Abstract: A convenient and efficient one-pot three-component reaction of acetyl acetone, malononitrile and ammonium acetate was investigated for the synthesis of 3-cyano-4,6-dimethyl-2-pyridone (PI) and 2-amino-3-cyano-4,6-dimethylpyridine (PII). The products were achieved with high purity, high yields and short reaction time. The yields of the two products depend on the concentration of ammonium acetate, reaction time and the solvent used. The structures of the isolated products were confirmed by elemental analysis and spectral data, supported by quantum chemical (MP2) calculations, both in gas phase and solvents (water and ethanol), that were also employed to track the reaction mechanisms and model vibrational spectral properties for final characterization and interpretation of spectral data. A remarkable matching between theoretical predictions and experiments was attained both for the geometrical parameters, as compared to X-Ray data available in the literature, and for vibrational frequencies, leading to a correlation coefficient (R^2) of 0.99.

Cyanopyridine; MP2; Solvent Effect; Vibrational Scale Factor; Reaction Mechanism; Energy Profile; Molecular Properties

Introduction

Pyridine derivatives are well known for their versatile biological activities such as anticancer [1], antimicrobial [2, 3], antiviral [4], anticonvulsant [5] and anti-human immunodeficiency viruses (AntiHIV) [6]. Cyanopyridines (nicotinonitriles) are associated with diverse pharmacological and chemotherapeutic activities as antitumor [7], protein kinase inhibitors [8], anxiolytic [9], antimicrobial [10] and antitubercular [11]. They have been also used as intermediates for the synthesis of vitamins and as ligands for transition metal ions in the formation of the nuclear factor kappa- β kinase subunit beta inhibitor (IKK- β -inhibitor) drug complexes [11]. 2-pyridones are biologically interesting molecules as they act as inhibitors of phosphodiesterase 3 (PDE3) a target for heart failure and platelet aggregation [12], anticancer agents [13], antiviral, antimicrobial, antiepilepsy, antidiabetic [14] and their chemistry has received considerable attention [15-20]. Thus, despite the large number of methods known for their synthesis, new procedures are continuously being developed [21, 22]. The Guareschi pyridone (3-cyano-4,6-dimethyl-2-pyridone) is

one of the most important methods for the synthesis of 2-pyridone from 1,3-diketone (PI) [23]. Catalysts such as zeolite [24], piprazine, piprazine carboxy aldehyde, and triethylamine [25] have implied in the synthesis of this compound. Specifically, F. A. Yassin has prepared PI and its derivatives through the reaction of cyanoacetamide and acetylacetone using piperidine as a catalyst in boiling n-butanol solvent[26].

Considerable attention to the synthesis of 2-amino-3-cyanopyridine derivatives is drawn by their interesting biological activity and photophysical properties. These compounds may act as ligands of adenosine receptors [27-29], inhibitors of activated protein kinase-2 for treatment of diseases caused by the tumor necrosis factor (TNF α) [30], as well as inhibitors of human cytomegalovirus [30], anti-inflammatory agents [31] and possess anti-microbial activity [32-36]. They were employed as an efficient organic catalyst in the facile synthesis of pharmaceutically important compounds[37, 38], on the other hand they work as inhibitor for corrosion of mild steel in acidic medium[39]. Additionally, they are promising in the development of agents for treatment of cardiovascular conditions [28]. Various approaches to the synthesis of these derivatives have been reported, including microwave irradiation[40], ultrasound irradiation [41, 42], reaction with hexadecyldimethyl benzyl ammonium bromide and triethylamine[43], and dimethylformamide (DMF)[44]. However, most of these methods suffer from several drawbacks like harsh reaction conditions, prolonged reaction times and low yields.

In view of these facts, the development of new methods for the synthesis of cyanopyridine derivatives is pursued. In this work, a new strategy for the synthesis of 3-cyano-4,6-dimethyl-2-pyridone and 2-amino-3-cyano-4,6-dimethylpyridine is introduced, involving combination of acetyl acetone, malononitrile and ammonium acetate. To the best of our knowledge, neither quantum chemical calculation, nor vibrational spectra analysis of the title molecules have been reported. Consequently, the experimental work is accompanied by a quantum chemical study to investigate the structural parameters, reaction pathways and vibrational spectroscopic properties of the synthesized compounds, together with the study of the solvent effect on the molecular properties.

