Abstract

Films of the chemical precursor ^tBoc-quinacridone obtained by the spin-coating and bar-assisted meniscus shearing methods were subjected to thermal deprotection to recover the organic semiconductor quinacridone in its crystalline form. We found that the final crystal structure of the semiconductor on the Si/SiO₂ substrate is in fact determined by the chemical precursor starting structure, which is in turn induced by the deposition method. Indeed, the samples prepared by spin coating display the precursor structure known from the literature, which transforms into the β-quinacridone phase. The shearing technique instead yields highly homogeneous films composed of a novel ^tBoc-quinacridone polymorph, which acts as a trigger for the subsequent formation of a pure, well oriented α-quinacridone phase. Although this crystalline form is the least stable of the many quinacridone polymorphs, here turns out to be selectively induced and stabilized. Finally, the organic field effect transistor charge mobility of the α-quinacridone films was measured.

1. Introduction

The field of organic electronics has grown considerably during the last two decades, resulting in a huge improvement of the electrical performances of materials, with several organic semiconductors (OSCs)¹⁻⁵ exhibiting charge mobilities higher than $1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$. Green policies impose the search of “green materials” with a reduced impact on the environment,⁶ and organic semiconductors represent a good alternative to the silicon-based electronics, coupling the low cost of both material and processability with high potential for applications which require flexible, stretchable and conformable devices.^{7,8}

Recently, compounds of the class of natural and synthetic pigments called indigoids⁹⁻¹¹ were found to display balanced, albeit not high, ambipolar charge transport coupled with operational stability at ambient conditions.¹² Among other candidate pigments, quinacridone (QA) has the peculiarity of possessing a molecular structure appearing like that of OSC pentacene, where however the π conjugation on the molecular skeleton is broken by the substituents on the rings. Thus, similar to the case of indigo,¹³ the solid-state assembly is driven both by the very strong intermolecular H bonds due to the substituents and by the π stacking of neighboring molecules. The interplay of interactions results for QA in the existence of four known polymorphs. These are characterized by quite different packing arrangements, for which different electronic and charge carrier properties can be foreseen, making this system an ideal benchmark for the theoretical study between crystal structure and charge transport.¹⁴ On more practical grounds, QA has been investigated in view of its use as a potential very low cost and stable active material for a variety of electronic devices.^{15,16} Owing to the ability to form H bonds, linked to a potential lack of toxicity, its versatility can in fact be extended to the possibility of using it as a living cell interface for applications in bioelectronics.¹⁷ The best performing QA based organic field effect transistor (OFET) has been reported by Glowacki and co-workers,¹² who demonstrated its ambipolar character with hole mobilities in the order of $0.1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ for high vacuum evaporated films having tetratetracontane as a gate dielectric. A good reason to prefer vapor deposition methods is the scarce solubility of QA in water and in most organic solvents, a factor which prevents its easy processability by large area scalable techniques based on solution processing. However, a strategy to overcome such a drawback is via the formation of the “latent pigment”, following the methodology developed by Zambounis of CIBA Specialty Chemicals in 1994 and applied to pyrrolo-pyrrole pigments.¹⁸ The chemical functionalization has also been applied to QA,¹⁹ using the same synthetic route (Figure 1).

Figure 1 Synthetic route from quinacridone pigment (QA) to the latent pigment (^tBoc-QA).

The latent pigment is prepared by replacing the H atom of the NH group with the t-butoxycarbonyl (^tBoc) group, a common “protective” agent in organic synthesis. This turns off the N–H···O intermolecular H bonds holding together neighboring molecules, thus highly increasing the solubility in all the common laboratory solvents with respect to the parent system. The pigment itself can be easily regenerated by the thermochemical cleavage of the ^tBoc group.

The aim of this work was to use the same strategy and prepare films of the QA pigment by large area solution printing techniques via the intermediate deposition of the t-butoxycarbonyl-quinacridone (^tBoc-QA) derivative. The focus of the study was on the influence of the process on the polymorphic composition of the resulting QA film.

