# PRICE PROBABILITIES: A CLASS OF BAYESIAN AND NON-BAYESIAN PREDICTION RULES

Filippo Massari\*

*Department of Decision Sciences, Bocconi University*<sup>†</sup>

April 15, 2020

## Abstract

This paper examines the implications of the market selection hypothesis on the accuracy of the probabilities implied by equilibrium prices and on the “learning” mechanism of markets. I use the standard machinery of dynamic general equilibrium models to generate a rich class of probabilities, *price probabilities*, and discuss their properties. This class includes the Bayes’ rule and known non-Bayesian rules. If the prior support is well-specified, I prove that all members of this class perform as well as Bayes’ rule in terms of likelihood. If the prior support is misspecified in that the bayesian prior does not converge, I demonstrate that some members of price probabilities significantly outperform Bayes’. Because these members are never worse and sometimes better than Bayes, my result challenges the prevailing opinion that Bayes’ rule is the only rational way to learn.

KEYWORDS: Non-Bayesian learning, efficient market, prediction market, market selection hypothesis.

JEL CLASSIFICATION: C53,D70, D81, D83

## 1 Introduction

It has long been argued that financial markets aggregate the different opinions of their participants efficiently. A possible explanation comes from the *market selection hypothesis* (Friedman, 1953) according to which selection forces push equilibrium prices to reflect the beliefs of the most accurate trader in the market. By selecting for the most accurate trader, the market

<sup>†</sup>Via Roentgen, 1 (3rd floor) 20136 Milano, Italy.

works as a learning algorithm that gives more weight to more accurate models. The market selection hypothesis has been extensively investigated and shown to hold in a variety of market structures including general equilibrium (Sandroni, 2000; Blume and Easley, 2006; Sandroni, 2005), general equilibrium models with some strategic agents that internalize their market impact (Leoni, 2008), or asymmetric information (Mailath and Sandroni, 2003), and in models of market with fixed investment strategies Bottazzi et al. (2018).<sup>1</sup>

The link between the market selection hypothesis and learning is evident in general equilibrium models with complete markets and equally patient traders having log-utilities, where the equilibrium dynamics of the state price densities coincide with the dynamic of the Bayesian posterior calculated from a prior on the set of trader beliefs (Rubinstein, 1974; Blume and Easley, 1993). In this paper, I relax the log-utility assumption and focus on the accuracy of the resulting state price densities.

*Price Probability* is the class of all probabilities that can be represented as state-price densities of an economy with complete markets, no aggregate risk, and in which the market selection hypothesis holds. This class is rich: Corollary 1, and 2 show that it includes Bayes' rule (BMA)<sup>2</sup> as well as known non-Bayesian rules such as the Normalized Maximum Likelihood (NML) (Rissanen, 1986; Shtar'kov, 1987; Grünwald, 2007) and the Sequential Normalized Maximum Likelihood (SNML) (Roos and Rissanen, 2008).

I find that most members of price probabilities are fundamentally not Bayesian because they do not make convex predictions — i.e., the predictive probability might not be a convex combination of the models in the support (see section 5) — and furthermore, some of its members are time-inconsistent.

Given the overwhelming experimental evidence showing that most agents are not Bayesian (Rabin, 2002; Kahneman, 2011), it is natural to ask if non-Bayesian members of the price probability class constitute a “rational” alternative to Bayes' rule. However, what does it mean to be “rational”? Contrary to the axiomatic approach to learning in the economics literature, according to which a prediction rule is rational if consistent with a set of axioms (Ghirardato, 2002; Gilboa and Marinacci, 2011), I take a point of view closer to machine learning (Breiman et al., 2001; Sutton and Barto, 1998) and propose a pragmatic notion of rationality. A prediction rule is pragmatically rational if it guarantees good predictions irrespective of the true probability. I consider these points of view as complementary. The former is appropriate in situations in which an agent is not subject to an external criterion of performance. In this case, a set of axioms can jointly determine an agent's preferences and beliefs. The latter is appropriate for

---

<sup>1</sup>Conversely, the market selection hypothesis does not hold when markets are incomplete (Coury and Sciubba, 2012) and in situations of asymmetric information in which information is costly (Sciubba, 2005).

<sup>2</sup>Bayesian Model Averaging: Hoeting et al. (1999)

cases in which agent decisions are evaluated according to an external criterion of performance (e.g., Sharpe ratio for portfolio managers, calibration for weather forecasters). Because the criterion pins down agent preferences, a pragmatic agent should internalize this constraint in his decision problem and choose a prediction rule that is optimal for his preferences. These two points of view coincide in well-specified learning problems, but might and often differ in misspecified learning problems.

Taking advantage of the almost universal predominance of Bayes' rule and its sound axiomatic foundation, I use BMA as a benchmark and propose an accuracy criterion for prediction rules based on likelihood comparisons. I find that if the learning problem is correctly specified all members of price probability are as good as Bayes' because they converge to the truth almost surely at a comparable rate (merge). I call this property  $\mathcal{P}$ -efficiency.

Facing a well-specified learning problem, however, is the exception rather than the rule for many practical prediction problems (predicting stock market returns, weather, outcomes of sport events...). So, it is pragmatically relevant to also compare the performance of prediction rules under model misspecification. I identify the following categories.

- A probability mixture,  $p$ , is *super-efficient* if the log-likelihood ratio between BMA and  $p$  is bounded above in every sequence, but there are probabilities,  $\hat{P}$ , such that it diverges to negative infinity  $\hat{P}$ -almost surely. That is,  $p$  is *super-efficient* if  $p$  and BMA use the same prior information, there are no sequences in which BMA is overwhelmingly more accurate than  $p$ , and there are cases of misspecification, in which  $p$  is overwhelmingly more accurate than BMA.
- A probability mixture,  $p$  is *universal-efficient* if the log-likelihood ratio between BMA and  $p$  is bounded above and below, in every sequence — that is, if  $p$  is qualitatively as accurate as BMA in every sequence.
- A probability mixture,  $p$  is *sub-efficient* if the log-likelihood ratio between BMA and  $p$  is bounded above almost surely when the model is well-specified, but there cases of misspecification such that it diverges to infinity.

The universal-efficient members of price probabilities are time-inconsistent (except for BMA), thus rational, in all settings in which time inconsistency cannot be used to construct arbitrages.

Time-consistent members of price probability (except for BMA) can either be sub-efficient or super-efficient, depending on the risk attitudes of the agents in the generating economy. The super-efficient members of price probability are generated by economies in which all agents have CRRA utility with parameter  $\gamma^i > 1$ . In these economies, consumption shares move slower than in log economies which determine a slower convergence toward the model with the maximum

likelihood probability. Although non-convex, they share important similarities with known robust algorithms in Computer Science and Game Theory (HEDGE algorithm by Freund and Schapire (1997); Safe Bayesian by Grünwald (2012); and Smooth Fictitious Player by Fudenberg and Levine (1998)). These algorithms show that if the loss (utility) function differs from log-likelihood, an agent can be better off abandoning Bayes' rule for a rule that underreacts to information by giving less weight to past realizations. My result contributes to this literature by showing that Baye's rule can be improved also when the loss (utility) function is log.

Conversely, the sub-efficient members of price probability are generated by economies in which all agents have CRRA utility with parameter  $\gamma^i < 1$ . In these economies, consumption shares move more slowly than in log economies which determine a slower convergence toward the model with the maximum likelihood probability. Although non-convex, they share similarities with the algorithms above-mentioned, albeit with parameters that would make them sub-optimally overreact to information.

Section 2 derives and defines the Price Probabilities class and presents known probability mixture models. Section, 3 characterizes members of price probability with analytical form. Section 4 discusses the relative accuracy of members of the price probability class, while Section 5 shows that most price probabilities are not Bayesian.

## 2 Price probabilities

### 2.1 Environment

Time is discrete and begins at date 0. At each date, a random variable (the economy) can be in  $S$  mutually exclusive states,  $\mathcal{S} := \{1, \dots, S\}$ , with a Cartesian product  $\mathcal{S}^t = \times^t \mathcal{S}$ . The set of all infinite sequences of states is  $S^\infty := \times^\infty \mathcal{S}$ , with a representative path,  $\sigma = (\sigma_1, \dots)$ .  $\sigma^t = (\sigma_1, \dots, \sigma_t)$  denotes the partial history until period  $t$  and  $(\sigma^{t-1}, \sigma_t)$  is the concatenation of  $\sigma^{t-1}$  and  $\sigma_t$ , i.e. the sequence whose first  $t-1$  realizations coincide with  $\sigma^{t-1}$  and last element is  $\sigma_t$ .  $\mathcal{C}(\sigma^t)$  is the cylinder set with base  $\sigma^t$ ,  $\mathcal{C}(\sigma^t) = \{\sigma \in S^\infty | \sigma = (\sigma^t, \dots)\}$ ,  $\mathcal{F}_t$  the  $\sigma$ -algebra generated by the cylinders,  $\mathcal{F}_t = \sigma(\mathcal{C}(\sigma^t), \forall \sigma^t \in S^t)$ , and  $\mathcal{F}$  is the  $\sigma$ -algebra generated by their union,  $\mathcal{F} = \sigma(\cup^\infty \mathcal{F}_t)$ . By construction  $\{\mathcal{F}_t\}$  is a filtration. In what follows, all variables with index  $t$  are assumed to be measurable according to the natural filtration  $\mathcal{F}_t$ .

For any probability measure  $p$  on  $\mathcal{F}$ ,  $p(\sigma^t) := p(\{\sigma_1 \times \dots \times \sigma_t\} \times S \times S \times \dots)$  denotes the marginal probability of the partial history  $\sigma^t$ , while  $p(\sigma_t |) := p(\sigma^t | \sigma^{t-1}) = \frac{p(\sigma^t)}{p(\sigma^{t-1})}$  denotes the conditional probability of the last observation of the partial history  $\sigma^t$  given its first  $t-1$  realizations.<sup>3</sup>  $P$  is the true probability on  $\mathcal{F}$ .

---

<sup>3</sup>For notation's sake, we assume that past realizations constitute all the relevant information, i.e.  $\mathcal{F}_t := \sigma^t$ .

## 2.2 The Economy

In this section, I introduce the economic setting I use to define price probabilities. Consider an Arrow-Debreu exchange economy with complete markets. The economy contains a finite set of traders  $\mathcal{I}$ . Each trader,  $i$ , has consumption set  $\mathbb{R}_+$ . A consumption plan  $c : S^\infty \rightarrow \prod_{t=0}^\infty \mathbb{R}_+$  is a sequence of  $\mathbb{R}_+$ -valued functions  $(c_t(\sigma))_{t=0}^\infty$ . Each trader  $i$  is characterized by a payoff function  $u^i : \mathbb{R}_+ \rightarrow \mathbb{R}$  over consumption, a discount factor  $\beta_i \in (0, 1)$ , and an endowment stream  $(e_t^i(\sigma))_{t=0}^\infty$ . Each trader has a subjective probability  $p^i$  on  $\mathcal{F}$ , his beliefs. I denote the set of trader beliefs by  $\mathcal{P} := \{p^i : i \in \mathcal{I}\}$ . Each trader,  $i$ , aims to solve:

$$\max E_{p^i} \sum_{t=0} \beta^t u^i(c_t^i(\sigma)) \quad s.t. \quad \sum_{t=0} \sum_{\sigma^t \in S^t} q(\sigma^t) (c_t^i(\sigma) - e_t^i(\sigma)) \leq 0;$$

where  $q(\sigma^t)$  is the price of a claim that pays a unit of consumption on the last realization of  $\sigma^t$ , in terms of consumption at time zero. Let  $q(\sigma_t |) := q(\sigma_t | \sigma^{t-1})$  be the price of a claim that pays a unit of consumption at period/event  $\sigma_t$ , in terms of consumption at period/event  $\sigma^{t-1}$ . It is worth noting the analogy between the equilibrium relation of time-zero and next-period prices,  $q(\sigma_t |) = \frac{q(\sigma^t)}{q(\sigma^{t-1})}$  (Ljungqvist and Sargent, 2004), and the way unconditional and conditional probabilities are linked,  $p(\sigma_t |) = \frac{p(\sigma^t)}{p(\sigma^{t-1})}$ . If the sum of next-period prices were 1, equilibrium prices would define a standard probability measure.

## 2.3 Assumptions

A competitive equilibrium is a sequence of prices and, for each trader, a consumption plan that is affordable, preference maximal on the budget set, and mutually feasible. Assumptions **A0-A4**, below, are sufficient for the existence of the competitive equilibrium (Peleg and Yaari, 1970) and for the market selection hypothesis to hold (Sandroni, 2000).

**A0** : The number of traders is finite.

**A1** : The payoff functions  $u^i : \mathbb{R}_+ \rightarrow [-\infty, +\infty]$  are  $C^1$ , concave, strictly increasing, and satisfy the Inada condition at 0 — that is,  $u^i(c)' \rightarrow \infty$  as  $c \searrow 0$ .

**A2** : For all agents  $i \in \mathcal{I}$  and for all  $(t, \sigma)$ ,  $p^i(\sigma^t) > 0 \Leftrightarrow P(\sigma^t) > 0$ .

**A3** : The aggregate endowment equals 1 in every period: for all  $(t, \sigma)$ ,  $\sum_{i \in \mathcal{I}} e_t^i(\sigma) = 1$ .