Experimental Details

All the chemicals used in the synthesis were purchased from Fluka and Sigma. Melting points were measured by MEL_TEMP II apparatus and are uncorrected. IR spectra (KBr) were recorded on Perkin–Elmer FT/IR spectrophotometer scanning between 400 and 4000 cm^{-1} , ^1H NMR and ^{13}C NMR spectra were obtained on JEOL (500 MHz) in $\text{DMSO}-d_6$ as solvent. Chemical shifts values are expressed in ppm relative to tetramethyl–silane (TMS) as internal reference standard. The IR and NMR spectra were performed at Faculty of Science, Alexandria University. Elemental analysis (C, H, and N) was performed by a Vario III CHN analyzer (Germany) at the Microanalytical Unit of Cairo University. Compounds were within $\pm 0.4\%$ of the theoretical values. Mass spectra were run on DI analysis Shimadzu QP–2010 plus mass spectrometer at the Microanalytical Unit of Cairo University. The purity of the compounds and the progress of the reaction were monitored by TLC analytical silica gel plates 60 F₂₅₄ using (ethyl acetate, and n–hexane) and UV lamp was applied for spot visualization.

Synthesis of 3–cyano–4,6–dimethyl–2–pyridone (PI) and 2–amino–3–cyano–4,6–dimethylpyridine (PII)

Method A:

Malononitrile (0.1 mol) and ammonium acetate (0.05 mol or 0.1 mol or 0.2 mol) were added to a solution of acetyl acetone (0.1 mol) in ethanol absolute (200 mL). The reaction was refluxed in water bath for the appropriate time as reported in **Table 1**. The formed precipitate was filtered on hot and washed several times with hot ethanol followed by washing with excess water and dried to afford **PI** (crystallized from mixture of DMF/ethanol (1:1) or acetic acid). The filtrate was concentrated, poured into crushed ice after cooling. The formed precipitate was filtered off, washed by water then dried to afford **PII** (crystallized from ethanol).

Method B:

To solution of acetyl acetone (0.1 mol) were added in glacial acetic acid (200 mL), malononitrile (0.1 mol) and ammonium acetate (0.05 mol or 0.1 mol or 0.2 mol). The reaction was refluxed for the appropriate time as reported in **Table 1**. The reaction mixture was left to cool at room temperature, the formed precipitate was filtered off

and washed several times with acetic acid followed by washing with excess water then dried to afford **PI** (crystallized from acetic acid or DMF/ethanol mixture). The filtrate was concentrated, poured into crushed ice after cooling then neutralized with ammonium hydroxide. The formed precipitate was filtered off, washed by water then dried to afford **PII** (crystallized from ethanol).

Computational details

The geometry optimizations of the investigated reactants, intermediates and products either in gas phase or in solvents (ethanol and acetic acid) were carried out using ab initio Moller–Plesset second–order perturbation MP2 method [45] which better estimates the correlation energy and the vibrational spectra for the class of studied molecules[46-48]. Geometry optimizations were performed without any constrain implying a relatively large–size basis set 6–311++g(d,p) [49, 50] where two diffuse and two polarized functionals were included to better account for the electron density. Frequency calculations were performed on top of the optimized structures at the same level of theory to ascertain their nature (minima or transition states). The solvent effect on the molecular properties were investigated by the integral equation formalism polarized continuum model (IEFPCM) [51]. This model is a modified version of PCM in which the cavity is considered as overlapping atomic spheres that are 20% larger than the van der Waals radii [52, 53]. All calculations have been carried out using Gaussian 09 [54], while GaussView 6 is used to visualize and assign the mode of vibrations.

Results and discussion

The reaction of acetyl acetone with malononitrile in the presence of ammonium acetate afforded a mixture of 3–cyano–4,6–dimethyl–2–pyridone (**PI**) and 2–amino–3–cyano–4,6–dimethylpyridine (**PII**) (**Scheme 1**). The reaction was carried out using different solvents, different concentrations of ammonium acetate and different reaction times to achieve a suitable condition for the synthesis of the two products. **Table 1** reports the yields of the two products at different reaction conditions. The obtained data showed high yield of 3–cyano–4,6–dimethyl–2–pyridone (**PI**) formation compared with 2–amino–3–cyano–4,6–dimethylpyridine (**PII**) in both solvents in short reaction times. This may be due to ammonium acetate

catalyzed the formation of **PI** at short reaction time. To study the solvent effect, ethanol (for environmental acceptability and cheapness) and acetic acid (for easier separation of the products from reaction mixture) were used.

