimentary infill, due to the high subsidence rates, allows preservation of the whole suite of Marine Isotope Stages (5 to 1) and, locally, even substages (5e-a; Figs. 6-7-8). Natural subsidence consists of a long-term component (tectonics, geodynamics, sediment load and compaction) and a short-term component due to deglaciation effects (Carminati et al., 2003, 2005). Identification of glacial and hydro-isostatic adjustment

446 component in the Mediterranean region is difficult though, especially in correspondence of major river deltas
447 (such as the Po River delta) where subsidence caused by sediment loading and compaction strongly affects the
448 relative sea level record (Vacchi et al., 2018). However, Spada et al. (2009) realized a model showing that,
449 south of the Po River, the post-LGM melting of the Alpine ice sheet reduced the sea-level rise generated by
450 the melting of the remote ice-sheet in the far-field of the Mediterranean alone. This result matches with other
451 studies (Vacchi et al., 2016; Antonioli et al., 2009) supporting a dominant role of the long-term geological
452 component of vertical deformation upon the isostatic terms in the southern Po Plain.

453 Apart from the two major transgressive pulsations, clearly marked by the two (MIS 5e and MIS 1)
454 coastal wedges, thin brackish and organic-rich intervals (Figs. 6-8) are interpreted to reflect minor
455 transgressions (i.e. MIS 5c, 5a, MIS 3) within the general sea-level fall that characterized the MIS 5e-MIS 2
456 interval. This interpretation is supported by: the i) OSL age on B1 core, dating the first non-marine sands
457 between MIS 5c and MIS 5a (Figs. 4-6b); and the ii) pollen associations from these horizons, which invariably
458 suggest phases of general climate amelioration. On the contrary, the fully alluvial MIS 5d and 5b stratigraphic
459 intervals are associated to pollen assemblages typical of colder conditions. This trend has also been observed
460 in the Rhine-Meuse system (Busschers et al., 2005; Peeters et al., 2015) and the Gulf of Mexico coastal plain
461 (Blum and Aslan, 2006; Otvos, 2005, 2013), where the re-establishment of alluvial settings is associated with
462 the switch to glacial climatic conditions. MIS 4, 3 and 2 are almost entirely composed of alluvial facies (with
463 the exception of a discontinuous, organic-rich interval assigned to MIS 3, Figs. 6-8), with pollen spectra
464 dominated by *Pinus* and mountain tree taxa. Locally, peaks of shrubs and herbs (e.g., Fig. 5) likely suggest the
465 episodic instauration of steppic environments. MIS 4 and MIS 2 intervals are characterized by two major
466 fluvial channel belts, up to 30 m thick. These laterally extensive fluvial sand bodies are coeval with vertically-
467 stacked paleosols (Figs. 6-8) that likely formed in response to abrupt sea-level falls at the transitions between
468 MIS 5/4 and MIS 3/2, respectively (Waelbroeck et al., 2002). The vertical stacking of fluvial channel-belts
469 contrasts with stratigraphy from several coastal plains worldwide, where stepped sea-level fall, down to -120
470 m at the onset of MIS 2 (Waelbroeck et al., 2002), led to the formation of well-developed incised-valley
471 systems (Blum et al., 2013; Busschers et al., 2005; Hori et al., 2002; Milli et al., 2016; Peeters et al., 2016;
472 Tanabe et al., 2013, 2006). This is likely due to high subsidence rates (~ 1 mm/y) in the Po Basin, associated

473 with high volumes of sediment supplied by distinct Alpine and Apennine sources (Campo et al., 2016; Fontana
474 et al., 2014).

475

476 **7.2 Structural control on thickness distribution**

477 The MIS 5e-MIS 1 Po Basin succession is characterized by an exceptional thickness (up to 130 m, Figs.
478 6-8). Coeval successions around the world do not provide such a highly-detailed continuous sedimentary
479 record for the last 130 ky. For example, in the marine core MD95-2042 located off the southwest coast of
480 Portugal (Sánchez Goñi et al., 1999), the thickness of the last 130 ky sedimentary record is about 26 m. In
481 other sedimentary successions, only distinct stratigraphic intervals are well preserved. For example, Amorosi
482 et al. (2014) documented an uninterrupted marine sedimentary record of MIS 5e, of just 8.5 m (Fronte section,
483 southern Italy).