**A4** : All traders have an identical discount factor: for all  $i \in \mathcal{I}$ ,  $\beta^i = \beta$ .

Because the second welfare theorem applies, I assume that the initial optimal consumption choices are known and given by  $C_0 = [c_0^1 \dots c_0^I] \gg 0$ . By **A3**,  $\sum_{i \in \mathcal{I}} c_0^i = 1$ , which allows us to interpret time-zero consumption shares as the weights that a hypothetical Bayesian prior gives

to probabilities in  $\mathcal{P}$ . The absence of aggregate risk is needed to eliminate biases on risk-neutral probabilities due to aggregate consumption fluctuations.

Last, I add a diversity of beliefs assumption to make the learning problem not trivial.

**A5** : The set of agents' beliefs  $\mathcal{P} := \{p^i : i \in \mathcal{I}\}$  has at least two orthogonal models.

For intuition, the reader can think of  $\mathcal{P}$  as being a set of distinct and time independent multinomial distributions.

## 2.4 The price probability class

Members of price probabilities are obtained by interpreting equilibrium prices of the Arrow securities as representing relative likelihoods and then using these relative likelihoods to construct probabilities via normalization. Given the set of (agents') probabilistic models  $\mathcal{P}$ , different time-zero (consumption-share) distributions ( $C_0$ ), preferences ( $\{u^i\}_{i=1}^I$ ) and normalization methods determine different probability measures. I call the class of all such probability measures price probabilities:

**Definition 1. Price probabilities**,  $\mathcal{M}(\mathcal{P})$ , is the class of all the probabilities that can be represented as normalized equilibrium prices of an economy that satisfies **A0-A4**.<sup>4</sup>

In the rest of the paper, I focus on two normalization methods:  $p^{NNL}$ , in which time-zero prices are normalized at every horizon; and  $p^{SNL}$ , in which next-period prices are normalized sequentially.

**Definition 2. Normalized Normed Likelihood (NNL)**:

$$\forall \sigma^t \in S^t, \quad p^{NNL}(\sigma^t) = \frac{q(\sigma^t)}{\sum_{\hat{\sigma}^t} q(\hat{\sigma}^t)} \quad ; \quad p^{NNL}(\sigma_t|) : \text{not defined.}$$

NNL is the only probability measure that preserves the relative likelihoods of time-zero prices at every horizon (a new normalization is done at every horizon). In economic terms,  $p^{NNL}$  is the cost of moving a unit of consumption in period/event  $\sigma^t$  in terms of time-zero consumption, divided by the cost of moving a unit of consumption from time-zero to time  $t$  for sure. Because all normalizations are conducted with respect to time-zero prices, a set of conditional probabilities such that  $p^{NNL}(\sigma^t) = \prod_{\tau=1}^t p^{NNL}(\sigma_\tau|)$  for all  $t$  is not guaranteed to exist. More generally,

---

<sup>4</sup>This definition can be extended naturally to the continuum by using the model and assumptions of Massari (2019). However,  $\mathcal{P}$ -efficiency of members of  $\mathcal{P}$  might not hold in the large as Massari (2019) showed that the MSH can fail in the large.

**Proposition 1.** Under **A0-A5**,  $p^{NNL}$  satisfies the following time-consistency property if and only if all agents in the generating economy have log utility

$$\forall \sigma^{t-1}, \quad \sum_{\hat{\sigma}^t \in S^t} p(\hat{\sigma}^t \cap \sigma^{t-1}) = p((\cup \hat{\sigma}^t \in S^t) \cap \sigma^{t-1}) = p(\sigma^{t-1}).$$

Thus,  $p^{NNL}$  generically defines a sequence of probability measures on  $S^t$ , which does not obey the chain rule of conditional probabilities.

**Definition 3. Sequential Normalized Normed Likelihood (SNNL):**

$$\forall \sigma^t \in S^t, \quad p^{SNNL}(\sigma^t) = \prod_{\tau=1}^t p^{SNNL}(\sigma_t |) \quad ; \quad p^{SNNL}(\sigma_t |) = \frac{q(\sigma_t |)}{\sum_{\hat{\sigma}_t} q(\hat{\sigma}_t |)}$$

SNNL is the only probability measure that preserves the relative likelihoods of next-period prices. It is the cost of moving a unit of consumption from period/event  $\sigma^{t-1}$  one period ahead in state  $\sigma_t$ , divided by the cost of moving a unit of consumption for sure. Unlike  $p^{NNL}$ ,  $p^{SNNL}$  is time-consistent because it is constructed recursively. In the economics literature,  $p^{SNNL}$  is also known as the equivalent martingale measure (Sandroni, 2000) or market consensus (Jouini and Napp, 2007; Dindo and Massari, 2020).

## 2.5 Probability mixture models

This section gives a brief overview of the definition probability mixture, it describes known probability mixture models that belong to the price probability class. These mixture models have been derived independently and with different objectives in mind. My framework is the first to encompass all of them at once. I refer the reader to Foster and Vohra (1999) and Grünwald (2007) for a more comprehensive discussion.

- **Probability mixture.** Given a reference set of probability measures  $\mathcal{P}$ , a probability mixture is any function that combines members of  $\mathcal{P}$  to deliver a sequence of probabilities  $(p_t)_{t=1}^\infty$ . If the probability mixture can be calculated recursively, its definition coincides with Dawid (1984)'s definition of a statistical forecasting scheme and each  $p_t$  is the marginal probability of a probability on  $\mathcal{F}$ . Otherwise, each  $p_t$  is defined only on  $\mathcal{F}_t$  and  $(p_t)_{t=1}^\infty$  represents a sequence of probability assessments.

Before presenting known probability mixtures and compare their properties, it is helpful to start with the instrumental definition of log-regret.

- **Log-regret:** Given a partial history  $\sigma^t$  and a (finite<sup>5</sup>) reference set of probabilities  $\mathcal{P}$ , the

---

<sup>5</sup>All definitions can be extended to the case in which  $|\mathcal{P}| = \mathbb{R}$  substituting sup for max.

log-regret of a probability  $p$  on  $\mathcal{F}_t$  is the log-likelihood ratio between the model in  $\mathcal{P}$  with the highest likelihood on  $\sigma^t$  (i.e. the most accurate model in  $\mathcal{P}$  with hindsight) and  $p$ : given  $\sigma^t$ ,  $R(p, \mathcal{P}, \sigma^t) = \max_{i \in \mathcal{I}} \{\ln p^i(\sigma^t)/p(\sigma^t)\}$ . The log-regret is a measure of how well  $p$  predicts vis a vis the most accurate model in  $\mathcal{P}$  with hindsight of the realized sequence. Different sequences have different log-regrets. To avoid this dependence, it is customary to focus on the worst-case log-regret — which means on the log-regret calculated on the least favorable sequence of realizations:  $\mathcal{R}^t(p; \mathcal{P}) = \max_{\sigma^t \in S^t} R(p, \mathcal{P}, \sigma^t)$ . A probability mixture with a small worst-case log-regret is desirable because in every sequence it is almost as accurate as the most accurate model in  $\mathcal{P}$  with hindsight.

### Known probability mixture models

- **BMA:** Bayesian Model Averaging is considered the “gold standard” among all probability mixtures. Given a Bayesian prior distribution  $C_0$  on a set of probabilities  $\mathcal{P}$ , BMA directly follows from Bayes’ rule:

$$\forall \sigma^t \in S^t, \quad p^{BMA}(\sigma^t) = \sum_{i \in \mathcal{I}} p^i(\sigma^t) c_0^i \quad ; \quad p^{BMA}(\sigma_t |) = \sum_{i \in \mathcal{I}} p^i(\sigma_t |) c_{t-1}^i(\sigma), \quad (1)$$

where  $c_{t-1}^i(\sigma) = p^i(\sigma^{t-1}) c_0^i / \sum_{i \in \mathcal{I}} p^i(\sigma^{t-1}) c_0^i$  are the weights of the prior distribution obtained via Bayes’ rule from  $C_0$ .<sup>6</sup> The prominence of BMA is due to its sound axiomatic foundation, its good predictive performance, and its tractability. BMA is directly implied by Kolmogorov (1933)’s axioms (adopting the standard definition of conditional probability  $p^{BMA}(\sigma_t |) := p^{BMA}(\sigma^t)/p^{BMA}(\sigma^{t-1})$ ), and it is compatible with Savage (1954)’s axioms (Ghirardato, 2002). Moreover, BMA is consistent — if the true probability belongs to  $\mathcal{P}$ , BMA’s predictions converge to it—, can be calculated recursively, and has bounded worst-case log-regret (if  $|\mathcal{P}|$  is finite).

- **NML:** Normalized Maximum Likelihood is the probability mixture which corresponds to the model that minimizes the maximal worst-case log-regret at any horizon:  $p^{NML}(\cdot, t) = \arg \min_p \mathcal{R}^t(p, \mathcal{P})$ . Rissanen (1986) and Shtar’kov (1987) independently showed that:

$$\forall \sigma^t \in S^t, \quad p^{NML}(\sigma^t) = \frac{\max_{i \in \mathcal{I}} p^i(\sigma^t)}{\sum_{\hat{\sigma}^t} \max_{i \in \mathcal{I}} p^i(\hat{\sigma}^t)} \quad ; \quad p^{NML}(\sigma_t |) : \text{not defined} \quad (2)$$

NML has bounded worst-case log-regret (if  $|\mathcal{P}|$  is finite), which makes it desirable on data compression tasks. However, NML is hardly used in prediction tasks because it cannot be calculated recursively, it is time-inconsistent across periods, and it defines a sequence

---

<sup>6</sup>The unusual notation “ $c_{t-1}^i(\sigma)$ ” for the weights of the prior distribution is to ease the comparison between consumption shares and probabilistic mass. In log-economies, they coincide (Section 3.2).

of unconditional probabilities that do not satisfy the chain-rule:  $\sum_{\sigma_t} p^{NML}(\sigma^{t-1}, \sigma_t) \neq p^{NML}(\sigma^{t-1})$ . Notably, NML does not uniquely define a set of conditional probabilities.

- **SNML**: Sequential Normalized Maximum Likelihood is the probability mixture that, in every period, prescribes using the model in  $\mathcal{P}$  that had the highest likelihood in the past. SNML was derived by Roos and Rissanen (2008) to obtain a recursive version of NML, and later applied to the problem of optimal portfolio allocation (Follow the Leader strategy, De Rooij et al., 2014; Massari, 2017). SNML's period  $t$  predictions coincide with the conditional probabilities that NML gives to  $\sigma_t$ , assuming that  $t$  is the final horizon:

$$\forall \sigma^t \in S^t, p^{SNML}(\sigma^t) = \prod_{\tau=1}^t p^{SNML}(\sigma_t |) \ ; \ p^{SNML}(\sigma_t |) = \frac{p^{NML}(\sigma^t)}{\sum_{\hat{\sigma}_t} p^{NML}(\sigma^{t-1}, \hat{\sigma}_t)} \quad (3)$$

SNML is consistent and it can be calculated recursively. However, unlike NML, SNML's worst-case regret is unbounded even if the cardinality of  $\mathcal{P}$  is finite.

Lemma 1 highlights a first similarity between members of price probabilities and NML and SNML mixture models. It shows that the relation between  $p^{NNL}$  and  $p^{SNNL}$  mimics that between NML and SNML:  $p^{SNNL}$ 's period  $t$  predictions coincide with the conditional probabilities that  $p^{NNL}$  gives to  $\sigma_t$ , assuming that  $t$  is the final horizon:

**Lemma 1.** *In an economy that satisfies **A0-A4**,*

$$\forall \sigma^t, p^{SNNL}(\sigma_t |) = \frac{p^{NNL}(\sigma^t)}{\sum_{\hat{\sigma}_t} p^{NNL}(\sigma^{t-1}, \hat{\sigma}_t)}.$$

### 3 Price probabilities in identical CRRA economies

If all traders have an identical CRRA utility function, members of price probabilities can be analytically characterized. This setting is flexible enough to show that BMA, NML, and SNML belong to price probabilities (Corollaries 1 and 2). In what follows, I use the notation:

**Definition 4.**  $p_\gamma^{NNL}$  and  $p_\gamma^{SNNL}$  denote the  $p^{NNL}$  and the  $p^{SNNL}$  probabilities obtained from an economy that satisfies **A0-A4** and in which all traders have an identical CRRA utility function with parameter  $\gamma$ , for all  $i \in \mathcal{I}, u^i(c) = (c^{1-\gamma} - 1) / (1 - \gamma)$ .<sup>7</sup>

---

<sup>7</sup>As is customary, I define  $\ln 0 = -\infty$ . Moreover, I use  $\gamma = 0$  as a short notation for the limit equilibrium quantities of an identical CRRA economy in which  $\gamma \rightarrow 0$  after the equilibrium quantities are calculated.

### 3.1 NNL in identical CRRA economies: $p_\gamma^{NNL}$

**Proposition 2.** *Given beliefs set  $\mathcal{P}$ , prior  $C_0$ , and parameter  $\gamma$ ,  $p_\gamma^{NNL}$  is given by:*

$$\forall \sigma^t \in S^t, \quad p_\gamma^{NNL}(\sigma^t) = \frac{\left(\sum_{i \in \mathcal{I}} p^i(\sigma^t)^{\frac{1}{\gamma}} c_0^i\right)^\gamma}{\sum_{\hat{\sigma}^t \in S^t} \left(\sum_{i \in \mathcal{I}} p^i(\hat{\sigma}^t)^{\frac{1}{\gamma}} c_0^i\right)^\gamma}. \quad (4)$$

Equation 4 shows that  $p_\gamma^{NNL}$  coincides with the normalized  $1/\gamma$  norm of the likelihoods of members of  $\mathcal{P}$  according to the measure  $C_0$ . Because BMA and NML are the normalized  $L_1$  and  $L_\infty$  norms, respectively, they both belong to price probabilities.