PII has higher yield in ethanol solvent, as compared to acetic acid. This may be attributed to the higher dissociation affinity of the ammonium acetate (a source of ammonia) in ethanol than in acetic acid (Lechatelier's principle). Also, the data showed remarkable decrease in **PI** yield in ethanol compared to acetic acid. So, the best solvent for **PII** synthesis is ethanol while acetic acid for **PI** synthesis. Furthermore, the obtained data showed gradual increase in **PI** and **PII** yields with increasing ammonium acetate concentration (from 0.05mol to 0.1mol). Which showed the role of ammonium acetate in the reaction (catalyzed **PI** synthesis and ammonia source for **PII** synthesis). Further increase in ammonium acetate concentration directed the reaction to **PII** synthesis. On the other hand, as expected, the reaction time showed great effect on the yield percent of the two products: where increasing the reaction time enhanced the yield of the products at low concentration of ammonium acetate (0.05 mol). Moreover, extending the reaction time (at the low or high ammonium acetate concentration) directed the reaction to the **PII** synthesis with gradual decrease in the **PI** percentage. This supported the reaction of **PI** with ammonium acetate to give **PII**. High concentration of ammonium acetate and longer reaction time afforded compound **PII** in good yields due to reaction of the formed **PI** with ammonia.

Scheme 1

The formation of compound **PI** is expected to proceed by condensation between acetyl acetone and malononitrile to afford compound **MI-II** which converted to its enol form **MI-2**; the latter cyclizes to **MI-3** followed by rearrangement to afford **PI** (**Scheme 2**), while the formation of **PII** is expected to proceed by reaction of compound **MI-II** with ammonia to yield **MII-2** which then cyclizes to **PII** (**Scheme 3**)

Table 1 Optimization of solvent, ammonium acetate conc. and reaction time in the synthesis of PI and PII

Solvent	[CH ₃ COONH ₄]	Reaction time (min)	PI yield %	PII yield %

Reaction Mechanisms

In the gas phase, according to our calculations, the reactant I (R-I) adapts symmetrical geometrical parameters where both the two C=O bonds display equal bond length (1.22 Å); also the two C–C bonds between the carbonyl groups are identical in bond length (1.53 Å) while the other C–C bonds are slightly shorter (1.51 Å). In the same way the charge is distributed in symmetric way over the entire molecule where the oxygen atoms bear negative charge of –0.64e each while each adjacent carbon atom has a positive charge of +0.67e. Each oxygen atoms makes a dihedral angle equals 90° with the three centered carbon atoms, the bond angle of these atoms is slightly deviated from the tetrahedral value to be 104°. Calculations in solvents (ethanol and acetic acid) show limited changes either in bond lengths or in bond angles, the only noticeably changes related to the charge distribution where the negative charge on the oxygen atoms is slightly enhanced to –0.68e and –0.69e in acetic acid and ethanol, respectively; the same is true for the positive charge on the carbonyl carbon which is changed to +0.71e and +0.72e in acetic acid and ethanol, respectively (see SI).

The same situation is also shown for reactant II, where in gas phase it displays a completely symmetric structure with the two CN bonds lying in the same plane; this planarity is slight broken down by about 2° in both solvents. Moreover, the charge distribution is also modified in solution where negative charge on nitrogen atoms is changed from –0.32e to –0.38 on going from gas phase to solvent calculations. On the other hand, the CN and CC bond display lengths of 1.173 Å and 1.468 Å respectively (according to their triple and single bond character) and are not affected upon solvation.

The proposed reaction mechanisms can be directly accounted for in terms of potential energy changes going from reactants, to intermediates and eventually to the final products, see Fig. 1. The reaction of I and II occur through the intermediate MI–II. This step is an endothermic process by ca. 3.9, 5.0 and 4.6 kcal/mol in gas phase,