The outcomes of the classical spin-coating technique and of the roll-to-roll compatible bar-assisted meniscus shearing (BAMS) method^{20,21} were compared, with lattice phonon Raman spectroscopy and X-ray diffraction (XRD) providing an efficient polymorph screening. Notably, after deprotection, the films prepared by spin-coating were found to display the β form of QA, whereas those prepared by BAMS turned out to be entirely consisting of the metastable α form. The most stable γ phase instead was never observed. As the thermal cleavage treatment was identical in the two cases, the structural characterization of the precursor phase was undertaken, showing that the two deposition techniques produce the growth of two different polymorphs of ^tBoc-QA. This is an example of how the control of the crystalline form of the compound also implies the knowledge of the history of the solid phase that generated it. The implications of this finding for film fabrication processes are discussed, and the characteristics of OFETs based on the α quinacridone polymorph reported.

2. Experimental

Materials and synthesis

Quinacridone was purchased from Sigma Aldrich, technical grade purity, and purified by sublimation at low pressure in nitrogen atmosphere. Reagent grade solvents bought from Sigma Aldrich were used without further purification.

The protection of the –NH groups of QA by ^tBoc groups was performed according to Ref. ²² by reacting QA pigment powder with di-tert-butyl dicarbonate and 4-dimethylaminopyridine in methylene chloride at room temperature under Ar atmosphere. The progression of the reaction was followed by TLC and after 48 h no trace of the starting product was found. ^tBoc-QA was purified with column chromatography and recrystallized from ethyl acetate. The ¹H-NMR spectrum of the obtained product shows five signals in the low-field region ascribable to the aromatic protons and a singlet at 1.77 ppm which is due to the methylic protons of the ^tBoc protecting group. The comparison between the integrated intensities of the aromatic protons and the aliphatic protons shows that all the aminic groups had been protected by ^tBoc. This result is also confirmed by the MS spectrum, in which the progressive loss of ^tBu and ^tBoc groups is clearly observable (Figure S1a,b). Pigment ^tBoc-QA may appear in two different polymorphic modifications, named here form I and II. Single crystals of ^tBoc-QA form I were grown by evaporation of an acetone solution kept at room temperature. The solution was previously filtered and ultra-sonicated. We obtained hexagonal prismatic yellowish crystallites.

In order to grow mainly ^tBoc-QA form II single crystals, an acetone solution was filtered, ultra-sonicated and left to evaporate on a hot stage at 75 °C. In addition to that, we used a crystallite of form II from the drop cast sample as growth seed to perform another crystallization from solution, with the aim of growing large crystal, suitable for X-ray analysis.

Raman and IR spectroscopy

Raman spectra of all the crystalline and thin film samples in the lattice phonon region (10-150 cm⁻¹) and on the intramolecular range (150-2000 cm⁻¹) were collected with a Horiba Jobin Yvon T64000 triple monochromator spectrometer interfaced with the optical stage of an Olympus BX40 microscope. The excitation wavelength was a Kr⁺ gas laser tuned at 647.1 nm with a nominal power of 1 W reduced by a neutral optical density filter to avoid sample damage.

FTIR-ATR measurements in the wavenumber range 400-4000 cm⁻¹ with a resolution of 2 cm⁻¹ were carried out on a Perkin Elmer Spectrum Two spectrophotometer, equipped with a Universal ATR accessory.

X-ray diffraction

Single-crystal data for all compounds were collected at RT on an Oxford XCalibur S CCD diffractometer equipped with a graphite monochromator (Mo-K α radiation, $\lambda = 0.71073 \text{ \AA}$). All the ^tBoc-QA form II samples displayed crystal twinning. Thus, data were treated with the default configuration for twinned crystals of CrysAlisPro, and structure solution and refinement were performed on the HKLF4 file containing the non-overlapped reflections. The structures were solved by intrinsic phasing with SHELXT²³ and refined on F² by full-matrix least squares refinement with SHELXL²⁴ implemented in the Olex²⁴ software.²⁵ All non-hydrogen atoms were refined anisotropically applying the rigid-body RIGU restraint.²⁶ H_{CH} atoms for all compounds were added in calculated positions and refined riding on their respective carbon atoms. Data collection and refinement details are listed in Table S1. The Mercury²⁷ program was used to calculate intermolecular interactions and for molecular graphics. Crystal data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; fax: (+44)1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk). CCDC numbers 2067646-2067647.