**Corollary 1.** *BMA and NML belong to price probabilities. Specifically,*

$$\begin{aligned} i) \quad & p_{\gamma=1}^{NNL}(\sigma^t) = p^{BMA}(\sigma^t); \\ ii) \quad & p_{\gamma=0}^{NNL}(\sigma^t) = p^{NML}(\sigma^t). \end{aligned}$$

*Proof.* *i)* Notice that if  $\gamma = 1$ , the denominator of Equation (4) equals 1, and compare Equation (4) with Equation (1).

*ii)* Notice that  $\lim_{\gamma \rightarrow 0} \left(\sum_{i \in \mathcal{I}} p^i(\sigma^t)^{\frac{1}{\gamma}} c_0^i\right)^\gamma = \|p^i(\sigma^t)\|_\infty$ : the sup norm; and compare Equation (4) with Equation (2).  $\square$

Taking Bayes' rule as a reference point, the effect of  $\gamma$  on  $p_\gamma^{NNL}$  is qualitatively as follows. In a log-economy ( $\gamma = 1$ )  $p_\gamma^{NNL}$  coincides with BMA and the interaction between prior information ( $C_0$ ) and empirical evidence ( $\sigma^t$ ) is regulated by Bayes' rule. For  $\gamma = 0$ ,  $p_\gamma^{NNL}$  coincides with NML (i.e., it is the optimal probability with respect to worst-case log-regret). Given the explosive nature of the log-likelihood on sequences whose frequencies are close to the boundary of the simplex, NML ignores the information of the prior ( $C_0$  plays no role), and it assigns a relatively higher probability to sequences whose frequency lies close to the boundary of the simplex. For values of  $\gamma \neq 1$ ,  $p_\gamma^{NNL}$  represents a compromise between the minimum log-regret approach behind NML and the Bayesian attempt to make the most out of the information in the prior. Compared with a BMA with the same Uniform prior on  $\mathcal{P}$ ,  $p_\gamma^{NNL}$  with  $\gamma < (>)1$  assigns more probability to those sequences whose frequency lies close to the boundary (center) of the simplex and penalizes those sequences whose frequency lies close to the center (boundary) of the simplex.

### 3.2 SNML in identical CRRA economies: $p_\gamma^{SNNL}$

**Proposition 3.** *Given beliefs set  $\mathcal{P}$ , prior  $C_0$ , and parameter  $\gamma$ ,  $p_\gamma^{SNNL}$  is given by:*

$$\forall \sigma^t \in S^t, \quad p_\gamma^{SNNL}(\sigma_t) = \frac{\left( \sum_{i \in \mathcal{I}} p^i(\sigma_t) \right)^{\frac{1}{\gamma}} c_{\gamma, t-1}^i(\sigma)}{\sum_{\hat{\sigma}_t \in S} \left( \sum_{i \in \mathcal{I}} p^i(\hat{\sigma}_t) \right)^{\frac{1}{\gamma}} c_{\gamma, t-1}^i(\sigma)}; \quad (5)$$

$$\text{with } c_{\gamma, t-1}^i(\sigma) \stackrel{\text{by Eq.10}}{=} \frac{p^i(\sigma^{t-1})^{\frac{1}{\gamma}} c_0^i}{\sum_{i \in \mathcal{I}} p^i(\sigma^{t-1})^{\frac{1}{\gamma}} c_0^i}.$$

By construction,  $\sum_{i \in \mathcal{I}} c_{\gamma, t-1}^i(\sigma) = 1$ , thus each  $c_{\gamma, t-1}^i(\sigma)$  can be interpreted as being the weight attached to model  $p^i$  by a prior distribution  $C_{\gamma, t-1}(\sigma)$ . Equation 5 shows that  $p_\gamma^{SNNL}$  coincides with the sequentially normalized  $1/\gamma$  norm of the next period probabilities members of  $\mathcal{P}$  according to the distribution  $C_{\gamma, t-1}(\sigma)$ . It is easy to verify that SNML belongs to price probabilities.

**Corollary 2.** *SNML belongs to price probabilities. Specifically,*

$$p_{\gamma=0}^{SNNL}(\sigma^t) = p^{SNML}(\sigma^t).$$

*Proof.*

$$\forall \sigma^{t-1}, \quad p_0^{SNNL}(\sigma_t) \stackrel{\text{Lem.1}}{=} \frac{p_0^{NNL}(\sigma^t)}{\sum_{\hat{\sigma}_t} p_0^{NNL}(\sigma^{t-1}, \hat{\sigma}_t)} \stackrel{\text{Cor.1}}{=} \frac{p^{NNL}(\sigma^t)}{\sum_{\hat{\sigma}_t} p^{NNL}(\sigma^{t-1}, \hat{\sigma}_t)} \stackrel{\text{Eq.3}}{=} p^{SNML}(\sigma_t). \quad \square$$

The  $p_\gamma^{SNNL}$  prediction scheme is closely related to other robust prediction schemes as the  $C_{\gamma, t-1}(\sigma)$  prior is the core of many known algorithms.  $C_{\gamma, t-1}^i(\sigma)$  is a special case of the ‘‘Generalized Bayes’ rule’’ introduced by Vovk (1990). The gamma parameter is often called the learning rate as it determines the convergence rate of the posterior. The choice of this parameter plays a fundamental role in both the HEDGE algorithm (Freund and Schapire, 1997) and the Safe Bayesian approach (Grünwald, 2012).  $p_\gamma^{SNNL}$  differs from these algorithms because instead of relying on the generalized prior to mix the probabilities in the support (or the actions) it directly relies on a generalized posterior that treats equally past and future performance. This symmetry of treatment comes with the need to normalize the predictive generalized distribution into a probability. This normalization makes  $p_\gamma^{SNNL}$  prediction non-convex in the sense that its prediction might fall out of the convex combination of models in the support (see Section 5). While the (generalized) prior evolution of the cited algorithm can be directly compared to standard Bayes and values of  $\gamma < (>)1$  mapped into predictions that over(under)-react to in-

formation with respect to Bayes' rule (Epstein et al., 2008), this is no longer possible for SNNL, which can deliver non-convex predictions (Section 5).<sup>8</sup> The algorithms mentioned above utilize values of  $\gamma \geq 1$ , indicating that under-reacting to information is the way to robustify standard Bayes. Similarly, I find that  $p_\gamma^{SNNL}$  can outperform Bayes' only for values of gamma greater than 1, and only in misspecified learning problems in which the Bayesian posterior does not eventually concentrate on a unique parameter.

## 4 Asymptotic performance of price probabilities

### 4.1 The criterion

In this section, I introduce the efficiency criterion I use to characterize the performance price probabilities. Following an established tradition across fields, the criterion I propose is based on *prequential likelihood ratios* (Dawid, 1984; Ploberger and Phillips, 2003).

**Definition 6.** Let  $p^{BMA}(\sigma^t) := p^{BMA}(\sigma^t|\mathcal{P})$  be the likelihood of a BMA with a full-support prior on  $\mathcal{P}$ ,

- a probability mixture,  $p$ , with belief set,  $\mathcal{P}$ , is  **$\mathcal{P}$ -efficient** if

$$\forall P \in \mathcal{P}, \ln \frac{p^{BMA}(\sigma^t)}{p(\sigma^t)} \underset{P\text{-a.s.}}{\succ} 1;$$

- a probability mixture,  $p$ , with belief set,  $\mathcal{P}$ , is **universal-efficient** if

---

<sup>8</sup> Following Epstein et al. (2008) approach,

**Definition 5.** A prediction rule (NB) **under-reacts** to information with respect to Bayes (B) if for every non-degenerate distribution on the support  $C^{NB}(\sigma^t)$  we have that

$$C^{NB}(\sigma^t) = C^B(\sigma^t) \Rightarrow \forall \sigma_{t+1}, C^{NB}(\theta|\sigma_{t+1}\sigma^t) \in \text{Conv}(C^B(\theta|\sigma^t), C^B(\theta|\sigma_{t+1}\sigma^t)).$$

A prediction rule (NB) **over-reacts** to information with respect to Bayes (B) if for every non-degenerate distribution on the support  $C^{NB}(\sigma^t)$  we have that

$$C^{NB}(\sigma^t) = C^B(\sigma^t) \Rightarrow \forall \sigma_{t+1}, C^B(\theta|\sigma_{t+1}\sigma^t) \in \text{Conv}(C^{NB}(\theta|\sigma^t), C^{NB}(\theta|\sigma_{t+1}\sigma^t)).$$

For intuition of the effect of  $\gamma$  on the evolution of  $C_{\gamma, t-1}^i(\sigma)$ , suppose that  $S := \{a, b\}$  and draws are believed i.i.d., so that all probabilities in  $\mathcal{P}$  are Bernoulli with, for all  $i \in \mathcal{I}$ ,  $p^i(a_t) = i$  in every period. Letting  $t_a$  and  $t_b$  representing the number of  $a$ ,  $b$  observations until period  $t-1$ , respectively, we obtain:

$$\forall i \in \mathcal{I}, c_{\gamma, t-1}^i(\sigma) = \frac{p^i(\sigma^t)^{\frac{1}{\gamma}} c_0^i}{\sum_{j \in \mathcal{I}} p^j(\sigma^t)^{\frac{1}{\gamma}} c_0^j} = \frac{i^{\frac{t_a}{\gamma}} (1-i)^{\frac{t_b}{\gamma}}}{\sum_{j \in \mathcal{I}} j^{\frac{t_a}{\gamma}} (1-j)^{\frac{t_b}{\gamma}}}.$$

So, if  $\gamma < 1$ , the model overreacts to empirical evidence: e.g.,  $\gamma = \frac{1}{2}$  is equivalent to updating using Bayes' rule "counting every past realization twice." If  $\gamma > 1$ , the model underreacts to empirical evidence: e.g.,  $\gamma = 2$  is equivalent to updating using Bayes' rule "counting every past realization as half."

$$\forall \sigma \in S^\infty, \ln \frac{p^{BMA}(\sigma^t)}{p(\sigma^t)} \asymp 1;$$

- a probability mixture  $p$  with belief set  $\mathcal{P}$  is **super-efficient** if is  $\mathcal{P}$ -efficient and

$$\left\{ \begin{array}{l} \forall \sigma \in S^\infty, \limsup \ln \frac{p^{BMA}(\sigma^t)}{p(\sigma^t)} < +\infty \\ \exists \hat{P} : \quad \lim \ln \frac{p^{BMA}(\sigma^t)}{p(\sigma^t)} =_{\hat{P}\text{-a.s.}} -\infty \end{array} \right. ;$$

- a probability mixture,  $p$ , with beliefs set,  $\mathcal{P}$ , is **sub-efficient** if is  $\mathcal{P}$ -efficient and

$$\left\{ \begin{array}{l} \forall \sigma \in S^\infty, \liminf \ln \frac{p^{BMA}(\sigma^t)}{p(\sigma^t)} > -\infty \\ \exists \hat{P} : \quad \lim \ln \frac{p^{BMA}(\sigma^t)}{p(\sigma^t)} =_{\hat{P}\text{-a.s.}} +\infty \end{array} \right. ;$$

where the notation  $f(x) \asymp g(x)$  abbreviates  $\limsup f(x)/g(x) < +\infty$  and  $\liminf f(x)/g(x) > -\infty$ .

So,  $p$ , is  $\mathcal{P}$ -efficient if it is as good as Bayes' when the learning problem is well-specified. The rest of the definition characterizes the relative performance of  $p$  and  $p^{BMA}$  in misspecified setting. I say that  $p$  is universal-efficient if it is as accurate as Bayes' in every sequence. A probability mixture  $p$  is super-efficient if it does at least as well as Bayes' in every sequence and there are probabilities  $\hat{P}$  for which it outperforms Bayes'  $\hat{P}$ -a.s. — that is, if it guarantees to do at least as well as using Bayes' rule and there are cases (when the model is misspecified) in which it does infinitely better. A probability mixture,  $p$ , is sub-efficient if there are no sequences in which it outperforms Bayes', and there are cases of misspecification in which it is infinitely worse.

## 4.2 Discussion

Objectively comparing different learning rules is not trivial. My criterion has been chosen to satisfy the following desiderata:

**D1:** The comparison must be performed in every sequence because in most cases in which we need to make predictions, we do not know the true probability. If we knew the true probability, we would not need to find the best mixture of members of  $\mathcal{P}$ .

**D2:** The benchmark must be appropriate. The BMA is chosen because it is widely known, utilized, and has a sound axiomatic foundation.<sup>9</sup>

---

<sup>9</sup>Moreover, BMA has finite worst-case log-regret (if  $|\mathcal{P}|$  is finite). Thus a likelihood comparison against BMA is also a way to verify if a probability mixture possesses this fundamental property.

**D3:** The probability mixture,  $p$ , and BMA must use the same support and empirical evidence to be comparable. Otherwise, the comparison would be about the quality of the information, rather than the way to use it.

**D4:** The criterion must be asymptotic to eliminate the small sample effect of the priors. Furthermore, small sample accuracy criteria should be avoided because they are potentially misleading (Massari, 2013).<sup>10</sup>

The possibility of super-efficient mixture models is, in my experience, often received with skepticism. Here are some responses to concerns raised at conferences and by referees.

- *The criterion is weak. For example, it would be satisfied by using Bayes’ rule in an enlarged prior support.*

This observation is correct. However, it violates **D3**: a different prior support implies different information on the set of possible models. Changing the support alters the intrinsic nature of the learning problem. What we want to achieve is to use the same information more efficiently, not show that a larger prior support can explain more sequences. A super-efficient mixture “beats” Bayes’ using the same information.