ethanol and acetic acid respectively, Fig. 1 (left panel). Ongoing from gas phase to the solvents, the MI-II shows a stabilization of 12.8 and 10.3 kcal/mol in ethanol and acetic acid, respectively. The charge distribution on MI-II is completely different than on the reactant compounds. The formation of MI-II is followed by 1,3 hydrogen shift which required additional energy of about 12 kcal/mol to afford the intermediate MI-2. The hydrogen shift preserves of intermediates relative stability where both MI-II and MI-2 intermediates are more stable in ethanol than in acetic acid by ca. 2.5 kcal/mol in. On the other hand, a change in the planarity of the molecule is observed where the C-O moiety is aligned in the same plane of the neighboring carbon atoms in MI-2 instead of being perpendicular as in MI-II intermediate. Such alignment allows spontaneous ring closure leading to an exothermic process for MI-3 intermediate formation (ca. -13.5, -12.1 and -12.2 kcal/mol in gas phase, ethanol and acetic acid, respectively), see Fig. 1 (left panel). Eventually, MI-3 affords the final product PI in the final step, which is extremely exothermic (ca. -28, -32 and -31 kcal/mol for gas phase, ethanol and acetic acid, respectively). This product exhibits two tautomeric forms, i.e. Lactam (PI-keto) and Lactim (PI-enol). Calculations show that PI-enol is more stable in gas phase by only ca. 1 kcal/mol in agreement with the experimental results of Break [46], while PI-keto is more stable in solvents by ca. 5.9 and 4.6 kcal/mol in ethanol and acetic acid, respectively, due to its tendency to form hydrogen bonds with the solvents [47]. On the other hand, the PI-keto in both solvents nearly shows the same stability, which accounts for the comparable yields observed in both cases. In all cases, the overall reaction is exothermic by ca. -25.6 kcal/mol in gas phase and -26.6 kcal/mol in both solvents. Moreover, the reaction is accomplished through a barrier which increase in the order gas (15.9 kcal/mol) < acetic acid (16.4 kcal/mol) < ethanol (16.9 kcal/mol). This order could explain the relative higher yield observed in acetic acid as compared to that in ethanol (e.g. 73% vs. 70% for acetic acid and ethanol, respectively).

The first step toward the formation of the product II (PII) is similar as in case of PI, i.e. the formation of MI-II. The next step is an endothermic reaction of ca. 6 kcal/mol between the ammonia and this intermediate, giving the intermediate MII-2 (see Fig. 1, right panel). The later displays a stability, with respect to the gas phase, of ca. 13 and 10 kcal/mol in ethanol and acetic acid, respectively. This step is followed by almost a barrierless 1,3 hydrogen shift from the carbon to the nitrogen to form the

intermediate MII-3, which displays a nearly planar geometry. Repeatedly, as in case of PI formation, MII-3 performs a ring closure to form the MII-4 in an exothermic step of ca. -24.4, -23.3 and -23.5 in gas phase, ethanol and acetic acid, respectively. In a further exothermic step, a 1,3-hydrogen shift in MII-4 affords the final product PII. The overall reaction of PII formation is exothermic by -29.6, -25.7 and -24.4 kcal/mol in gas phase, acetic acid and ethanol, respectively, with a barrier order of gas (12.0 kcal/mol) < acetic acid = ethanol (11.6 kcal/mol), see Fig. 1(right panel).

Fig. 1 The potential energy profile for the reaction path of PI (a) and PII (b), in gas phase, ethanol and acetic acid.