For phase identification and variable temperature X-ray powder diffraction experiments, diffractograms were recorded on a PANalytical X'Pert Pro automated diffractometer equipped with an X'Celerator detector in Bragg–Brentano geometry, using Cu–K α radiation ($\lambda = 1.5418 \text{ \AA}$) without monochromator in the 2 θ range between 5° and 40° (continuous scan mode, step size 0.0167°, counting time 19.685 s, Soller slit 0.04 rad, antiscatter slit 1/2, divergence slit 1/4, 40 mA·40 kV), and an Anton-Paar TTK 450+LNC. The Mercury²⁷ program was used for the calculation of the X-ray powder patterns on the basis of single-crystal data either retrieved from the Cambridge structural database (CSD): α -QA: QNACRD06, β -QA: QNACRD07, and γ -QA: QNACRD08, or collected in this work: ^tBoc-QA form I and form II, see Supporting information (Figure S2-S4).

Hot stage (HSM) and cross-polarized optical microscopy (POM)

Hot stage experiments were carried out using a Linkam TMS94 device connected to a Linkam LTS350 platinum plate and equipped with polarizing filters. Pictures were collected with the VisiCam Analyzer imaging software, from an Olympus BX41 stereomicroscope.

Polarized optical microscopy (POM) images were taken with an Olympus BX51 microscope equipped with polarizer and analyzer at 90° in reflection mode.

Thermal analysis

Thermogravimetric analyses (TGA) were performed with a Perkin-Elmer TGA-7. Each sample, contained in a platinum crucible, was heated in a nitrogen flow ($20 \text{ cm}^3 \text{ min}^{-1}$) at a rate of $5 \text{ }^\circ\text{C min}^{-1}$, up to decomposition. Samples weights were in the range 5-10 mg.

Differential scanning calorimetric (DSC) measurements were performed with a Perkin-Elmer DSC-7 equipped with a PII intracooler. Temperature and enthalpy calibrations were performed using high-purity standards (n-decane, benzene and indium). The heating of the aluminium open pans containing the samples (3-5 mg) was carried out at $5 \text{ }^\circ\text{C min}^{-1}$ in the temperature range of 40-300 $^\circ\text{C}$.

Thin films and OFET fabrication

Spin-coated films were prepared with 50 μL of solutions of ${}^t\text{Boc-QA}$ (10 mg/mL) in various solvents (namely, hexane, diethyl ether, ethanol and acetonitrile) deposited at 1500 rpm for about two minutes either on $10 \times 10 \text{ mm}^2$ glass microscope slides or on Si/SiO₂ substrates from Si-Mat (thermally grown SiO₂ with thickness of 200 nm).

For the preparation of the films by the BAMS method, the solution concentration of the latent pigment ${}^t\text{Boc-QA}$ in chlorobenzene (CB, Sigma Aldrich) was fixed at 20 mg/mL, and the experimental setup used was the one reported in detail in previous works.^{20,21} The BAMS hot bed was kept at a constant temperature of 105 $^\circ\text{C}$, and the best optimal speed (*i.e.* yielding highly homogeneous films) was found to be 1 mm/s. Before depositing the layer of material, the gold electrodes were functionalized with pentafluorobenzothiol (PFBT, Sigma-Aldrich) by first exposing the substrates for 25 minutes to ozone and then immersing them for 15 min in a 2 $\mu\text{L/mL}$ PFBT solution in isopropanol (IPA) solution.

Bottom gate/bottom contact (BGBC) OFETs were fabricated on p-doped Si/SiO₂ wafers purchased from Si-Mat (SiO₂ of thickness 200 nm, $C = 17,25 \text{ nF/cm}^2$) with pre-patterned interdigitated Cr/Au (5 nm/40 nm) electrodes with different channel lengths ($L = 25$ or $50 \text{ }\mu\text{m}$, W/L ratio =100) fabricated by means of photolithography (Micro-Writer ML3 from Durham Magneto Optics Ltd.) with a lateral resolution of 5 μm .

The de-protection process needed to obtain the films of QA was performed by heating the ${}^t\text{Boc-QA}$ samples at 180-200 $^\circ\text{C}$ on a hot plate for 5 min. The color change observed in the organic material is a good indicator of the progress of the reaction.