- *Price probabilities are Bayesian in disguise.*

This statement is false. In Section 5, I prove that under **A5**, unless all agents in the generating economy have log-utility,  $p^{NNL}$  and  $p^{SNNL}$  are not Bayesian because they might make predictions that are not convex combinations of models in  $\mathcal{P}$ .

- *Bayesian updating is almost a tautology if we think of probabilities as empirical frequencies. Why should we abandon it?*

Bayes rule is not defined when updating from sets of measure 0. When the model is misspecified, the Bayesian measure attaches 0 probability to all tail events that occur  $P$ -a.s., thus its application is far from natural. In these cases, and if our ultimate goal is making predictions, it seems natural to compare Bayes’ rule against alternative rules on the basis of accuracy, rather than internal consistency. As Dawid (1982) eloquently said: “If a subjective distribution  $P$  attaches probability zero to a non-ignorable event, and if this event happens, then  $P$  must be treated with suspicion, and modified or replaced.”

- *The super-efficiency result must be incorrect because it is in contrast with Wald (1947)’s Complete Class Theorem (CCT).*

My result is orthogonal to the CCT. CCT is a result about the optimality of the Bayesian procedure for decision in a static setting. Therefore, CCT is moot about the efficiency of

---

<sup>10</sup>Massari (2013) shows that given two probabilities  $\{p^a\}, \{p^b\}$ , it is not true that if  $p^a$ ’s next-period predictions are infinitely often more accurate than  $p^b$  and never less accurate, then  $p^a$ ’s predictions are more accurate than  $p^b$  on long sequences.

Bayes' rule to incorporate empirical evidence in a prior distribution. More generally, there is no tension between my super-efficiency result and the known optimality of Bayesian decision criteria. If the model is well-specified, all members of price probability are asymptotically indistinguishable from Bayes. If the model is misspecified, while Bayesian predictions are guaranteed to be exactly as accurate as the most accurate model in the support (Berk, 1966),  $p^{SNNL}$  can deliver predictions that are even more accurate than that.

- *Where are the tricks/hidden assumptions?*

The crucial assumption needed to ensure super-efficiency is the non-convex prior support. In Proposition 4, I show that super-efficiency occurs only on those sequences on which the Bayesian posterior does not concentrate fast enough on a unique model. By concavity of the log-likelihood function, this event can happen only if the support contains two orthogonal models with similar likelihood, but no intermediate model (i.e. if the prior support is not convex).<sup>11</sup>

- *These results are practically irrelevant.*

Regarding relevance, the super-efficiency properties of the parameters I identify apply verbatim to all standard prediction problems. I choose to work in a parametric setting with finitely many parameters only for ease of exposition and to maintain the state price interpretation. For applications of similar results, I refer the reader to Grünwald and van Ommen (2014), which shows that underreacting rules outperform the BMA with prior on a finite set of linear regression models. Furthermore, consistent with our results, Timmermann (2006) brings evidence that forecasting combinations of statistical models with weights evolving slower than BMA outperform BMA in many cases of misspecification. Avramov (2002); Cremers (2002) have found that BMA guarantees better out-of-sample prediction than that obtained using model selection criteria — which are qualitatively equivalent to  $p_0^{SNNL}$  — in the context of forecasting U.S. stock market indices.

- *Asymptotic criteria are not relevant for investment decisions on a finite horizon (Samuelson, 1971, 1979).*

Samuelson's critique is based on the argument that, given beliefs and prices, different preferences determine different optimal investment strategies. His critique does not apply here because preferences play no role in my accuracy criterion.

---

<sup>11</sup>To convexify the prior support is hardly a solution. First, to convexify the prior support violates **D3**. Second, it is often difficult to do in a non-parametric context. Last, increasing the dimensionality of the prior support is undesirable as it reduces the learning rate (Schwarz, 1978; Clarke and Barron, 1990).

### 4.3 Asymptotic performance of $p^{SNNL}$

**Theorem 1.**  $p^{SNNL}$  is  $\mathcal{P}$ -efficient in any economy that satisfies **A0-A5**. Furthermore,

i)  $p_{\gamma^i > 1}^{SNNL}$  is super-efficient;

ii)  $p_{\gamma^i = 1}^{SNNL}$  is universal-efficient;

iii)  $p_{\gamma^i < 1}^{SNNL}$  is sub-efficient;

where  $p_{\gamma^i > 1}^{SNNL}$ ,  $p_{\gamma^i = 1}^{SNNL}$  and  $p_{\gamma^i < 1}^{SNNL}$  denote the  $p^{SNNL}$  probabilities obtained from an economy that satisfies A2-A4 and in which all traders have CRRA utility function with parameter  $\gamma^i > 1$ ,  $\gamma^i = 1$ , and  $\gamma^i < 1$ , respectively.

So,  $p^{SNNL}$ , is as good as Bayes' when the learning problem is well-specified. Furthermore, Theorem 1 specifies how risk attitudes of agents in the generating economy affects the accuracy of  $p^{SNNL}$  in misspecified learning problems.

**Intuition:**

-  $p^{SNNL}$  is  $\mathcal{P}$ -efficient irrespective of preferences because when there is an agent who knows the truth,  $P$ , he dominates  $P$ -a.s.. Furthermore, inspection of the FOC shows that his consumption-share converges to one at an exponential rate, which guarantees that  $p^{SNNL} \rightarrow P$  at an exponential rate (i.e.  $p^{SNNL}$  merges to  $P$ ).

-  $p_{\gamma^i = 1}^{SNNL}$  is universal-efficient because it coincides with Bayesian updating.

-  $p_{\gamma^i > (<) 1}^{SNNL}$  is super-efficient (sub-efficient). Let us focus on the (more interesting) case of  $\gamma^i > 1$  and make use of the economy generating  $p_{\gamma^i > 1}^{SNNL}$  to gain intuition. From the proof of Theorem 1, we see that

$$\begin{aligned} \ln \frac{p^{BMA}(\sigma^t)}{p^{SNNL}(\sigma^t)} &= \ln \frac{\beta^t p^{BMA}(\sigma^t)}{q(\sigma^t)} + \sum_{\tau=1}^t \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau |) \right) \\ &\stackrel{\text{by Massari (2017) Corollary 1}}{=} O(1) + \sum_{\tau=1}^t \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau |) \right) \end{aligned}$$

So,  $p_{\gamma^i > 1}^{SNNL}$  is super-efficient if there are paths on which  $\sum_{\tau=1}^t \ln (\sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau |) / \beta) \rightarrow -\infty$  and no path on which  $\sum_{\tau=1}^t \ln (\sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau |) / \beta) \rightarrow +\infty$ . In economic terms, for all  $(t-1, \sigma)$ ,  $\sum_{\hat{\sigma}_t} q_t(\hat{\sigma}_t |)$  is the cost of moving a unit of consumption for sure a period ahead, i.e., the reciprocal of the risk-free rate. The effect of risk attitudes on the risk-free rate follows this intuition. In every period most agents subjectively believe that assets are mispriced and trade for speculative reasons because they disagree. When agents have log utility ( $\gamma = 1$ ), prices (and thus interest rates) do not affect optimal saving choices (the substitution effect equals the income effect) and the reciprocal of the risk-free rate is given by the discount factor: for all  $(t, \sigma)$ ,  $\beta = \sum_{\hat{\sigma}_t} q_t(\hat{\sigma}_t |)$ . However, if  $\gamma > 1$ , the substitution effect is stronger than the income effect; so, agents opti-

mally invest less than if they had log utility, and a higher risk-free rate arise  $\sum_{\tilde{\sigma}_\tau} q_\tau(\tilde{\sigma}_\tau) < \beta$  for all  $(t, \sigma)$  in which the consumption-share is not degenerate. When the consumption share distribution is non-degenerate a positive fraction of periods, this effect cumulates to  $-\infty$ .

The argument above suggests that non-concentration of the Bayesian prior plays a special role in determining the (sub)super-efficient condition. This is indeed the case:

**Proposition 4.**

*i) In every path in which  $p^{BMA}$ 's posterior does not concentrate on a unique model,*

$$\lim \ln \frac{p_{\gamma^i > 1}^{SNNL}(\sigma^t)}{p^{BMA}(\sigma^t)} = +\infty \quad \text{and} \quad \lim \ln \frac{p_{\gamma^i < 1}^{SNNL}(\sigma^t)}{p^{BMA}(\sigma^t)} = -\infty.$$

*ii) In every path in which  $p^{BMA}$ 's posterior concentrates exponentially fast on a unique model,*

$$\ln \frac{p_{\gamma^i > 1}^{SNNL}(\sigma^t)}{p^{BMA}(\sigma^t)} \asymp 1.$$

Proposition 4 tells us that  $\gamma^i < 1$  is detrimental while  $\gamma^i > 1$  is desirable in cases in which the Bayesian prior does not concentrate on a unique model in the support. If the Bayesian posterior does not concentrate, then the true model must be somewhere in the middle because the data supports more than one model. In this case, the generalized prior, by giving more (less) weight to empirical evidence produces forecasts that are closer (further) to the truth than the Bayesian.

Known asymptotic results in Bayesian statistics<sup>12</sup> make Proposition 4 useful in recognizing the probabilities that determine the (sub)super-efficiency condition.<sup>13</sup> For economically relevant examples in which concentration of the Bayesian posterior does not occur we refer the reader to Beker and Espino (2011).

Next, we make use of the analytical form of  $p_\gamma^{SNNL}$  to present three cases showing that  $p_\gamma^{SNNL}$  can significantly outperform but never underperform BMA if  $\gamma > 1$ ; whereas  $p_\gamma^{SNNL}$  can significantly underperform but never outperform BMA with if  $\gamma < 1$ . The generality of the example rests in the choice of the sequences in Cases 1 and 2. Case 1 utilizes the sequence on which the Bayesian posterior concentrates the least; case 2 utilizes the sequence in which the convergence rate of the Bayesian posterior is the fastest. Case 3 illustrates Proposition 3.

**Example 1:** Let  $S = \{a, b\}$ ,  $C_0 = [.5 .5]$ , and  $\mathcal{P} = \{p^1, p^2\}$ , with  $p^1, p^2$  i.i.d. measures:

<sup>12</sup>If  $|\mathcal{P}| < \infty$ , in most standard settings (if members of  $\mathcal{P}$  are either i.i.d. or conditionally iid), the Bayesian posterior does not concentrate if and only if there is more than one model with the same K-L divergence. Otherwise, it concentrates exponentially fast.

<sup>13</sup>Proposition 4 enormously simplifies this task. Even if traders' beliefs and the true measure are iid,  $p^{SNNL}$ 's dynamic is path-dependent.

$\forall t, p^1(a_t) = 1/3 = p^2(b_t)$ . Consider three  $p_j^{SNNL}$ s with parameters  $\gamma_0 = 0$ ,  $\gamma_1 = 1$  and  $\gamma_2 = 2$ , respectively.

**Case a:** The true probability,  $P$ , is degenerate. It gives probability 1 to the alternating sequence  $\{a, b, a, \dots\}$ . This is the most favourable case for probability mixtures with slow concentration rate of the prior. Because both models are equally (in)accurate, the best predictor is the one giving equal weight to  $p^1$  and  $p^2$  in every period (as  $C_0$  does). By Equation 5:

$$\begin{aligned} p_0^{SNNL}(a_t|) &= \frac{p^{NML}(\sigma^t)}{\sum_{\hat{\sigma}_t} p^{NML}(\sigma^{t-1}, \hat{\sigma}_t)} = \begin{cases} \frac{1}{2} & \text{if } t \text{ odd} \\ \frac{2}{3} & \text{if } t \text{ even} \end{cases} \\ p_1^{SNNL}(a_t|) &= \sum_{i \in \mathcal{I}} p^i(a) \frac{p^i(\sigma^{t-1}) c_0^i}{\sum_{i \in \mathcal{I}} p^i(\sigma^{t-1}) c_0^i} = \begin{cases} \frac{1}{2} & \text{if } t \text{ odd} \\ \frac{5}{9} & \text{if } t \text{ even} \end{cases} \\ p_2^{SNNL}(a_t|) &= \frac{\left( \sum_{i \in \mathcal{I}} p^i(a)^{\frac{1}{2}} \frac{p^i(\sigma^{t-1})^{\frac{1}{2}} c_0^i}{\sum_{i \in \mathcal{I}} p^i(\sigma^{t-1})^{\frac{1}{2}} c_0^i} \right)^2}{\sum_{\hat{\sigma}_t} \left( \sum_{i \in \mathcal{I}} p^i(\hat{\sigma}_t)^{\frac{1}{2}} \frac{p^i(\sigma^{t-1})^{\frac{1}{2}} c_0^i}{\sum_{i \in \mathcal{I}} p^i(\sigma^{t-1})^{\frac{1}{2}} c_0^i} \right)^2} = \begin{cases} \frac{1}{2} & \text{if } t \text{ odd} \\ \frac{9}{17} & \text{if } t \text{ even} \end{cases} \end{aligned}$$

$$\text{Thus, on } \{a, b, a, \dots\}, \forall \mu \in (0, 1), \begin{cases} \frac{p_\mu^{BMA}(\sigma^t)}{p_0^{SNNL}(\sigma^t)} = \frac{\mu(\frac{1}{3})^{\frac{t}{2}}(\frac{2}{3})^{\frac{t}{2}} + (1-\mu)(\frac{2}{3})^{\frac{t}{2}}(\frac{1}{3})^{\frac{t}{2}}}{(\frac{1}{2})^{\frac{t}{2}}(\frac{1}{3})^{\frac{t}{2}}} \rightarrow +\infty \\ \frac{p_\mu^{BMA}(\sigma^t)}{p_1^{SNNL}(\sigma^t)} = \frac{\mu(\frac{1}{3})^{\frac{t}{2}}(\frac{2}{3})^{\frac{t}{2}} + (1-\mu)(\frac{2}{3})^{\frac{t}{2}}(\frac{1}{3})^{\frac{t}{2}}}{(\frac{1}{2})^{\frac{t}{2}}(\frac{4}{9})^{\frac{t}{2}}} = O(1) \\ \frac{p_\mu^{BMA}(\sigma^t)}{p_2^{SNNL}(\sigma^t)} = \frac{\mu(\frac{1}{3})^{\frac{t}{2}}(\frac{2}{3})^{\frac{t}{2}} + (1-\mu)(\frac{2}{3})^{\frac{t}{2}}(\frac{1}{3})^{\frac{t}{2}}}{(\frac{1}{2})^{\frac{t}{2}}(\frac{9}{17})^{\frac{t}{2}}} \rightarrow 0 \end{cases} .$$

Case *a* shows that,  $p_2^{SNNL}$  produces predictions that are closer to the empirical frequency than  $p_1^{SNNL}$  and  $p_0^{SNNL}$  and thus more accurate.