484 Relatively thick successions have been reported from the subsurface of modern subsiding basins. In the
485 Versilian plain (central Italy), for example, MIS 5e-MIS 1 deposits are 72 m thick (Carboni et al., 2010).
486 However, in most alluvial systems worldwide, Late Pleistocene-Holocene strata are generally poorly-
487 preserved due to river incision driven by stepped post-MIS 5e sea-level fall (Blum et al., 2013; Blum and
488 Törnqvist, 2000). In the Netherlands, the MIS 5e-MIS 1 succession is preserved only within incised valleys,
489 with thicknesses ranging between 25-60 meters along-dip (Busschers et al., 2007; Peeters et al., 2016, 2015).

490 In the Po Basin, the MIS 5e-MIS 1 succession has also variable thickness along-dip, between 25 and
491 130 meters (Figs. 6-8), where minimum values are recorded close to Apennine margin (Fig. 6a). Comparable
492 limited thickness is also observed close to the buried growing anticlines (Fig. 6b), where the MIS 5e coastal
493 sands can be displaced up to 70 m (Fig. 6b), and the thickness of the post-MIS 5e succession can be as little as
494 ~ 30 m. As a whole, the general thickness distribution of the post-MIS 5e interval clearly reflects the structural
495 setting of the Po Basin, and thus the distribution of the NNE verging fold-and-thrust systems of the Apennines
496 (Ghielmi et al., 2013). The effect on stratigraphy of the buried Apennine structures is clearly observed between
497 cores 205 S10 and B1 (Figs. 6b and 7c), where the thickness of the post-MIS 5e succession changes abruptly
498 from 127 m to 51 m in about 10 km (Fig. 6b). Similarly, a change in thickness of about 30 m is recorded
499 between well 222070P618 and core 204 S17 (Fig. 7c).

500 Thickness variations and deformation of stratigraphic units that compose the Plio-Quaternary Po Basin
501 fill have been observed in numerous seismic profiles (Pieri and Groppi, 1981). In this work a significant lateral
502 variations in thickness and deformation of Late Pleistocene strata at the subseismic-scale (Figs. 6-8) has been
503 documented. Based on the elevation of the MIS 5e coastal sands and the modern coastal deposits, subsidence
504 rates have been calculated dividing the MIS 5e-MIS 1 sediment thickness for the time interval (i.e., 125 ky).
505 During the last 125 ky, subsidence ranged between 0.20 mm/y, close to the Apennine margin (in proximity of
506 the city of Rimini), and 1.05 mm/y between the city of Cervia and the modern Po Delta (Figs. 6-9). Since the
507 structures of the Emilia and Ferrara Arcs are tectonically active (Amadori et al., 2019), it is very difficult to
508 rule out the possible influence of recent tectonic activity on thickness distribution and deformation of Late
509 Pleistocene strata, with a significant contribution of differential sediment compaction.

510 It is possible to speculate that certain thrusts were most likely already active during the deposition (i.e.,
511 syntectonic) of the MIS 5e-MIS 1 strata. Similarly, during the last 125 ky, the study area could have been hit
512 by several major earthquakes. These events may provoke up to 17 cm anticlinal crest growth, as shown by
513 InSAR data analysis after the 2012-earthquake (Caputo et al., 2015). On the other hand, the interplay between
514 sedimentary processes and high-sedimentation rates could have exceeded the velocity of the growing structures
515 (as documented by Carminati et al., 2010 for the Mirandola area) and temporarily cover the tectonic effect
516 (and the potential erosion) on sedimentary bodies. For example, a relative tectonic uplift of 0.16 mm/y was
517 calculated for the Mirandola anticline (Scrocca et al., 2007), whereas the velocity of backstepping-barrier
518 systems or delta progradation during Holocene reached 10 and 15 m/y, respectively (Bruno et al., 2017;
519 Amorosi et al. 2019 SED).

520 Preexisting or new (e.g., seismogenically) generated structural highs could also have been playing a key
521 role (morpho-tectonic?) on sediment and facies distribution, as suggested by the abrupt landward replacement
522 of Holocene beach-barrier deposits with thick lagoonal deposits between cores 204 S3 and B1 (Fig. 6b). Given
523 the intrinsic complexity of the geological and structural framework and the interplay between all the processes
524 acting at different time/intensity scales, additional investigations are needed to better define and quantify the
525 role of neo-tectonics on the MIS 5e-MIS 1 deposits of the Po Basin.