The α -QA film electrical characteristics were assessed under ambient conditions using an Agilent B1500A semiconductor parameter analyzer coupled with a Karl SÜSS probe station. Transfer characteristics were measured in the linear regime, with the drain voltage V_D fixed at -5 V , while

the gate voltage V_G was scanned between +10 V and -60 V backward and forward. Output characteristics were measured under constant V_G from 0 to -60 V with a step of 10 V, while V_D was scanned between +2 V and -40 V, also backward and forward. Mobility values, threshold voltages and on/off current ratios were extracted in the linear regime using the classic MOSFETs equation:

$$\mu_{LIN} = \frac{L}{WCV_D} \left(\frac{\partial I_D}{\partial V_G} \right)$$

3. Results and discussion

The synthesized ^tBoc-QA was repeatedly purified by recrystallization in ethyl acetate (EtOAc), obtaining platelet-like yellow crystals (Figure S5). Single-crystal X-ray diffraction (SC-XRD) analysis yielded a monoclinic structure belonging to $P2_1/n$ space group with $Z = 2$ molecules per unit cell, and crystallographic parameters (Table S1) in agreement with those of the previously reported ^tBoc-QA structure, hereafter denoted as form I.²⁸

The regeneration of the parent QA in the bulk state was easily achieved by thermochemical treatment, as shown by the TGA analysis of Figure S6. The thermochemical process starts at 150 °C and ends at 230°C with a loss of about 38% of the initial weight due to the decomposition of the two ^tBoc functionalities which evolve into the release of CO₂ and isobutene.²⁹ Hot stage microscopy images (Figure S5) and XRD (Figure 2) reveal that in the bulk, and for the indicated temperature range, the transformation proceeds through a crystal-to-crystal process with the formation of the β -QA polymorph as the only product.^{30,31}

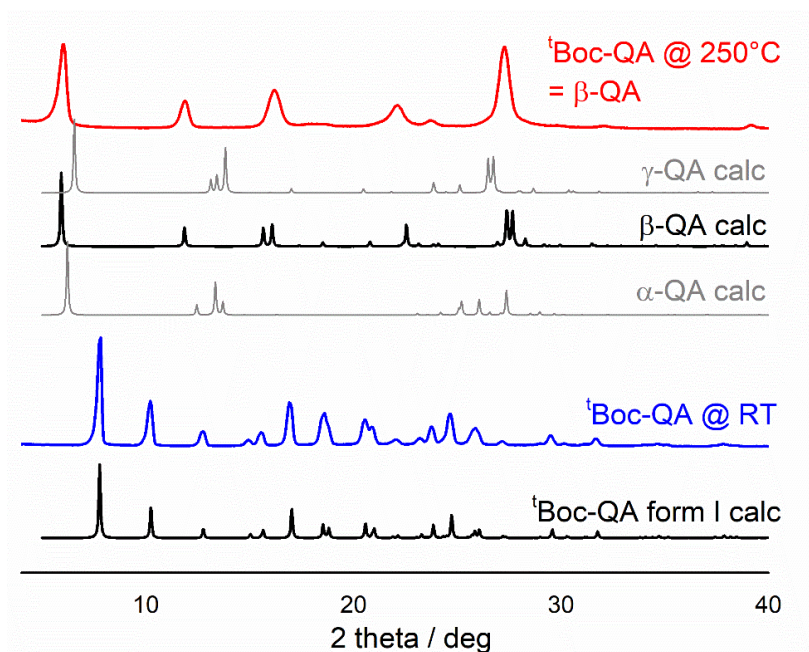

Figure 2 Comparison of the experimental powder XRD patterns with those calculated on the basis of the single-crystal data for compounds³⁰. Top: thermal deprotection of a polycrystalline sample of ^tBoc-QA leads to formation of β-QA.