**Case b:** The true probability,  $P$ , is degenerate. It gives probability 1 to the sequence  $\{a, a, a, \dots\}$ . Because  $p^2$  is clearly the best model, case *b* is the most favourable sequence for probability mixtures that overreact to empirical evidence.

$$\text{Thus, on } \{a, a, a, \dots\}, \forall \mu \in (0, 1), \begin{cases} \frac{p_\mu^{BMA}(\sigma^t)}{p_0^{SNNL}(\sigma^t)} = \frac{\mu(\frac{2}{3})^t + (1-\mu)(\frac{1}{3})^t}{\frac{1}{2}(\frac{2}{3})^{t-1}} = O(1) \\ \frac{p_\mu^{BMA}(\sigma^t)}{p_1^{SNNL}(\sigma^t)} = \frac{\mu(\frac{2}{3})^t + (1-\mu)(\frac{1}{3})^t}{\frac{1}{2}(\frac{2}{3})^t + \frac{1}{2}(\frac{1}{3})^t} = O(1) \\ \frac{p_\mu^{BMA}(\sigma^t)}{p_2^{SNNL}(\sigma^t)} = \frac{\mu(\frac{2}{3})^t + (1-\mu)(\frac{1}{3})^t}{\left(\frac{1}{2}(\frac{2}{3})^{\frac{t}{\gamma}} + \frac{1}{2}(\frac{1}{3})^{\frac{t}{\gamma}}\right)^\gamma * e^{-\sum_{\tau=1}^t \ln(q(a) + q(b))}} = O(1) \end{cases} .^{14}$$

Case *b* shows that, although  $p_0^{SNNL}$  only takes one observation to correctly identify the most accurate model,  $p_0^{SNNL}$  and  $p^{BMA}$  converge to  $p^2$  fast enough not to compromise their asymptotic likelihood performance.

---

<sup>14</sup>By Proposition 4, *ii*)

**Case c:** Draws are i.i.d.; for all  $t$ , the true probability of  $a$  is  $P(a_t) = .5$ . Because  $p^1$  and  $p^2$  are equally (in)accurate, the Bayesian posterior does not concentrate (Massari, 2013),

$$\text{and Proposition 4 implies, } \begin{cases} \frac{P^{BMA}(\sigma^t)}{p_0^{SNNL}(\sigma^t)} \rightarrow^{P\text{-a.s.}} +\infty \\ \frac{P^{BMA}(\sigma^t)}{p_1^{SNNL}(\sigma^t)} \underset{P\text{-a.s.}}{\asymp} 1 \\ \frac{P^{BMA}(\sigma^t)}{p_2^{SNNL}(\sigma^t)} \rightarrow^{P\text{-a.s.}} 0 \end{cases} .$$

**Remark:** The relationship between  $p^{NNL}$  and  $p^{SNNL}$  mimics that between NML and SNML. Each next-period forecast of the  $p^{SNNL}$  corresponds to the last period conditional distribution of the corresponding  $p^{NNL}$  probability. Thus,  $p^{SNNL}$  can be thought of as a compromise to make  $p^{NNL}$  recursive. This interpretation makes the super-efficiency part of Theorem 1 even more surprising. It shows that a forecaster can perform significantly better by using a recursive method even when he knows the final horizon of his prediction task. Because a recursive method does not use the length of the sequence he is forecasting as an input, this result illustrates a case in which ignoring some relevant information increases prediction accuracy.

#### 4.4 Asymptotic performance of $p^{NNL}$

**Theorem 2.**  $p^{NNL}$  is universal-efficient in any economy that satisfies **A0-A4**.

Theorem 2 tells us that, although non-convex and time-inconsistent,  $p^{NNL}$  performs qualitatively as well as BMA in terms of likelihood in any sequence (and thus  $P$ -a.s.). If we are only concerned about accuracy, there is no reason to consider non-convexity or time-consistency to be a fundamental property of rational forecasts.

**Intuition:** universal efficiency of  $p^{NNL}$  implies that the prediction of  $p^{NNL}$  and those of  $p^{BMA}$  must be asymptotically equivalent. For intuition, consider Equation 16 in the proof of Theorem 2 and the unconditional Bayesian probabilities from a full support prior  $C_0$ :

$$p^{NNL}(\sigma^t) \propto \frac{\sum_{i \in \mathcal{I}} p^i(\sigma^t) \frac{1}{u'_i(c_0^i)}}{\sum_{j \in \mathcal{I}} \frac{1}{u'_j(c^j(\sigma^t))}}$$

$$p^{BMA}(\sigma^t) = \sum_{i \in \mathcal{I}} p^i(\sigma^t) c_0^i.$$

If the term  $\sum_{j \in \mathcal{I}} 1/u'_j(c^j(\sigma^t))$  were time and state-independent, the proportionality sign would incorporate it with  $1/u'_j(c^j(\sigma^t))$  into a prior so that  $p^{NNL}$  would map into a  $p^{BMA}$  with different prior. However, the time-dependence of  $\sum_{j \in \mathcal{I}} 1/u'_j(c^j(\sigma^t))$  makes  $p^{NNL}$  time-inconsistent (to act as if it had a prior distribution that depends on the predictions horizon), while its dependence on states makes  $p^{NNL}$  non-convex. Asymptotically,  $p^{NNL}$  and  $p^{BMA}$  are equivalent because

the time and state dependence of this term becomes negligible since differences on prior distributions have negligible effect compared to that of models' likelihoods.

Theorem 2 does not justify the systematic use of time-inconsistent probabilities in every decision problem. Time-inconsistent members of  $\mathcal{M}(\mathcal{P})$  are undesirable in many economic settings because they do not rule out dynamic arbitrage (Lehrer and Teper, 2016).

**Example 2:** Let  $S = \{a, b\}$ ,  $C_0 = [.5 \ .5]$ , and  $\mathcal{P} = \{p^1, p^2\}$ , with  $p^1, p^2$  i.i.d. measures:  $\forall t, p^1(a_t) = 1/3 = p^2(b_t)$ . It can be easily calculated that  $p_0^{NNL}(\sigma^t) = \max_i p^i(\sigma^t) / \sum_{\hat{\sigma}^t} \max_i p^i(\hat{\sigma}^t)$  attaches the following three of unconditional probabilities. Notably, these unconditional probabilities cannot be reduced to a unique sequence of conditional probabilities because they are time-inconsistent.

So, a risk-neutral agent with  $p_0^{NNL}$  beliefs who does not discount the future is at time-zero indifferent between:

- \$1/3 and a lottery, L1, that pays \$1 if  $\{a, a\}$  realizes, \$0 otherwise;
- \$2/10 and a lottery, L2, that pays \$1 if  $\{a, a, a\}$  realizes, \$0 otherwise;
- \$1/10 and a lottery, L3, that pays \$1 if  $\{a, a, b\}$  realizes, \$0 otherwise.

Selling L1 to him for \$1/3 and buying from him L2 and L3 for a total of \$3/10 constitutes an arbitrage: if  $\{a, a\}$  does not realize, I make a profit  $1/3 - 3/10 > 0$ . If  $\{a, a\}$  does realize, I make the same profit because I can use the market to pay the dollar I lose in  $t = 2$  with the dollar I win for sure in  $t=3$  (because either  $\{a, a, a\}$  or  $\{a, a, b\}$  will happen for sure).

However, this arbitrage opportunity can be generated only if  $p^{NNL}$  is used in markets that allow for both time-zero and sequential trading. An arbitrage can be constructed against an agent with  $p^{NNL}$  beliefs only because his beliefs correspond to a state of mind in which trade can only occur at time-zero. If he knew his final horizon  $t$  and he was given the possibility to trade sequentially, then he could use his  $p^{NNL}$  at  $t$  to construct a set of prequential conditional probabilities via backward induction to avoid arbitrages.

## 5 Price probabilities are not Bayesian

In this section, I show that members of price probability are generically not Bayesian because  $p^{NNL}$  and  $p^{SNNL}$  produce convex predictions if and only if all agents in the generating economy have log utility ( $\gamma = 1$ ).

**Definition 7.** A probability mixture  $p$  has **convex predictions** if in every application (i.e. for every state space  $S$ , for every prior support  $\mathcal{P}$ , prior distribution  $C_0$ , and path) its predictions belongs to  $Conv(\mathcal{P})$ .

The Bayesian predictive distribution has convex predictions because in every application the predictive distribution is a prior-weighted average of the models in the support. So, probability mixtures that have non-convex predictions are fundamentally non-Bayesian.  $\mathcal{P}$ -efficiency of probability mixture with non-convex predictions shows that making convex prediction is orthogonal to consistency, and thus not a fundamental property of rational learning.

**Proposition 5.**  $p^{SNNL}$  and  $p^{NNL}$  are convex if and only if all agents in the generating economy have log utility.

Example 3 shows that  $p_{\gamma}^{SNNL}$  is not convex for  $\gamma \neq 1$ .

**Example 3:** Let  $S = \{a, b, c\}$ ,  $C_0 = [.5 \ .5]$ , and  $\mathcal{P} = \{p^1, p^2\}$ , with  $p^1, p^2$  i.i.d. measures:  $\forall t, [p^1(a_t) \ p^1(b_t) \ p^1(c_t)] = [.2 \ .6 \ .2]$  and  $[p^2(a_t) \ p^2(b_t) \ p^2(c_t)] = [.2 \ .2 \ .6]$ , . Consider  $p_{\gamma}^{SNNL}$  obtained with  $\gamma_0 = 0$  and  $\gamma_1 = 1$  and  $\gamma_2 = 2$ , respectively.

$$\begin{aligned}
 p_{\gamma_0}^{SNNL}(a_1) &= \frac{\max_{i=1,2} p^i(a_1)}{\sum_{\sigma_1} \max_{i=1,2} p^i(\sigma_1)} = \frac{.2}{.2 + .6 + .6} = \frac{1}{7} \neq .2 && \Rightarrow p_{\gamma_0}^{SNNL} \notin Conv\{p^1, p^2\} \\
 p_{\gamma_1}^{SNNL}(a_1) &= \frac{p^1(a_1)c_0^1 + p^2(a_2)c_0^2}{\sum_{\sigma_1} p^i(\sigma_1)c_0^i} = .2 && \Rightarrow p_{\gamma_1}^{SNNL} \in Conv\{p^1, p^2\} \\
 p_{\gamma_2}^{SNNL}(a_1) &= \frac{(p^1(a_1) \cdot^5 c_0^1 + p^2(a_2) \cdot^5 c_0^2)^2}{\sum_{\sigma_1} (p^1(\sigma_1) \cdot^5 c_0^1 + p^2(\sigma_2) \cdot^5 c_0^2)^2} \\
 &= \frac{.2}{.2 + 2(\sqrt{.6 \cdot 5} + \sqrt{.2 \cdot 5})^2} \approx .21 \neq .2 && \Rightarrow p_{\gamma_2}^{SNNL} \notin Conv\{p^1, p^2\}
 \end{aligned}$$

## 6 Conclusion

I use the standard machinery of dynamic general equilibrium models to generate a rich class of probabilities and to discuss their properties. All members of price probability do as well as Bayes' when the learning problem is well-specified while some of them can significantly improve on Bayes' in misspecified settings. My result challenges the prevailing opinion that Bayes' rule is the only rational way to learn.