Geometrical parameters of the products PI and PII

Generally, solvent has very tiny effect on the calculated geometrical parameters i.e. bond lengths, bond angles, and dihedral angles, therefore hereafter we will discuss the result calculated in gas phase in comparison to available single-crystal X-ray data. Data computed in solvents are reported in the supporting information (see below). The optimized geometries for the PI-keto and PII are shown in the Fig. 2. Consistently with its experimental rotational parameter [57, 58], the ground state geometry of PI-keto is slightly distorted from planarity by ca. 5° as confirmed from the dihedral angle value within the pyridine ring (i.e. N₁-C₂-C₃-C₄, C₂-C₃-C₄-C₅, C₃-C₄-C₅-C₆, C₄-C₅-C₆-N₁, C₅-C₆-N₁-C₂ and C₆-N₁-C₂-C₃), their computed values agree with the crystallographic values for the unsubstituted compound [59], Table 2. In contrast, the crystal X-ray structure of PI [23] displays almost planar geometry with only a deviation of ca. 1.1° for the D values of N₁-C₂-C₃-C₅ and C₂-C₃-C₄-C₅. Their corresponding computed values are 5.5 and 4.3°, respectively. Such small deviation could be attributed to the different phase (solid vs. vacuum). This conclusion was further supported by the enhanced observed planarity in solvent calculations (corresponding data calculated in solvents are reported in the supporting information, Table S1). The carbonyl and cyano groups are in the same plane as established from the calculated and experimental D values of both O₇-C₂-C₃-C₈ and O₇-C₂-C₃-N₉, see Table 2. All the other dihedral angles show considerable matching between the estimated and experimental values, see Table 2. In the same way, all the calculated bond distances of C₁-C₂, C₂-O₇, C₃-C₄, C₄-C₅, C₅-C₆ and C₃-C₈ are 1.403, 1.225, 1.383, 1.425, 1.372 and 1.431 Å respectively, within ~0.01 Å the corresponding experimental ones, whereas the calculated values of N₁-C₆ and C₂-C₃ are 1.463 and 1.367 Å i.e. slightly off the experimental one by ca. -0.02 and -0.03 Å, respectively. The nitrile group which displays the standard linear structure has a bond distance of 1.130 Å deviated by ca. -0.05 Å from the calculated value. On the other hand, all the calculated and the experimental bond angle are in well agreement (within only ±3°). The good agreement between experimental and calculated geometrical parameters demonstrate the reliability of the computational model employed to study such organic systems.

To the best of our knowledge, there is no available crystallographic data available for PII, therefore we will discuss its calculated parameters in comparison with

experimental values of the 2-amino pyridine. Generally, PII displays a geometry very close to that of PI, see Table 2. The bond lengths of C₃–C₈, C₈–C₉, C₄–C₁₀ and C₆–C₁₁ show almost the same value calculated for PI, some other bonds such as C₃–C₄, C₄–C₅, C₅–C₆ and C₆–N₁ are deviated by ca. $\pm 0.02 \text{ \AA}$ from the calculated values of PI. On the other hand, the N–C₂ and C₃–C₄ bonds are increased by ca. 0.06 and 0.05 \AA compared to their PI values, this effect being mainly attributed to the conjugation of the amino group with the pyridine ring. This conjugation is confirmed from the calculated bond distance (1.381 \AA) of the C₂–N₇ bond which shows double bond character (a typical value for a single C–N bond is 1.43 \AA [60]). Moreover, all the calculated bond distances are in a good agreement with the experimental values reported for the unsubstituted 2-amino pyridine [61] within a slight deviation of ca. $\pm 0.02 \text{ \AA}$.

The exchange of the O and NH₂ groups in the pyridine ring at position 2 in PI and PII shows an observed effect on the calculated bond angles of the neighboring moiety where in PII the N₁–C₂–C₆ bond angle is increased by ca. 10° while C₂–C₁–C₆ is decreased by 8° compared to their values in PI. The other bond angles are slightly modified by this substitution. In all cases, all the calculated bond angles matches perfectly their experimental values [61]. Moreover, as in the case of PI, PII is slightly distorted from planarity by ca. 4° which is in agreement with the experimental assignment [61]; however this is not the case for unsubstituted pyridine which displays completely planar ring [62]. The substitution of O and NH₂ groups also affects the calculated NBO charge density where all atomic charges are slightly modified by ca. $\pm 0.03e$ except for the atom at substitution position that is changed from $-0.77e$ to -0.55 for PI and PII, respectively.

The chemical reactivity of the reacting species mainly depends on the interaction among the frontier molecular orbitals (FMO), i.e. the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO)[63, 64]. The HOMO is associated with the ability of the molecules to donate electrons while the LUMO provides a measure for the molecules' affinity to accept electrons. The HOMO and the LUMO are depicted in Fig. 2 for calculations in gas phase, whereas HOMO and LUMO for calculations in solvents, as well as the contribution of the atoms and atomic orbitals in their composition, are shown in the supporting information (Figure S7, Figure S8 and Table S2, Table S3, respectively). Calculation in gas phase on PI shows that the HOMO is mainly localized over C₅(54%) with small contribution from

C₃(9%), C₄(14%) and C₅(8%) atoms; in solvents other atoms participate in the composition of HOMO such as O₇(9%) and N₁(7%). The LUMO in vacuum is delocalized over C₈(24%), N₉(19%), C₃(20%), C₄(10%), C₅(11%), C₂(8%) and C₆(5%) while in solvents, only C₁, C₅, C₁₅ and N₁₈ atoms contribute by ca. 27%, 42%, 14% and 13%. On the other hand, in PII, the solvent has no significant effect on the shape of the HOMO and LUMO, where the HOMO is being delocalized over the ring and C₈, N₉ and N₇ while the LUMO is mainly localized over the C₈N₉(66%) group.