Characterization of films prepared by spin-coating

The preparation of homogeneous films of QA from solution requires achieving homogeneous films of its precursor first, and thus a number of different organic solvents were tested for the ^tBoc-QA spin-coating deposition, as well as different spinning conditions. Notwithstanding the excellent ^tBoc-QA solubility in all most solvents, the best film morphology and homogeneity was realized with ethanol solutions, as shown in the optical image of Figure 3a. Based on literature data²⁹ and on the ^tBoc-QA DSC and TGA thermograms of Figure S6, the film deprotection process was performed as reported in the “Experimental” section, and the complete removal of the ^tBoc group was assessed by spectroscopic and XRD measurements prior to and following the thermochemical deprotection process, as reported in the following. FTIR spectroscopy is an effective and well-established method to verify that a complete deprotection of the latent pigment has taken place. The intensity decrease of the strong C=O stretching signal, detected around 1750 cm⁻¹, and the appearance of the characteristic signal of the N–H stretching mode between 3000 cm⁻¹ and 3200 cm⁻¹, which confirms the activation of H-bonding sites (Figure S7), are the markers for the reaction progress.³² We also employed Raman microscopy over the range 10-4000 cm⁻¹ to probe both the removal of the ^tBoc groups and the formation of the QA crystalline structure on the same area of the film. With different selection rules, infrared and Raman spectroscopies provide similar information over the wavenumber range where molecular vibrations are detected and can both be used to monitor the

chemical reaction. In addition, the Raman spectra in the terahertz range probe the so-called lattice vibrations (or lattice phonons), originating from the weak intermolecular force field. These yield a unique spectral pattern, which is representative of the crystal structure and can be used to identify the phases present in the films.

In Figure 3 we report Raman spectra, which include the lattice phonon modes (Figure 3c) and the range of the molecular vibrations (Figure 3d), of the ^tBoc-QA spin-coated films spin-cast from an ethanol solution before and after the deprotection process, along with the optical images of the sample.

Figure 3 Optical images of the Raman characterized films as prepared (a) and after the thermochemical cleavage (b); Raman spectra in the lattice phonon range for spin-coated film of ^tBoc-QA before and after de-protection process compared with QA α and β polymorphs spectra from literature³³ (c); 1400-1700 cm^{-1} intramolecular range for ^tBoc-QA spin-coated film before (yellow trace, assignment in-plane NRH bending modes) and after de-protection (red trace, assignment in-plane C–H bendings and ring C–C stretchings) (d).

In Figure 3d the intramolecular vibrational range 1400-1800 cm^{-1} is reported, which represents a diagnostic region sensitive to the ^tBoc cleavage process. The strongest bands (1567 and 1598 cm^{-1}) detected here for QA belong to in-plane total symmetric NRH bending modes which are not present in the derivative. In fact, all the in plane bending modes in the region contain a contribution of this group, as confirmed by DTF simulations (see SI). Accordingly, the strongest bands of the derivative owe their intensity to total symmetric in-plane C–H bendings and ring C–C stretchings, with the mode at 1622 cm^{-1} mostly describing a CO bending.

The analysis of the lattice phonon region of the Figure 3, with its intense peaks, reveals the high degree of crystallinity of the ^tBoc-QA spin-coated samples. The spectral features recorded over this

energy range result to be independent of the solvent used for the fabrication (Figure S8) and do correspond to those found for the freshly synthesized and re-crystallized ^tBoc-QA, confirming that form I is present in these films.²⁸ The corresponding Raman spectra at a first approximation can be interpreted in the framework of the so-called rigid body approach, which considers separately vibrational modes arising from the intermolecular and intramolecular force fields.³⁴ In a centrosymmetric structure with $Z = 2$, we can predict at low frequencies the occurrence of six Raman active intermolecular modes, classified according to the irreducible representations of the factor symmetry group in $3 A_g + 3 B_g$. Each of these modes describes a pure concerted vibration of the whole molecule around its inertia axes. In the spectrum of Figure 3c, ^tBoc-QA displays at least six easily identifiable peaks below 100 cm^{-1} . Additional less intense scatterings might be indeed hidden in the envelope of the strong broad bands that make up the spectrum and could be solved by deconvolution. This is not surprising, as the ^tBoc substituent endows the parent pigment molecule with highly flexible groups, activating intramolecular modes at low wavenumbers and making in fact the rigid body approximation not fully effective for a detailed spectral analysis. However, what is important here is that the unique phonon pattern of ^tBoc-QA first allows for the identification of the compound crystal state, and then for the in situ detection of its cleavage reaction, which proceeds with the formation of the QA crystalline form. The previously reported spectral and structural characterization of several QA polymorphs^{30,33} allows in turn for the identification of the one occurring in the film. Based on the presence of the broad bands at 111 cm^{-1} and at 78 cm^{-1} , as well as of the features below 50 cm^{-1} ,³³ the pattern of Figure 3c is recognized as that of the powder of the QA β -form, given for comparison in the same Figure. The presence of β -QA is further confirmed by the pair of bands at 215 and 230 cm^{-1} ,³³ normally used to discriminate this polymorph from γ -QA, which is the structure most commonly occurring in the bulk. The similarity of the spectrum to that of a powder hints to the absence of a texture in the film.