# A Appendix

## Proof of Lemma 1

*Proof.*

$$\begin{aligned} p^{SNNL}(\sigma_t) &=_{By\ Def.3} \frac{q(\sigma_t)}{\sum_{\hat{\sigma}_t} q(\hat{\sigma}_t)} = q(\sigma_t) * \frac{q(\sigma^{t-1})}{\sum_{\bar{\sigma}^t} q(\bar{\sigma}^t)} * \frac{\sum_{\bar{\sigma}^t} q(\bar{\sigma}^t)}{q(\sigma^{t-1})} * \frac{1}{\sum_{\hat{\sigma}_t} q(\hat{\sigma}_t)} \\ &= \frac{q(\sigma^t)}{\sum_{\bar{\sigma}^t} q(\bar{\sigma}^t)} * \frac{1}{\frac{\sum_{\hat{\sigma}_t} q(\sigma^{t-1}, \hat{\sigma}_t)}{\sum_{\bar{\sigma}^t} q(\bar{\sigma}^t)}} =_{By\ Def.2} \frac{p^{NNL}(\sigma^t)}{\sum_{\hat{\sigma}_t} p^{NNL}(\sigma^{t-1}, \hat{\sigma}_t)}. \end{aligned}$$

□

**Lemma 2.** *In an economy that satisfies **A0-A4**, equilibrium prices are given by:*

$$q(\sigma^t) = \frac{\beta^t \sum_{i \in \mathcal{I}} p^i(\sigma^t) \frac{1}{u^i(c_0^i)'}}{\sum_{j \in \mathcal{I}} \frac{1}{u^j(c_1^j(\sigma))'}} \quad (6)$$

*Proof.* The Lagrangian problem associated with each trader's maximization problem is

$$L_i = E_{p^i} \sum_{t=0}^{\infty} \beta^t u^i(c_t^i(\sigma)) + \lambda_i \left( \sum_{t=0}^{\infty} \sum_{\sigma^t \in S^t} q(\sigma^t) (c_t^i(\sigma) - e_t^i(\sigma)) \right).$$

By equating the derivatives of this Lagrangian to 0 I get, for all  $(t, \sigma)$ ,

$$\frac{\partial L_i}{\partial c_t^i(\sigma)} = 0 \Rightarrow \beta^t p^i(\sigma^t) u^i(c_t^i(\sigma))' = \lambda_i q(\sigma^t) \quad (7)$$

Letting  $q_0 = 1$  (the price of one unit of consumption at  $t=0$  equals 1) I find that  $\lambda_i = u^i(c_0^i)'$ , the result follows rearranging summing over traders and rearranging. □

## Proof of Proposition 1

*Proof.* By contradiction, assume  $H_0$ : there exists a non-log economy such that

$$\forall \sigma^{t-1}, \quad \sum_{\hat{\sigma}^t \in S^t} p(\hat{\sigma}^t \cap \sigma^{t-1}) = p((\cup \hat{\sigma}^t \in S^t) \cap \sigma^{t-1}) = p(\sigma^{t-1}).$$

$$\begin{aligned}
& \text{Then, } \forall \sigma^t \in S^t, \frac{q(\sigma^t)}{q(\sigma^{t-1})} \stackrel{\text{Eq. condition}}{=} q(\sigma_t|) \\
& \Leftrightarrow \forall \sigma^t \in S^t, \frac{p^{NNL}(\sigma^t)}{p^{NNL}(\sigma^{t-1})} = \frac{\frac{q(\sigma^t)}{\sum_{\hat{\sigma}^t} q(\hat{\sigma}^t)}}{\frac{q(\sigma^{t-1})}{\sum_{\hat{\sigma}^{t-1}} q(\hat{\sigma}^{t-1})}} = q(\sigma_t|) \frac{\sum_{\hat{\sigma}^{t-1}} q(\hat{\sigma}^{t-1})}{\sum_{\hat{\sigma}^t} q(\hat{\sigma}^t)} \\
& \Leftrightarrow \forall \sigma^{t-1}, \sum_{\sigma_t} \frac{p^{NNL}(\sigma^{t-1}, \sigma_t)}{p^{NNL}(\sigma^{t-1})} = \sum_{\sigma_t} q(\sigma_t|) \frac{\sum_{\hat{\sigma}^{t-1}} q(\hat{\sigma}^{t-1})}{\sum_{\hat{\sigma}^t} q(\hat{\sigma}^t)} \\
& \stackrel{\text{If } H_0 \text{ is true}}{\Leftrightarrow} \forall \sigma^{t-1}, 1 = \sum_{\sigma_t} q(\sigma_t|) \frac{\sum_{\hat{\sigma}^{t-1}} q(\hat{\sigma}^{t-1})}{\sum_{\hat{\sigma}^t} q(\hat{\sigma}^t)} \\
& \Leftrightarrow \forall \sigma^{t-1}, \frac{\sum_{\hat{\sigma}^t} q(\hat{\sigma}^t)}{\sum_{\hat{\sigma}^{t-1}} q(\hat{\sigma}^{t-1})} = \sum_{\sigma_t} q(\sigma_t|) \\
& \Leftrightarrow \forall \bar{\sigma}^{t-1}, \bar{\sigma}^{t-1}, \sum_{\sigma_t} q(\sigma_t|\bar{\sigma}^{t-1}) = \frac{\sum_{\hat{\sigma}^t} q(\hat{\sigma}^t)}{\sum_{\hat{\sigma}^{t-1}} q(\hat{\sigma}^{t-1})} = \sum_{\sigma_t} q(\sigma_t|\bar{\sigma}^{t-1});
\end{aligned}$$

the last equality tells us that the risk-free rate is independent of histories and thus of consumption shares. In economies with heterogeneous beliefs (**A5**), this property can hold only if all agents have log utility.  $\square$

### Proof of Proposition 2 and 3:

*Proof.* Substituting  $c_t^i(\sigma)^{-\gamma}$  for  $u^i(\sigma^t)'$  and  $u^i(c_0^i)$  for  $\lambda_i$  in Equation 7,

$$\beta^t p^j(\sigma^t) c_t^j(\sigma)^{-\gamma} = (c_0^j)^{-\gamma} q(\sigma^t) \quad (8)$$

taking the ratio of traders  $i, j$  FOCs:  $\frac{\beta^t p^i(\sigma^t) c_t^i(\sigma)^{-\gamma}}{\beta^t p^j(\sigma^t) c_t^j(\sigma)^{-\gamma}} = \frac{(c_0^i)^{-\gamma} q(\sigma^t)}{(c_0^j)^{-\gamma} q(\sigma^t)}$ ; solving for  $c^i(\sigma^t)$ :

$$c_t^i(\sigma) = \left( \frac{p^i(\sigma^t)}{p^j(\sigma^t)} \right)^{\frac{1}{\gamma}} \frac{c_0^i}{c_0^j} c_t^j(\sigma). \quad (9)$$

Substituting Equation 9 in the market-clearing condition (which holds with equality because of monotonicity of  $u^i$ ):  $1 = \sum_{i \in \mathcal{I}} c_t^i(\sigma) = c_t^j(\sigma) \frac{\sum_{i \in \mathcal{I}} p^i(\sigma^t)^{\frac{1}{\gamma}} c_0^i}{p^j(\sigma^t)^{\frac{1}{\gamma}} c_0^j}$ ; solving for  $c_t^j(\sigma)$ :

$$c_t^j(\sigma) = \frac{p^j(\sigma^t)^{\frac{1}{\gamma}} c_0^j}{\sum_{i \in \mathcal{I}} p^i(\sigma^t)^{\frac{1}{\gamma}} c_0^i}. \quad (10)$$

Substituting  $c_t^j(\sigma)$  in Equation 8 and rearranging, I obtain

$$q(\sigma^t) = \beta^t \left( \sum_{i \in \mathcal{I}} p^i(\sigma^t)^{\frac{1}{\gamma}} c_0^i \right)^\gamma \quad (11)$$

The result follows substituting Equations 11 in Definition 2 and 3, respectively.  $\square$

**Lemma 3.** Under **A0-A4**, if agents' utilities are CRRA, for all  $(t, \sigma)$ ,

$$\begin{aligned}
\forall i, \gamma^i \geq 1 & \Rightarrow \frac{1}{\beta} \sum_{\sigma_t} q(\sigma_t|) \leq 1 \\
\forall i, \gamma^i \leq 1 & \Rightarrow \frac{1}{\beta} \sum_{\sigma_t} q(\sigma_t|) \geq 1,
\end{aligned}$$

with equality if and only if either the consumption share is degenerate, or  $\gamma^i = 1$  for all agents, or all agents have identical beliefs.

*Proof.* On every equilibrium path  $\forall(t, \sigma)$  and for all  $i$ ,

$$c_t^i(\sigma) = \left( \frac{\beta p^i(\sigma_t)}{q(\sigma_t)} \right)^{\frac{1}{\gamma^i}} c_{t-1}^i(\sigma).$$

Multiplying on both sides by  $\frac{q(\sigma_t)}{\beta}$ ,

$$\frac{q(\sigma_t)}{\beta} c_t^i(\sigma) = p^i(\sigma_t)^{\frac{1}{\gamma^i}} \left( \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^i}} c_{t-1}^i(\sigma).$$

Summing on both sides over all the agents,

$$\frac{q(\sigma_t)}{\beta} \sum_{i \in \mathcal{I}} c_t^i(\sigma) = \sum_{i \in \mathcal{I}} p^i(\sigma_t)^{\frac{1}{\gamma^i}} \left( \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^i}} c_{t-1}^i(\sigma).$$

Dividing on both sides by the aggregate endowment (which is constant over  $t$ )

$$\frac{q(\sigma_t)}{\beta} = \sum_{i \in \mathcal{I}} p^i(\sigma_t)^{\frac{1}{\gamma^i}} \left( \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^i}} \phi_{t-1}^i,$$

where  $[\phi_{t-1}^1, \dots, \phi_{t-1}^I]$  is the consumption shares distribution in  $(t-1, \sigma^{t-1})$ .  
Summing on both sides over the states:

$$\sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} = \sum_{i \in \mathcal{I}} \sum_{\sigma_t} p^i(\sigma_t)^{\frac{1}{\gamma^i}} \left( \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^i}} \phi_{t-1}^i.$$

Multiplying the right-hand side by  $\frac{\prod_{k \in \mathcal{I}} \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^k}}}{\prod_{j \in \mathcal{I}} \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^j}}} = 1$  we can express the left-hand side as a function of  $p^{SNNL}$ .

$$\sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} = \sum_{i \in \mathcal{I}} \sum_{\sigma_t} p^i(\sigma_t)^{\frac{1}{\gamma^i}} p^{SNNL}(\sigma_t)^{1 - \frac{1}{\gamma^i}} \phi_{t-1}^i \frac{\prod_{k \in \mathcal{I}} \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^k}}}{\prod_{j \neq i} \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^j}}}. \quad (12)$$

- Let us focus on the case in which  $\forall i, \gamma^i \geq 1$ .

Let  $i^* := \arg \max_{i \in \mathcal{I}} \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^i}}$ , so that  $\forall k, i \in \mathcal{I}, \frac{\prod_{k \neq i^*} \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^k}}}{\prod_{j \neq i} \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^j}}} \leq 1$ .

It follows that

$$\begin{aligned} \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} &= \sum_{i \in \mathcal{I}} \sum_{\sigma_t} p^i(\sigma_t)^{\frac{1}{\gamma^i}} p^{SNNL}(\sigma_t)^{1 - \frac{1}{\gamma^i}} \phi_{t-1}^i \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^{i^*}}} \frac{\prod_{k \neq i^*} \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^k}}}{\prod_{j \neq i} \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^j}}} \\ &\leq \sum_{i \in \mathcal{I}} \sum_{\sigma_t} p^i(\sigma_t)^{\frac{1}{\gamma^i}} p^{SNNL}(\sigma_t)^{1 - \frac{1}{\gamma^i}} \phi_{t-1}^i \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^{i^*}}}. \end{aligned}$$

Rearranging,

$$\begin{aligned}
\left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{\frac{1}{\gamma^{i^{**}}}} &\leq \sum_{i \in \mathcal{I}} \sum_{\sigma_t} p^i(\sigma_t)^{\frac{1}{\gamma^i}} p^{SNNL}(\sigma_t)^{1 - \frac{1}{\gamma^i}} \phi_{t-1}^i \\
&\stackrel{(a)}{\leq} \sum_{i \in \mathcal{I}} \sum_{\sigma_t} \left( \frac{1}{\gamma^i} p^i(\sigma_t) + \left(1 - \frac{1}{\gamma^i}\right) p^{SNNL}(\sigma_t) \right) \phi_{t-1}^i = 1 \\
\Rightarrow \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} &\leq 1.
\end{aligned} \tag{13}$$

(a) :  $\forall i \in \mathcal{I}, \gamma^i \geq 1 \Rightarrow \forall \sigma_t, p^i(\sigma_t)^{\frac{1}{\gamma^i}} p^{SNNL}(\sigma_t)^{1 - \frac{1}{\gamma^i}} \leq \frac{1}{\gamma^i} p^i(\sigma_t) + \left(1 - \frac{1}{\gamma^i}\right) p^{SNNL}(\sigma_t)$ , because strict concavity of log ensures that

$$\begin{aligned}
\ln \left( p^i(\sigma_t)^{\frac{1}{\gamma^i}} p^{SNNL}(\sigma_t)^{1 - \frac{1}{\gamma^i}} \right) &= \frac{1}{\gamma^i} \ln p^i(\sigma_t) + \left(1 - \frac{1}{\gamma^i}\right) \ln p^{SNNL}(\sigma_t) \\
&\leq \ln \left( \frac{1}{\gamma^i} p^i(\sigma_t) + \left(1 - \frac{1}{\gamma^i}\right) p^{SNNL}(\sigma_t) \right).
\end{aligned}$$

- Let's focus on the case in which  $\forall i, \gamma^i \leq 1$ .

Let  $i^{**} := \arg \min_{i \in \mathcal{I}} \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{\frac{1}{\gamma^i}}$ ; thus  $\forall k, i \in \mathcal{I}, \frac{\prod_{k \neq i^{**}} \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^k}}}{\prod_{j \neq i} \left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{1 - \frac{1}{\gamma^j}}} \geq 1$ .