Dipole moments for PI and PII were also calculated at the same level of theory. The dipole moment is a function of the molecular charge distribution and can be considered as an indicator for the direction of charge transfer between positive and negative centers of the investigated molecule. The calculated value of dipole moment for PI is 8.4 D, which is in a good agreement with the experimental value of 8.8 D for the isolated molecule [56]. This value is slightly enhanced in acetic acid and ethanol to 10.9 and 11.5 D, respectively, while PII possess small dipole moment values of 3.2, 4.0 and 4.2D in gas, acetic acid and ethanol, respectively.

Fig. 2 The optimized geometry, HOMO and LUMO of PI (top) and PII (bottom) in vacuum; NBO charge distribution of the non-hydrogen atoms as well as the atom numeration employed in this work are reported on the optimized structures (the corresponding figures for calculation in ethanol and acetic acid are reported in the supporting information).

A and B: values taken from references[23] and [61] for PI and 2-amino pyridine, respectively.

Calculated and experimental vibrational modes in PI and PII

The optimized structural of the investigated molecules were used to compute the vibrational frequencies at MP2 level of theory. The linear correlation between the experimental frequencies and the corresponding unscaled harmonic calculated for PI and PII compounds are graphically depicted in Fig. 3, top panels while the experimental and theoretical IR spectra are shown in Figs. 3, bottom panels. Generally, there is a certain agreement between the unscaled and experimental frequencies, however, in some cases, considerable deviations exist. To overcome these disagreements, two different methods were used to scale the calculated wavenumbers: in the first method (M1), a uniform scaling factors of 0.98 and 0.94 are used for wavenumbers smaller and larger than $1,700\text{ cm}^{-1}$, respectively [65-67], while in the second method (M2), the scaling procedure is generated from the linear relationship equations calculated from the graphs, (see Fig. 3, top panel), leading to $\nu_{scaled} = 0.94\nu_{unscaled} + 48.7$ and to $\nu_{scaled} = 0.91\nu_{unscaled} + 60.0$ for PI and PII, respectively (where ν_{scaled} and $\nu_{unscaled}$ are the scaled and unscaled frequencies, respectively). Corresponding graphs for the calculation in ethanol and acetic acid are reported in the supporting information, Figs S8 and S13. Generally, the solvent effect does not show considerable effect neither on the calculated frequencies nor their intensities, see Table SXX in supporting information. The scaled frequencies, force constants (FC), relative IR intensities (Rel. Int.) and Raman activities of the vibrational modes of PI and PII in comparison to their experimental values are reported in Tables 3 and 4. Theoretically, PI and PII compounds possess 51 and 54 normal modes of vibrations, respectively. The illustration of these normal vibrational modes are shown in the supporting information Figs. SXX4. Very remarkably, a correlation coefficient (R^2) of 0.99 was obtained for M2 (see top panels of Fig. 3).