The β -QA polymorph assignment given by Raman on the spin-coating samples is confirmed by XRD measurements and agrees with the transformation taking place for the ^tBoc-QA form I polycrystalline sample (see Figure 2). As for the films, the most recent literature reports that those grown by direct QA sublimation also belong to β -QA phase.^{12,16} Previously, the only growth of the γ -QA phase was observed by sublimation at high temperature ($\approx 600 \text{ K}$). This phase was then assumed to be the most stable in these conditions, whereas β -QA would grow at much lower temperatures, around 500 K .^{28,35,36} In some instances, small changes in the sublimation conditions have been found to induce the concomitant growth of β -QA and α -QA forms,¹⁶ similarly to what is

known for systems such as of pentacene.³⁷ Finally, the films obtained via the precursor by Yanagisawa et al.¹⁹ contained β -QA.

Characterization of films prepared by the BAMS technique

The fabrication of films by the BAMS technique²⁰ was undertaken to obtain more homogeneous and reproducible samples, compatible with the requirements of large area processing. As previously reported, the BAMS technique is a variant of the traditional blade coating method, which consists in pouring the solution of the material to deposit between a substrate placed on a hot plate and a bar located $\sim 500 \mu\text{m}$ apart. This allows for the formation of a confined meniscus, which is subsequently displaced when the substrate itself is moved horizontally at a constant speed. In recent years, this method has proved to induce high crystallinity in thin-films at a speed compatible with roll-to-roll processes using as active materials OSCs and OSCs blended with insulating polymers, and even for the more challenging formation of charge transfer complexes.³⁸

The ^tBoc-QA films prepared by this simple and yet effective solution processing technique feature a high homogeneous deposition, with a very good degree of coverage of the whole substrate area. This can be seen in Figure 4a, which shows the optical microscopy image of a thin-film fabricated on a Si/SiO₂ substrate having interdigitated gold-prepatterned contacts, prepared for OFET measurements. The images recorded in cross-polarized optical microscopy (POM) highlight the morphology and the polycrystalline texture of the sample (Figure 4b). It is worth noting that such characteristics are retained after the annealing process at 200 °C (see Figure 4c,d), confirming that the thermal cleavage is accompanied by a crystal-to-crystal transformation, in which the formation of the new lattice of QA follows the disruption of that of ^tBoc-QA.

Figure 4 Optical (a, c) and POM (b, d) images of ^tBoc-QA thin films fabricated by BAMS technique before (a, b) and after (c, d) the thermal treatment which leads to QA.

The analysis of such a QA lattice reveals the presence of the α form, as demonstrated in Figure 5. Figure 5a shows the comparison of the Raman lattice phonon spectra of the film formed by thermal annealing with that of the α -QA single crystal from the literature.³³ The assignment is unmistakable, as the spectrum of the $Z = 1$ triclinic α form is characterized by the same broad and structureless band centred at 97 cm^{-1} .³³ The β form found in the spin-coated samples is absent and cannot be found even by the Raman mapping of extended areas of the films. The XRD data of Figure 5c, where the patterns of the various QA polymorphs are compared to that of the films, clearly confirm that the metastable α -QA is the only structure occurring in the BAMS films. The stabilization of metastable forms in growth processes that take place at the interfaces is a common phenomenon. What is surprising in this case is that contrary to what happens in samples obtained by spin-coating, there is complete selectivity towards this structure, to the detriment of the more widely encountered β form. The reasons for the formation of the different QA phases must be traced back to the crystalline phase of the precursor itself in the two deposition methods. In Figure 6 the ^tBoc-QA Raman spectra of films obtained by spin coating and BAMS are compared. The spectra differ in the lattice phonon region (Figure 6a), which is indicative of different crystal structures. As mentioned before, the $1400\text{-}1800 \text{ cm}^{-1}$ interval selected in Figure 6b is specific for intramolecular modes sensitive to the cleavage process and is thus relevant to chemical diagnostics. The lack of significant