526

527 **Conclusions**

528 Last Interglacial (MIS5e) coastal deposits represent a stratigraphic marker of worldwide significance
529 that provides specific information about paleoclimate and paleo-sea level, and that can be used on a basin-
530 scale to infer regional tectonics. MIS 5e strata have been reported from the subsurface of the Po Plain in several
531 local studies, but basin-scale stratigraphic reconstructions have never been carried out. Based on 876
532 stratigraphic data (e.g. cores, well logs and piezocone tests), with the aid of micropaleontological, pollen, and
533 chronological data (i.e. radiocarbon, ESR and OSL), regional stratigraphic correlation of MIS 5e deposits was
534 established and the high-resolution facies architecture of the Late Pleistocene-Holocene succession was
535 reconstructed with high stratigraphic detail.

536 The MIS 5e coastal wedge can be tracked continuously for > 100 km along strike and up to 140 km
537 along dip. It includes the retrogradational stacking of paralic and coastal facies, overlain by prograding deltaic
538 deposits. Coastal sands, up to 25 m thick, thin-out southwards and westwards, where they are progressively
539 replaced by lagoon, swamp and alluvial facies.

540 The post-MIS 5e succession, dated between about 85 and 12 ky BP, exhibits an overall shallowing-
541 upward trend due to the general sea-level fall: lagoon and swamp deposits are abundant atop the MIS 5e
542 deposits, but they become thinner upsection, where alluvial facies are dominant. Stacked fluvial channel belts
543 formed during MIS 4-2 due to the combination of high-subsidence rates and high-sediment supply. This overall
544 trend reflects the stepped basinward shift of facies induced by sea-level drop, between MIS 5d and MIS 2.
545 Brackish and swamp horizons are associated with minor transgressions (MIS 5c, 5a, MIS 3) within the general
546 sea-level fall.

547 The Holocene (MIS 1) deposits record the post-LGM sea-level rise and subsequent Po-delta
548 progradation under highstand conditions. The MIS 1 coastal wedge shares many characteristics in terms of
549 pollen signals, facies trends, geometry and thickness of sedimentary bodies with its older (MIS 5e) counterpart.
550 Due to higher global sea-level during the Last Interglacial, however, the MIS 5e shoreline reached a 9.5 km
551 more landward position than maximum marine ingressions during MIS 1: 36.5 km landwards of the modern
552 shoreline.

553 The MIS 5e-MIS 1 succession displays an extremely variable thickness across the Po Basin. The
554 exceptional thickness (~130 m) preserved in the depocenters makes the Po Plain succession one of the most
555 extensive, continuous and highly-resolved stratigraphic records of the last 130 ky. The elevation of the MIS

556 5e stratigraphic marker changes dramatically on top of the major buried thrust fronts, where subsidence in the
557 last 130 ky decreases from 1.0 to 0.2 mm/y.

- 565 • Pollen data are available from nine reference cores. For each core the source of data is provided:

566 Core 187 S1: pollen data (only in Italian) at

567 http://www.isprambiente.gov.it/Media/carg/note_illustrative/187_Codigoro.pdf, pages 132-133.

568 Core 223 S17: pollen spectra published by Amorosi et al., 2004, 1999a.

569 Core 240 S8: pollen spectra published by Amorosi et al., 2004.

570 Core 255 S4: pollen spectra (only in Italian) at

571 http://www.isprambiente.gov.it/Media/carg/note_illustrative/255_Cesena.pdf, p. 76.

572 Core 222 S2: pollen spectra (only in Italian) at

573 http://www.isprambiente.gov.it/Media/carg/note_illustrative/222_Lugo.pdf, p. 92.

574 Core 240 S13: pollen spectra published by Amorosi et al., 2004.

575 Core Idroser: pollen spectra published by Amorosi et al., 2001.

576 Core CdB: pollen data (only in Italian) at

577 http://www.isprambiente.gov.it/Media/carg/note_illustrative/200_Reggio_nellEmilia.pdf, pages 91-95.

578 Core Mn S1: pollen spectra published by Amorosi et al., 2008.

- 579 • EPR ages for cores 205 S10, 222 S2 and 240 S8 published by Ferranti et al., 2006, page 45, their Table
580 2.

- 581 • Original radiometric ages from the Geological Map of Italy (only in Italian) at 1:50,000 scale
582 (Geological Survey of Italy and CARG Project):

583 Sheet 182, http://www.isprambiente.gov.it/Media/carg/note_illustrative/182_Guastalla.pdf, Table 1,