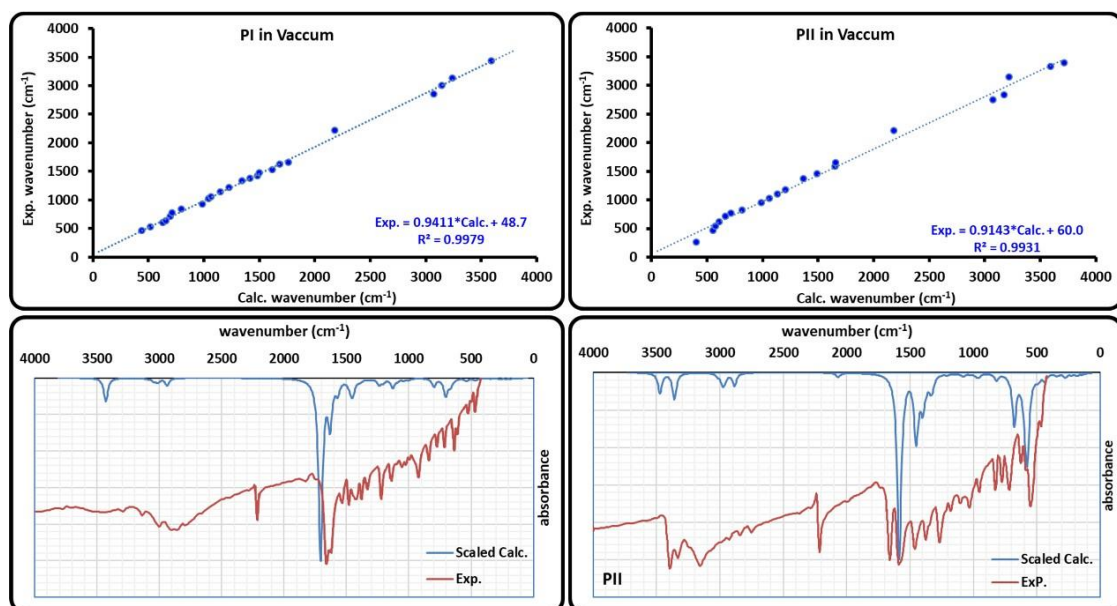

Fig. 3 Top: (Top) Linear correlation between of the experimental and unscaled calculated wave numbers; (Bottom) the experimental and scaled calculated (Method M2) vibrational spectra of PI and PII in vacuum.

The IR intensities were normalized to the strongest bands observed at 1586 cm^{-1}

Generally, scaling the calculated frequencies using the M2 method gives better agreement among the experimental and the scaled frequencies, therefore, hereafter unless differently specified we will discuss the calculated frequencies scaled by this method in comparison with the experimental ones. The presence of $\nu\text{-C-H}$ stretching vibration is one of the distinctive mode for most of the heterocyclic aromatic compounds[68]. Two types of $\nu\text{-C-H}$ modes are assigned in the compound PI corresponding to the aliphatic and the aromatic hydrogens. The asymmetrical aliphatic C-H modes appears at 3003 cm^{-1} in excellent agreement with the calculated value 3010 cm^{-1} while the symmetric mode is overestimated in calculation by ca. 85 cm^{-1} . On the other hand, the aromatic modes show a considerable agreement for the experimental and calculated values (3138 vs. 3098). The calculated values of $\nu\text{-C-H}$ modes in compound PII deviate from their experimental values by ca. 100 cm^{-1} . This could be attributed to extend resonance structure of PII as depicted in Fig. 2. All the $\nu\text{-C-H}$ modes in both molecules display high Raman activity due to the strong polarization. The in-plane C- $\delta\text{-C-H}$ bending vibration usually appears within $1300\text{--}1000\text{ cm}^{-1}$ while the out of plane mode ($\gamma\text{-C-H}$) [69] falls within $1000\text{--}750\text{ cm}^{-1}$. On most cases these vibrations are coupled with others. For the PI molecule the $\delta\text{-C-H}$ and $\gamma\text{-C-H}$ modes are observed at 1221 and 840 cm^{-1} , in good agreement with their calculated values 1205 and 798 cm^{-1} , respectively. Such agreement is also shown for PII where the calculated values for the $\delta\text{-C-H}$ and $\gamma\text{-C-H}$ modes at 1162 and 808 cm^{-1} are nicely matching the experimental wavenumbers at 1177 and 825 cm^{-1} .

The exchange of OH and NH_2 in PI and PII, respectively, insignificantly affect the bond length of the nitrile group $\text{C}\equiv\text{N}$ (1.18\AA). Consequently, the stretching mode of this group $\nu\text{-C}\equiv\text{N}$, characteristic by strong Raman activity, is observed nearly at the same frequency in both PI and PII (2217 and 2211 cm^{-1}) in matching with previously reported values[69-71]. The $\nu\text{-C-N}$ modes show good agreement for the calculated and observed frequencies. Moreover, this mode is observed at slightly higher in energy (1425 cm^{-1}) in PI than the corresponding one in PII (1374 cm^{-1}), this difference could be attributed to more double bond character associated for the C-N bond in PI.

The theoretically calculated wave numbers of $\nu\text{-C=C}$ modes in PI at 1569 and 1631 cm^{-1} concur well the experimentally observed values at 1536 and 1625 cm^{-1} . The same concurrent is also true in case of PII where the $\nu\text{-C=C}$ mode is assigned at 1586 and 1573 cm^{-1} for the experiential and calculated values, respectively. The ring breathing is a characteristic mode for cyclic aromatic molecules, this band is usually strong and appear in the range 700–750 cm^{-1} . Such band with strong intensity appears in both PI and PII in the range 715–773 cm^{-1} . The scaled wave numbers calculated for this mode being 702 and 669/715 for PI and PII, respectively, in a good agreement with the observed values.