differences between the spectra over this range is an indication that the two processing methods do not modify the chemical nature of ^tBoc-QA. Such a test is fully justified by the BAMS higher deposition temperature, which could have promoted the precursor partial cleavage, with the restoration of a fraction of amine groups. In agreement with the Raman findings, the X-ray diffraction pattern of these samples (Figure 5c) displays peaks which do not correspond to reflections of the known ^tBoc-QA form I. Thus, a new ^tBoc-QA polymorph, hereafter named form II, must be responsible for the formation of the α -QA films after the thermal treatment. Its range of thermodynamic stability is expected to fall at temperatures higher than those of existence of form I. Further, it should be noted that the BAMS technique in these conditions tends to give rise to kinetic and metastable polymorphs.^{1,39,40}

Figure 5 a) Raman characterization in the lattice phonon and b) in the intramolecular range used for the compound identification of the films fabricated by BAMS technique. c) XRD patterns of the same BAMS films as prepared and after thermochemical cleavage of ^tBoc groups compared with the different QA and ^tBoc-QA polymorphs.

To isolate and characterize the new phase, ¹Boc-QA solutions in acetone were drop cast at increasing temperatures and recovered after solvent evaporation at ambient conditions. At a solution and substrate $T = 75\text{ }^{\circ}\text{C}$, the block shaped crystallites obtained at ambient T were accompanied by the formation of needle shaped specimens, as shown in the images of Figure S9. Accordingly, two distinct lattice phonon patterns were identified by Raman, one related to ¹Boc-QA form I, the other to the phase presented in the BAMS processed films. Raman spectra recorded in polarized light for the two cases (Figure S9) assist the analysis of each of the patterns in more detail and confirm their belonging to two different structures, proving the existence of a second crystal phase. Crystallites of this phase singled out by probing their Raman spectrum could finally be structurally characterized by SC-XRD (Table S1).

Figure 6 a) lattice phonon and b) intramolecular Raman spectra of spin cast and BAMS ¹Boc-QA films; c) Diffraction patterns of BAMS films and the two ¹Boc-QA polymorphs. Inset: orientation of the two ¹Boc-QA molecules with respect of the (20-2) and (200) Miller planes in form II. H_{CH} atoms omitted for clarity.

Like form I, ^tBoc-QA form II is found to have a monoclinic unit cell with space group $P2_1/c$ and the parameters reported in Table S1. Also, the SI detail the main structural differences between form I and form II.

As expected, the peak positions of the XRD spectrum collected on the BAMS ^tBoc-QA film correspond to those of form II, as displayed in detail in Figure 6c. In particular, two sets of Miller planes progressions can be identified. The first one coincides with the (2_n00) series of ^tBoc-QA $P2_1/c$ form II, an indication of a growth with the (100) plane lying on the surface. The second, much weaker, coincides with the series (2_n0-2_n) of the same structure. The molecular orientations within these planes are shown in the Figure 6c, where also the arrangement of the quinacridone core face-to-face stackings with respect to the interface is easily recognizable in either case. Information about the presence of two predominant arrangements of the precursor molecule on the surface is also supplied by the Raman spectra of the films reported in Figure S10. Basically, only two lattice phonon patterns are found in the Raman mapping of large areas of a film kept in a fixed position with respect to the laboratory reference frame. Each pattern is characterized by its own motif of relative peak intensities. This suggests the presence of two (main) different ways in which the crystalline domains are oriented with respect to the impinging polarized excitation laser beam, which agrees with the observation of two different series of peaks in the diffractograms.

The knowledge of how the crystal lattice of the latent pigment is oriented in the film may help the modeling of the arrangement of the QA molecules with respect to the substrate after deprotection. In fact, since the thermochemical cleavage is found to proceed through a crystal-to-crystal transformation, the removal of the gaseous products must take place without a large disruption of the reactant lattice, possibly with small movements of the molecular cores to adjust in the product lattice.