Proceeding as above, we obtain the opposite inequality:

$$\left( \sum_{\sigma_t} \frac{q(\sigma_t)}{\beta} \right)^{\frac{1}{\gamma^{i^{**}}}} \geq \sum_{i \in \mathcal{I}} \sum_{\sigma_t} p^i(\sigma_t)^{\frac{1}{\gamma^i}} p^{SNNL}(\sigma_t)^{1 - \frac{1}{\gamma^i}} \phi_{t-1}^i. \tag{14}$$

The result follows by showing that

$$\gamma^i \leq 1 \quad \forall i \Rightarrow \ln \sum_{i \in \mathcal{I}} \sum_{\sigma_t} p^i(\sigma_t)^{\frac{1}{\gamma^i}} p^{SNNL}(\sigma_t)^{1 - \frac{1}{\gamma^i}} \phi_{t-1}^i \geq 0.$$

For convenience, let  $\forall i, \eta_i := \frac{1}{\gamma^i}$ ; so that  $\forall i, \eta_i \in (1, \infty)$ .

$$\begin{aligned}
\ln \sum_{i \in \mathcal{I}} \sum_{\sigma_t} p^i(\sigma_t)^{\frac{1}{\gamma^i}} p^{SNNL}(\sigma_t)^{1 - \frac{1}{\gamma^i}} \phi_{t-1}^i &= \ln \sum_{i \in \mathcal{I}} \sum_{\sigma_t} \frac{p^i(\sigma_t)^{\eta_i}}{p^{SNNL}(\sigma_t)^{\eta_i - 1}} \phi_{t-1}^i \\
&\stackrel{(a)}{\geq} \sum_{i \in \mathcal{I}} \phi_{t-1}^i \ln \sum_{\sigma_t} \frac{p^i(\sigma_t)^{\eta_i}}{p^{SNNL}(\sigma_t)^{\eta_i - 1}} \\
&= \sum_{i \in \mathcal{I}} (\eta_i - 1) \phi_{t-1}^i \left( \frac{1}{\eta_i - 1} \ln \sum_{\sigma_t} \frac{p^i(\sigma_t)^{\eta_i}}{p^{SNNL}(\sigma_t)^{\eta_i - 1}} \right) \\
&= \stackrel{(b)}{=} \sum_{i \in \mathcal{I}} (\eta_i - 1) \phi_{t-1}^i D_{\eta^i}(p_t^i || p_t^{RN}) \\
&\stackrel{(c)}{\geq} 0.
\end{aligned}$$

(a): By concavity of log.

(b): Recognizing the definition of the Rényi divergence ( $D_{\eta^i}(p_t^i || p_t^{RN})$ ) between  $p_t^i$  and  $p_t^{RN}$  (Rényi, 1961; Van Erven and Harremoës, 2014).

(c): Rényi divergence is weakly positive, it equals 0 if and only if  $p^i = p^{SNNL}$  (Van Erven

and Harremos, 2014).

An inspection of Equation (12) shows that equality holds if and only if  
— all agents have identical beliefs because

$$\forall i, p_t^i = p_t = p_t^{SNNL} \Rightarrow \forall i, \left( \sum_{\sigma_t} \frac{q(\sigma_t|)}{\beta} \right)^{1-\frac{1}{\gamma^i}} = \sum_{i \in \mathcal{I}} \sum_{\sigma_t} p_t(\sigma_t|)^{\frac{1}{\gamma^i}} p_t(\sigma_t|)^{1-\frac{1}{\gamma^i}} \phi_{t-1}^i = 1;$$

— or the consumption share distribution is degenerate because

$$\phi_{t-1}^i = 1 \Rightarrow p_t^i = p_t = p_t^{SNNL} \Rightarrow \left( \sum_{\sigma_t} \frac{q(\sigma_t|)}{\beta} \right)^{1-\frac{1}{\gamma^i}} = \sum_{i \in \mathcal{I}} \sum_{\sigma_t} p_t(\sigma_t|)^{\frac{1}{\gamma^i}} p_t(\sigma_t|)^{1-\frac{1}{\gamma^i}} \phi_{t-1}^i = 1;$$

— or  $\gamma^i = 1$  for all agents because  $\sum_{\sigma_t} \frac{q(\sigma_t|)}{\beta} = \sum_{i \in \mathcal{I}} \sum_{\sigma_t} p^i(\sigma_t|) = 1$ . □

**Lemma 4.** *In an economy that satisfies **A0-A4**,*  $\left\{ \begin{array}{l} \inf_{(t,\sigma)} \sum_{i \in \mathcal{I}} \frac{1}{u'_i(c^i(\sigma))} > a > 0 \\ \sup_{(t,\sigma)} \sum_{i \in \mathcal{I}} \frac{1}{u'_i(c^i(\sigma))} < b < \infty \end{array} \right.$

*Proof.*

- $\forall (t, \sigma), \sum_{i \in \mathcal{I}} \frac{1}{u'_i(c^i(\sigma))} \geq \min_{[c^1, \dots, c^I]} \sum_{i \in \mathcal{I}} \frac{1}{u'_i(c^i)} > 0$  because  $\sum_{i \in \mathcal{I}} \frac{1}{u'_i(c^i)} = 0$  if and only if  $\forall i, u'_i(c^i) = \infty \Leftrightarrow^{A1} \forall i, c^i = 0$ , which violates market-clearing ( $\forall t, \sum_{i \in \mathcal{I}} c^i = \sum_{i \in \mathcal{I}} e^i =^{A3} 1$ ).
- $\forall (t, \sigma), \sup \sum_{i \in \mathcal{I}} \frac{1}{u'_i(c^i(\sigma))} \leq \max_{[c^1, \dots, c^I]} \sum_{i \in \mathcal{I}} \frac{1}{u'_i(c^i)} < |\mathcal{I}| \max_i \frac{1}{u'_i(1)} < \infty$  because market clearing and **A3** implies  $\max_i c^i = 1$ ; and **A1** implies  $\forall i, \max_{c \leq 1} \frac{1}{u^i(c)^{\gamma}} = \frac{1}{u^i(1)^{\gamma}} < \infty$ . □

### Proof of Theorem 1:

*Proof.* Definition 3 allows to rewrite  $\ln \frac{p^{BMA}(\sigma^t)}{p^{SNNL}(\sigma^t)}$  as follows:

$$\begin{aligned} \ln \frac{p^{BMA}(\sigma^t)}{p^{SNNL}(\sigma^t)} &= \sum_{\tau=1}^t \sum_{\sigma_\tau} I_{\sigma_\tau} \ln \frac{p^{BMA}(\sigma^\tau|)}{\frac{q(\sigma^\tau|)}{\sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau|)}} = \ln \frac{\beta^t p^{BMA}(\sigma^t)}{q(\sigma^t)} + \sum_{\tau=1}^t \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau|) \right) \\ &\stackrel{\text{by Massari (2017) Corollary 1}}{=} O(1) + \sum_{\tau=1}^t \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau|) \right) \end{aligned}$$

- $p^{SNNL}(\sigma^t)$  is  $\mathcal{P}$ -efficient.

It follows from the above that I need to show that

$$\sum_{\tau=1}^t \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau|) \right) \asymp^{P\text{-a.s}} 1. \quad (15)$$

Let  $i^*$  denote the agent  $i$  with  $p^i = P$ .

Taking ratio of the FOCs, in every equilibrium path and for every agent  $i \neq i^*$  it holds

$$\frac{\frac{1}{u^i(c^i(\sigma))^\gamma}}{\frac{1}{u^{i^*}(c^{i^*}(\sigma))^\gamma}} = \frac{p^i(\sigma^t)}{P(\sigma^t)} \frac{\frac{1}{u^i(c_0^i)^\gamma}}{\frac{1}{u^{i^*}(c_0^{i^*})^\gamma}};$$

so,  $\frac{1}{u^{i^*}(c_t^{i^*}(\sigma))'} \rightarrow^{P\text{-a.s.}} \frac{1}{u^{i^*}(1)'}$  at an exponential rate.

By Equation 6 and the definition of  $q(\cdot|)$  we have that for all  $(t, \sigma)$

$$q(\sigma_t|) = \frac{q(\sigma^t)}{q(\sigma^{t-1})} = \frac{\frac{\beta^t \sum_{i \in \mathcal{I}} p^i(\sigma^t) \frac{1}{u^i(c_0^i)'}}{\sum_{j \in \mathcal{I}} \frac{1}{u^j(c_t^j(\sigma))'}}}{\frac{\beta^{t-1} \sum_{k \in \mathcal{P}} p^k(\sigma^{t-1}) \frac{1}{u^k(c_0^k)'}}{\sum_{l \in \mathcal{I}} \frac{1}{u^l(c_{t-1}^l(\sigma))'}}}} = \beta \sum_{i \in \mathcal{I}} p^i(\sigma^t|) \frac{p^i(\sigma^{t-1}) \frac{1}{u^i(c_0^i)'}}{\sum_{k \in \mathcal{P}} p^k(\sigma^{t-1}) \frac{1}{u^k(c_0^k)'}} \frac{\sum_{l \in \mathcal{I}} \frac{1}{u^l(c_{t-1}^l(\sigma))'}}{\sum_{j \in \mathcal{I}} \frac{1}{u^j(c_t^j(\sigma))'}}.$$

Thus,  $\frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}^\tau|) \rightarrow^{P\text{-a.s.}} 1$  at an exponential rate which is sufficient to bound the sum in Equation 15.<sup>15</sup>

- $p_{\gamma^i=1}^{SNNL}$  is universal-efficient. By Lemma 3,  $\gamma = 1 \Rightarrow \forall(t, \sigma), \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}^\tau|) = 1$ , so that

$$\forall(t, \sigma), \sum_{\tau=1}^t \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau|) \right) = 0 \asymp 1.$$

- $p_{\gamma^i < (>) 1}^{SNNL}$  is sub-efficient (super-efficient).  
We have to verify two conditions:

$$\text{First : } \gamma^i < (>) 1 \Rightarrow \forall \sigma \in S^\infty, \liminf(\limsup) \sum_{\tau=1}^t \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau|) \right) > (<) - (+) \infty$$

The first claim follows from Lemma 3, which guarantees that

$$\forall i \in \mathcal{I}, \gamma^i < (>) 1 \Rightarrow \forall(\sigma^{\tau-1}), \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau|) \right) \geq (<=) 0.$$

$$\text{Second : } \gamma^i < (>) 1 \Rightarrow \exists \hat{P} : \sum_{\tau=1}^t \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau|) \right) \rightarrow^{\hat{P}\text{-a.s.}} +(-) \infty.$$

To prove the second claim I proceed by steps:

i)  $\sum_{\tau=1}^t \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau|) \right) \rightarrow \pm \infty$  if consumption shares do not concentrate on one trader.

*Proof:* By Lemma 3,  $\forall i \in \mathcal{I}, \gamma^i < (>) 1 \Leftrightarrow \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau|) \right) \geq (<=) 0$ , with equality if and only if the consumption-share distribution is degenerate (or beliefs are identical). Thus, if for all  $i \in \mathcal{I}, \gamma^i < (>) 1$ , all terms of the sum have the same sign. So, if consumption shares do not concentrate on a unique trader,  $\exists \eta > 0 : \left| \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau|) \right) \right| > \eta$  infinitely often and the sum diverges.

ii)  $p^{BMA}(\sigma^t)$ 's prior,  $C_{t, \gamma=1}$ , does not eventually concentrate on a unique trader if and only if,  $\forall \gamma \in (0, +\infty)$ ,  $p^{SNNL}(\sigma^t)$ 's generalized prior,  $C_{t, \gamma}$ , does not concentrate on a

<sup>15</sup>While the convergence results in section 7 of Sandroni (2000) imply that  $\sum_{\hat{\sigma}_\tau} q(\hat{\sigma}^\tau|) \rightarrow \beta$ , these results are too weak to prove that  $p^{SNNL}(\sigma^t)$  is  $\mathcal{P}$ -efficient because they are mute about the convergence rate. The result proven above is stronger than those of Sandroni (2000) in that it shows that the convergence rate to the rational expectation equilibrium is exponentially fast.

unique trader.<sup>16</sup>

*Proof:*  $C_{t,\gamma=1}$  does not concentrate on a unique trader

$$\begin{aligned} &\Leftrightarrow \exists \eta > 0, \exists i, j \in \mathcal{I} : \limsup \frac{p^i(\sigma^t)}{\sum_{i \in \mathcal{I}} p^i(\sigma^t)} > \eta \text{ and } \limsup \frac{p^j(\sigma^t)}{\sum_{i \in \mathcal{I}} p^i(\sigma^t)} > \eta \\ &\Leftrightarrow \exists \eta_\gamma > 0 : \limsup \frac{p^i(\sigma^t)^{\frac{1}{\gamma}}}{\sum_{i \in \mathcal{I}} p^i \sigma^{t \frac{1}{\gamma}}} = c_{\gamma,t}^i(\sigma) > \eta_\gamma \text{ and } \limsup \frac{p^j(\sigma^t)^{\frac{1}{\gamma}}}{\sum_{i \in \mathcal{I}} p^i \sigma^{t \frac{1}{\gamma}}} = c_{\gamma,t}^j(\sigma) > \eta_\gamma \\ &\Leftrightarrow C_{t,\gamma} \text{ does not concentrate on a unique trader.} \end{aligned}$$

iii)  $\exists \hat{P}$  such that  $C_{t,1}$  does not concentrate on a unique trader:

*Proof:* The proof is constructive. Letting  $i, j \in \mathcal{I}$  be two orthogonal models, it is easy to verify that the Bayesian posterior does not converge  $P_{\theta_0}$ -a.s. for  $P_{\theta_0}$  defined recursively as follows:

$$\forall \sigma^{t-1}, P_{\theta_0}(\sigma_t) := \begin{cases} p^i(\sigma_t), & \text{if } p^j(\sigma^{t-1}) \in \arg \max_{i \in \mathcal{I}} \\ p^j(\sigma_t), & \text{otherwise} \end{cases} .$$