The strong band observed at 3434 cm^{-1} for the $\nu\text{-N-H}$ mode of PI perfectly matches the calculated value at 3430 cm^{-1} . In PII instead, two $\nu\text{-N-H}$ modes appear experimentally at 3329 and 3391 cm^{-1} due to the symmetric and asymmetric vibration of the NH_2 group, these bands coincide with the theoretical ones calculated at 3343 and 3457 cm^{-1} , respectively. The strong bands due to $\delta\text{-NH}_2$ bending modes in PII are calculated at 1540, 1573 and 1577 cm^{-1} in coupling with the $\nu\text{-C=C}$ and $\nu\text{-C=N}$ showing considerable agreement with the experimental results. On the other hand, the strongest IR band in PI is assigned to the $\nu\text{-C=O}$, the calculated value deviates by ca. 58 cm^{-1} from the experimental value 1659. This deviation is attributed to the coupling of this mode with the in-plane bending of $\delta\text{-C-H}$ mode.

Experimental Data

3-cyano-4,6-dimethyl-2-pyridone (PI)

White crystals, mp: 293–295°C; IR (KBr) cm^{-1} : 3434 (NH), 3138 (C–H aromatic), 3003 (C–H aliphatic), 2217 ($\text{-C}\equiv\text{N}$), 1659 (C=O), 1625 (C=C); ^1H NMR (DMSO- d_6) δ ppm: 2.18 (s, 3H, -CH_3), 2.26 (s, 3H, -CH_3), 6.12 (s, 1H, pyridine-H), 12.28 (s, 1H, NH (D_2O exchangeable)); MS: m/z 148 (M^+ , 100%); Anal. Calcd for $\text{C}_8\text{H}_8\text{N}_2\text{O}$ (148): C, 64.86; H, 5.41; N, 18.92. Found: C, 65.01; H, 5.32; N, 18.71.

2-Amino-3-cyano-4,6-dimethylpyridine (PII)

Yellow crystals, mp: 256–258°C; IR (KBr) cm^{-1} : 3391, 3330 (NH_2), 3153 (C–H aromatic), 2839, 2749 (C–H aliphatic), 2213 ($\text{-C}\equiv\text{N}$), 1656 (NH bending), 1589, 1568 (C=C, C=N); ^1H NMR (DMSO- d_6) δ ppm: 2.22 (s, 3H, -CH_3), 2.24 (s, 3H, -CH_3), 6.4 (s, 1H, pyridine-H), 6.63 (s, 2H, NH_2 (D_2O exchangeable)); ^{13}C NMR (DMSO- d_6) δ ppm: 19.74

(aliphatic CH₃ at 4), 24.14 (aliphatic CH₃ at 6), 87.01 (pyridine C bearing CN), 112.94 (–C≡N), 116.55, 152.40, 160.09, 161.49 (pyridine carbons); Anal. Calcd for C₈H₉N₃ (147): C, 65.31; H, 6.12; N, 28.57. Found: C, 65.08; H, 6.20; N, 28.61.

Conclusion

In conclusion, a facile, simple and efficient one–pot protocol for the synthesis of 3–cyano–4,6–dimethyl–2–pyridone (PI) and 2–amino–3–cyano–4,6–dimethylpyridine (PII) using acetyl acetone, malononitrile and ammonium acetate is reported. Ammonium acetate acts as a base in PI synthesis and nitrogen source in PII synthesis. This method offers several advantages as shorter reaction time, high yields and easy work up. The effect of solvent, ammonium acetate concentration and reaction time on the products yield were studied. The synthesized compounds as well as reactants and intermediates were investigated at the MP2/6–311++G(d,p) level of theory. Calculations provide a clear explanation for the reaction mechanism in gas phase, ethanol and acetic acid. No significant effects for the geometrical parameter, charges or spectroscopic **properties** were encountered due the solvent effects. Two different methods have been applied to scale the computed vibrational frequencies of the investigated compound. The calculated scaled frequencies are in good agreement with the experimental results with a **correlation coefficient** R²=0.99 for both PI and PII, supporting the reliability of the method used in the calculations.