OFET performance of α -QA films

The interest in the QA system as a semiconductor material lies in its high stability in air, which arises from the HOMO level being lower in energy than in its analogue in the acene series, *i.e.* pentacene, due to the presence of heteroatoms in the skeleton. The resulting increase of the HOMO-LUMO bandgap is confirmed by the blue shifted electronic absorption.¹²

Previous works and a patent have reported QA based OFETs obtained using high vacuum deposited thin films fabricated both on the classical Si/SiO₂ wafer substrates and on tetracontane (TTC), where the best mobilities were achieved.⁴¹⁻⁴³ In fact, the evaporation of the semiconducting QA layer on

the aliphatic, low surface energy TTC drives the growth of the H-bonded molecules towards a standing up configuration, in which the π -stacks are aligned parallel to the gate dielectric substrate, in an optimal configuration for charge transport.^{41–43}

On the other hand, QA relevance for applications could be greatly increased if crystalline films for OFETs were prepared by printing, overcoming the disadvantages due to the lack of solubility in most solvents. Obviously, and regardless of the manufacturing method, thin film crystallinity and polymorph composition, together with the molecular orientation requirements, are crucial factors in determining the performance of the devices.^{44,45}

β -QA OFETs fabricated by the spin-coating technique via the formation of the latent pigment as a chemical precursor were characterized by Yanagisawa and co-workers.¹⁹ In the present work we evaluate the electrical performances of the α -polymorph based OFETs prepared by the BAMS technique, to assess if the semiconducting properties are preserved in this crystal form.

OFETs were fabricated using a bottom gate/bottom contact configuration on Si/SiO₂ substrates with pre-patterned gold interdigitated electrodes and channel dimensions of 25 and 50 microns, keeping constant $W/L = 100$. Figure 7a and 7b show their transfer curves (drain current I_D vs. gate voltage V_G) in the linear regime and the output characteristic curves (drain current I_D vs. drain voltage V_D), respectively, measured at room temperature under ambient conditions.

Figure 7 a) Transfer characteristic curves in linear regime in forward (full line) and backward (dotted line) sweeps and b) corresponding output electrical characteristics of the QA thin film transistor prepared ($L = 25 \mu\text{m}$, $W/L = 100$) by depositing by BAMS ¹BOC-QA followed by cleavage of ¹Boc groups.

The curves display typical FET characteristics, with an almost linear region at low V_D (-5 V) and some hysteresis between the forward and backward sweeps. The negative sign of the gate and drain voltages indicates a hole transport mechanism of the QA based devices. From the linear regime, we

determined the average linear mobility on at least 20 devices, giving a value of $\mu_{h,av} = (1.15 \pm 0.19) \cdot 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ with a threshold voltage of $V_{TH,av} = -7.90 \pm 3.68 \text{ V}$ and on-off ratio of 300. The performances are not influenced by the different channel lengths, suggesting low contact resistance in agreement with the linearity of the output curves at low drain voltages. The mobility values found here are slightly higher than the ones reported for the spin-coated β -QA films.¹⁹

Conclusions

The strategy of preparing films of crystalline QA via a chemical precursor with higher solubility, coupled to the deposition of the precursor by means of the BAMS method, has proved to be successful in improving sample homogeneity and reproducibility. Unexpectedly, however, the films thus prepared are entirely formed by the α quinacridone polymorph, at variance from what is commonly observed if the deposition is performed by spin coating which leads to the β form of the pigment. The formation of α -QA turns out to be induced by the presence of a different polymorph of the precursor itself, whose growth is most likely triggered by the induced solution shearing crystallisation process combined with the higher deposition temperatures used. The α -QA films display OFET hole mobility values comparable or even slightly higher to those measured in Ref. 19 for the β form prepared by either the same chemical precursor method or high vacuum deposition on Si/SiO₂. Much better mobilities were recorded for QA by combining ultra-high vacuum fabrication with different substrates and electrode materials,¹² but a direct comparison with these experiments is not meaningful. Detecting here a promising OFET behaviour in the α -QA films represents a further assessment of the intrinsic OSC properties of this pigment, which can be in the future optimized by the modification of the device architecture, the choice of the substrate or other external parameters of the system. However, what it is necessary to stress here is the relevant finding that when chemical precursor methods are employed, the precursor polymorph may determine the resulting OSC polymorph. This is a factor crucial for the charge transport properties of the device and represents an aspect of the manufacturing process that is necessary to know and control. Further investigations must certainly aim to improve the crystallinity of the films prepared by the latent pigment at all stages of fabrication. There are two main reasons to do this: first, to increase mobilities; second, having at disposal crystalline films of different QA polymorphs, it will be possible to explore their performances against their different structures and the predictions of computational approaches.^{14,46}