Concentration cannot occur because  $j$  has maximal expected likelihood (thus highest expected survival index) whenever his likelihood is comparatively low; he cannot, however, dominate since he cannot beat agent  $i$ , because  $i$  becomes the most accurate as soon as agent  $j$ 's consumption share passes a threshold (i.e., his likelihood becomes comparative large). □

### Proof of Theorem 2:

*Proof.* Substituting Equation 6 in the definition of  $p^{NNL}$ .

$$p^{NNL}(\sigma^t) = \frac{q(\sigma^t)}{\sum_{\sigma^t} q(\sigma^t)} = \frac{\frac{\beta^t \sum_{i \in \mathcal{I}} p^i(\sigma^t) \frac{1}{u'_i(c_0^i)}}{\sum_{j \in \mathcal{I}} \frac{1}{u'_j(c_j^j(\sigma^t))}}}{\beta^t \sum_{\hat{\sigma}^t \in \mathcal{S}^t} \left( \frac{\sum_{k \in \mathcal{I}} p^k(\hat{\sigma}^t) \frac{1}{u'_k(c_0^k)}}{\sum_{l \in \mathcal{I}} \frac{1}{u'_l(c_l(\hat{\sigma}^t))}} \right)} \quad (16)$$

Let  $\inf \sum_{i \in \mathcal{I}} \frac{1}{u'_i(c(\hat{\sigma}^t))} = a$  and  $\sup \sum_{i \in \mathcal{I}} \frac{1}{u'_i(c(\hat{\sigma}^t))} = b$ ; by Lem.4;  $0 < a \leq b < \infty$ . So, for all  $(t, \sigma)$ ,

$$\begin{aligned} p^{NNL}(\sigma^t) &\in \left[ \frac{\frac{\beta^t \sum_{i \in \mathcal{I}} p^i(\sigma^t) \frac{1}{u'_i(c_0^i)}}{b}}{\beta^t \sum_{\sigma \in \mathcal{S}^t} \left( \frac{\sum_{k \in \mathcal{I}} p^k(\sigma) \frac{1}{u'_k(c_0^k)}}{a} \right)}, \frac{\frac{\beta^t \sum_{i \in \mathcal{I}} p^i(\sigma^t) \frac{1}{u'_i(c_0^i)}}{a}}{\beta^t \sum_{\sigma \in \mathcal{S}^t} \left( \frac{\sum_{k \in \mathcal{I}} p^k(\sigma) \frac{1}{u'_k(c_0^k)}}{b} \right)} \right] \\ &\Rightarrow p^{NNL}(\sigma^t) \in \left[ \frac{a}{b} \sum_{i \in \mathcal{I}} p^i(\sigma^t) \frac{\frac{1}{u'_i(c_0^i)}}{\sum_{k \in \mathcal{I}} \frac{1}{u'_k(c_0^k)}}, \frac{b}{a} \sum_{i \in \mathcal{I}} p^i(\sigma^t) \frac{\frac{1}{u'_i(c_0^i)}}{\sum_{k \in \mathcal{I}} \frac{1}{u'_k(c_0^k)}} \right] \\ &\Rightarrow \ln \frac{p^{BMA}(\sigma^t)}{p^{NNL}(\sigma^t)} \asymp 1. \end{aligned}$$

□

### Proof of Proposition 4:

<sup>16</sup>The proof slightly differs for  $\gamma = 0$  because I need the stronger condition that the model with the highest likelihood changes infinitely to ensure  $\sum_{\tau=1}^t \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau) \right) \rightarrow \pm \infty$  (See Massari (2017)).

*Proof.* As in the proof of Th.1:  $\ln \frac{p^{BMA}(\sigma^t)}{p^{SNNL}(\sigma^t)} = O(1) + \sum_{\tau=1}^t \ln \left( \frac{1}{\beta} \sum_{\hat{\sigma}_\tau} q(\hat{\sigma}_\tau) \right)$ .

- Part *i*) mimics the step of Theorem 1, except that non-concentration is now assumed.
- Part *ii*) mimics the proof of  $\mathcal{P}$ -efficiency in Theorem 1, except that the exponential concentration rate is assumed rather than deduced from the fact that one agent knows the truth. For an application, consider Example 1:

$$\begin{aligned} e^{-\sum_{\tau=1}^t \ln(q(a) + q(b))} &= EXP \left[ - \sum_{\tau=1}^t \ln \frac{\left( \frac{1}{2} \left( \frac{2}{3} \right)^{\frac{\tau}{\gamma}} + \frac{1}{2} \left( \frac{1}{3} \right)^{\frac{\tau}{\gamma}} \right)^\gamma + \left( \frac{1}{2} \left( \frac{1}{3} \right)^{\frac{1}{\gamma}} \left( \frac{2}{3} \right)^{\frac{\tau-1}{\gamma}} + \frac{1}{2} \left( \frac{2}{3} \right)^{\frac{1}{\gamma}} \left( \frac{1}{3} \right)^{\frac{\tau-1}{\gamma}} \right)^\gamma}{\left( \frac{1}{2} \left( \frac{2}{3} \right)^{\frac{\tau-1}{\gamma}} + \frac{1}{2} \left( \frac{1}{3} \right)^{\frac{\tau-1}{\gamma}} \right)^\gamma} \right] \\ &= EXP \left[ - \sum_{\tau=1}^t \ln \frac{\left( \left( \frac{2}{3} \right)^{\frac{1}{\gamma}} + \left( \frac{1}{3} \right)^{\frac{1}{\gamma}} \left( \frac{1}{2} \right)^{\frac{\tau-1}{\gamma}} \right)^\gamma + \left( \left( \frac{1}{3} \right)^{\frac{1}{\gamma}} + \left( \frac{2}{3} \right)^{\frac{1}{\gamma}} \left( \frac{1}{2} \right)^{\frac{\tau-1}{\gamma}} \right)^\gamma}{\left( 1 + \left( \frac{1}{2} \right)^{\frac{\tau-1}{\gamma}} \right)^\gamma} \right] \end{aligned}$$

Taylor-expanding the two terms on the numerator around  $\frac{2}{3}^{\frac{1}{\gamma}}$  and  $\frac{1}{3}^{\frac{1}{\gamma}}$  and the term in the denominator around 1, respectively, it follows that  $\exists \eta \in (0, \frac{1}{2})$ :

$$EXP \left[ - \sum_{\tau=1}^t \ln \frac{\left( \left( \frac{2}{3} \right)^{\frac{1}{\gamma}} + \left( \frac{1}{3} \right)^{\frac{1}{\gamma}} \left( \frac{1}{2} \right)^{\frac{\tau-1}{\gamma}} \right)^\gamma + \left( \left( \frac{1}{3} \right)^{\frac{1}{\gamma}} + \left( \frac{2}{3} \right)^{\frac{1}{\gamma}} \left( \frac{1}{2} \right)^{\frac{\tau-1}{\gamma}} \right)^\gamma}{\left( 1 + \left( \frac{1}{2} \right)^{\frac{\tau-1}{\gamma}} \right)^\gamma} \right] \in \left[ e^{-\sum_{\tau=1}^t (1/2 + \eta)^\tau}; e^{-\sum_{\tau=1}^t (1/2 - \eta)^\tau} \right] = O(1).$$

□

### Proof of Proposition 5:

*Proof.*  $\gamma = 1 \Rightarrow p_\gamma^{NNL} = p_\gamma^{SNNL} = p^{BMA}$  which is convex.

Generically,  $p^{SNNL}$  is not convex: For intuition, let us start with the case of identical CRRA economies. If the state space has at least 3 states and all models in  $\mathcal{P}$  attach the same probability to state  $\hat{s}, p(\hat{s})$  then  $p_\gamma^{SNNL}$  is not convex in non-log economies because:

$$\begin{aligned} p^{SNNL}(\hat{s}_t)_\gamma &= \frac{\left( \sum_{i \in \mathcal{I}} p^i(\hat{s}_t)^{\frac{1}{\gamma}} c_{\gamma, t-1}^i(\sigma) \right)^\gamma}{\sum_{\hat{\sigma}_t \in \mathcal{S}} \left( \sum_{i \in \mathcal{I}} p^i(\hat{\sigma}_t)^{\frac{1}{\gamma}} c_{\gamma, t-1}^i(\sigma) \right)^\gamma} \\ &= \frac{p^i(\hat{s}_t)}{\sum_{\hat{\sigma}_t \in \mathcal{S}} \left( \sum_{i \in \mathcal{I}} p^i(\hat{\sigma}_t)^{\frac{1}{\gamma}} c_{\gamma, t-1}^i(\sigma) \right)^\gamma} \\ &\neq p^i(\hat{s}_t) \end{aligned}$$

where the last inequality follows because  $\sum_{\hat{\sigma}_t \in \mathcal{S}} \left( \sum_{i \in \mathcal{I}} p^i(\hat{\sigma}_t)^{\frac{1}{\gamma}} c_{\gamma, t-1}^i(\sigma) \right)^\gamma \neq 1$  for all non degenerate consumption shares.

For the general case, I first show that there are cases in which the normalizing factor in

$p^{SNNL}$  is different from 1. Then generalize the above example.

$$\begin{aligned}
\forall \sigma^t, p^{SNNL}(\sigma_t|) &\stackrel{\text{by Lemma 1}}{=} \frac{p^{SNNL}(\sigma^t)}{\sum_{\hat{\sigma}_t} p^{SNNL}(\sigma^{t-1}, \hat{\sigma}_t)} \\
&\stackrel{\text{by Equation 16}}{=} \frac{\frac{\sum_{i \in \mathcal{I}} p^i(\sigma^t) \frac{1}{u'_i(c_0^i)}}{\sum_{j \in \mathcal{I}} \frac{1}{u'_j(c^j(\sigma^t))}}}{\sum_{\hat{\sigma}_t} \frac{\sum_{k \in \mathcal{I}} p^k(\sigma^t) \frac{1}{u'_k(c_0^k)}}{\sum_{l \in \mathcal{I}} \frac{1}{u'_l(c^l(\sigma^{t-1}, \hat{\sigma}_t))}}} = \frac{\sum_{i \in \mathcal{I}} p^i(\sigma^t) \frac{1}{u'_i(c_0^i)}}{\sum_{\hat{\sigma}_t} \sum_{k \in \mathcal{I}} p^k(\sigma^t) \frac{1}{u'_k(c_0^k)} \frac{\sum_{j \in \mathcal{I}} \frac{1}{u'_j(c^j(\sigma^{t-1}, \hat{\sigma}_t))}}{\sum_{l \in \mathcal{I}} \frac{1}{u'_l(c^l(\sigma^{t-1}, \hat{\sigma}_t))}}} \\
&= \frac{\sum_{i \in \mathcal{I}} p^i(\sigma^t|) g^i(\sigma^{t-1})}{\sum_{\hat{\sigma}_t} \sum_{k \in \mathcal{I}} p^k(\hat{\sigma}_t|) g^k(\sigma^{t-1}) \frac{\sum_{j \in \mathcal{I}} \frac{1}{u'_j(c^j(\sigma^{t-1}, \hat{\sigma}_t))}}{\sum_{l \in \mathcal{I}} \frac{1}{u'_l(c^l(\sigma^{t-1}, \hat{\sigma}_t))}}};
\end{aligned}$$

where  $\forall i, g^i(\sigma^{t-1}) := \frac{\frac{p^i(\sigma^{t-1})}{u'_i(c_0^i)}}{\sum_{j \in \mathcal{I}} \frac{p^j(\sigma^{t-1})}{u'_j(c_0^j)}}$  can be thought of as the weight of a prior distribution

$G(\sigma^{t-1})$ . Suppose that the distribution of consumption is not degenerate and such that  $\sum_{j \in \mathcal{I}} \frac{1}{u'_j(c^j(\sigma^{t-1}, \hat{\sigma}_t))} \in \text{argmax}_{\hat{\sigma}} \sum_{j \in \mathcal{I}} \frac{1}{u'_j(c^j(\sigma^{t-1}, \hat{\sigma}_t))}$ . It follows that

$$\sum_{\hat{\sigma}_t} \sum_{k \in \mathcal{I}} p^k(\hat{\sigma}_t|) g^k(\sigma^{t-1}) \frac{\sum_{j \in \mathcal{I}} \frac{1}{u'_j(c^j(\sigma^{t-1}, \hat{\sigma}_t))}}{\sum_{l \in \mathcal{I}} \frac{1}{u'_l(c^l(\sigma^{t-1}, \hat{\sigma}_t))}} \neq 1.$$

So, if the state space has at least 3 states and all models in  $\mathcal{P}$  attach the same probability to state  $\hat{s}, p(\hat{s})$  then  $p^{SNNL}$  is not convex in non-log economies because:

$$p^{SNNL}(\hat{s}_t|) = \frac{\sum_{i \in \mathcal{I}} p^i(\hat{s}_t|) g^i(\sigma^{t-1})}{\sum_{\hat{\sigma}_t} \sum_{k \in \mathcal{I}} p^k(\hat{\sigma}_t|) g^k(\sigma^{t-1}) \frac{\sum_{j \in \mathcal{I}} \frac{1}{u'_j(c^j(\sigma^{t-1}, \hat{s}_t))}}{\sum_{l \in \mathcal{I}} \frac{1}{u'_l(c^l(\sigma^{t-1}, \hat{\sigma}_t))}}} \neq p(\hat{s}).$$

Generically,  $p^{SNNL}$  is not convex because  $p^{SNNL}(\sigma_1) = p^{SNNL}(\sigma_1)$ . □
