Abstract

Entheses are acknowledged as skeletal markers capable of revealing several biological and behavioral aspects of past individuals and populations. However, enthesal changes (ECs) of juvenile individuals have not yet been studied with a systematic approach. This contribution aims at investigating the morphological changes occurring at the femoral insertion of the *gluteus maximus* and tibial origin of the *soleus* muscles to highlight a potential link between the morphological features of those entheses and skeletal maturity in relation to sex, age and locomotor developmental patterns. The sample consisted of 119 skeletons (age-at-death: 0-30 years) belonging to the Documented Human Skeletal Collection of the Certosa Cemetery (Bologna, Italy). The enthesal variation during the last stages of skeletal maturation in young adults was assessed using existing recording standards. A recording protocol for each enthesis was developed for immature individuals to subdivide the morphological variability into discrete categories. Univariate, bivariate and multivariate statistical analyses were performed to investigate the variation of enthesal morphologies and measurements in relation to bone metrics, degree of epiphyseal closure, sex, age and locomotor developmental patterns. A statistically significant relationship was observed between ECs morphological patterns and age for both entheses, while sexual differences were negligible. A relationship between ECs morphological pattern and locomotor milestones emerged only for the *gluteus maximus*. Even though further testing is needed on other documented skeletal collections, our protocol could be usefully applied in forensic and archaeological fields and serving as important reference for evolutionary investigations.

Enthesal Changes; Locomotor Development; Documented Skeletal Collections; Skeletal Maturation

1. Introduction

The entheses are the areas where tendons, ligaments and joint capsules attach to the bone (Benjamin et al., 2002), and represent the only direct evidence of the musculotendinous system on skeletal remains. The enthesal changes (ECs; this term designates all alterations of entheses seen in the skeletal material; Jurmain and Villotte, 2010) have been largely explored in the last decades. The entheses are physiologically subjected to significant mechanical stress, which inevitably leads to some reaction in the bone tissue. Even if the extent to which the mechanical stress influences enthesal morphology with respect to other factors (age, hormonal factors, etc) cannot be ascertained, entheses are widely used in the attempt to reconstruct biological and behavioral aspects (Dutour, 1986; Hawkey and Merbs, 1995; Kennedy, 1998; Weiss, 2003; Belcastro et al., 2006; Mariotti and Belcastro, 2011; Villotte and Knüsel, 2013; Belcastro and Mariotti, 2017; Belcastro et al., 2020;

Karakostis and Harvati, 2021; Karakostis et al., 2021). However, ECs expression (robusticity and pathological features) has a multifactorial etiology, where the aging process in adulthood is one of the main factors involved (Cunha and Umbelino, 1995; Robb, 1998; Mariotti et al., 2004, 2007, 2009; Villotte, 2009; Alves Cardoso and Henderson, 2010; Villotte, 2009; Villotte et al., 2010; Niinimäki, 2011; Milella et al., 2012; Villotte and Knüsel, 2013). As far as sex is concerned, some dimorphism has been observed in adults, often, but not always, corresponding to a greater enthesal robusticity in males (Mariotti et al., 2007; Alves Cardoso and Henderson, 2010; Milella et al., 2012). Different observational recording standards have been so far developed, but only on bones of adult individuals (e.g., Hawkey and Merbs, 1995; Mariotti et al., 2004, 2007; the Coimbra method by Henderson et al., 2016, 2017), while little attention has been given to the ECs during growth in juvenile skeletons.

Our previous investigations have shown different patterns in some lower limb enthesal morphologies between Neanderthals (Krapina, 130 000 BP and El Sidrón, 49 000 BP) and modern humans (Belcastro et al., 2006; Mariotti and Belcastro, 2011; Belcastro and Mariotti, 2017; Belcastro et al., 2020). Our results showed that the morphological variability of the *gluteus maximus* enthesis exceeded that observed in modern humans, while the variability of the *soleus* was comparable to modern humans'. In detail, we observed a low intrapopulation variability in each Neanderthal sample (despite small sample size) between the adult and juvenile morphology of *gluteus maximus* muscle, and a large intrapopulation variability in modern humans between the adults and juvenile individuals on the same enthesis. Furthermore, we empirically observed that modern juveniles exhibited characteristics that exceeded the variability seen in the adults and the absence of standardized recording systems hindered our ability to quantify these differences. Many entheses in the adults were completely covered by variably developed *mineralized tissue formations* (Villotte et al., 2016), formerly known as crests or ridges (Peterson, 1998; Robb, 1998; Hawkey and Merbs, 1995; Eshed et al., 2004; Mariotti et al., 2007; Milella et al., 2012). Juvenile individuals, on the other hand, systematically presented *surface discontinuities* (like diffuse porosity and furrows) covering the entire enthesal surface, as also previously observed by other authors (Matyas et al., 1990; Wei and Messner, 1996). A recording standard for juvenile entheses has been recently published by Palmer et al. (2023). However, of age (Bly, 1994) the authors just score a set of features already known in the literature (e.g., enthesophytes; cf. Villotte et al., 2016) that could be recorded on any individuals regardless to their age class. On the contrary, in the present work, we specifically investigate the variability of juvenile enthesal morphologysex and , focusing on surface architecture and texture. These features allow to univocally recognize juvenile morphologies. Additionally, we had the possibility to study a much larger sample where most of the age classes are better represented.

Our work is aimed at investigating the enthesal morphometric variability of the femoral insertion of *gluteus maximus* (hereinafter “GM”) and tibial origin of *soleus* (hereinafter “SOL”) muscles (already studied in the Neanderthal samples) in juvenile individuals in relation to age, sex and locomotor pattern during growth, adding new insights on the biological and biomechanical aspects of bipedalism, from an ontogenetic and evolutionary point of view, already explored in our research group also with other approaches (Sorrentino et al., 2020a, 2020b, 2020c, Figus et al., 2022, 2023; Pietrobelli et al., 2022a, 2022b, 2023; Colombo et al., 2019). In detail, we developed a recording standard method to better classify the enthesal (continuous) variability into discrete classes and verify its applicability in response to the locomotor pattern (detailed below). In this frame, the availability to access to the Documented Human Skeletal Collection (Belcastro et al., 2017, 2022), sampling individuals with known sex and age, allowed us for trying to meet those objectives.

1.1. GM and SOL in locomotion development

GM and SOL muscles are highly involved in human bipedal locomotion. The human gait cycle can be divided into two phases (Whittle, 2006; Neumann, 2009): a stance phase, where the foot is in contact with the ground, and a swing phase, where the foot swings before touching the ground. The GM and the SOL are both involved in the stance phase. Specifically, the GM is involved from the moment the heel contacts the ground (i.e., Initial Contact) and remains active until the moment the heel leaves the ground (i.e., Heel Rise) to promote hip extension; the SOL, instead, contracts during late mid-stance and terminal stance to promote plantar flexion and control dorsiflexion.

During the first six months after birth the infant performs precursory locomotor movements like supine kicking and supported sitting, while weight-bearing on lower limbs is completely absent (Thelen and Fisher, 1982; Thelen et al., 1984). Afterwards, the child goes through a short period (up to 8 months) of dependent/independent crawling and scooting. Infants typically gain a standing position and start cruising towards the end of the first year of life, at first while holding on to objects or caregivers for support and eventually transitioning to independent toddling (Bly, 1994; Adolph et al., 1998). From about one year of life, the toddler goes through various stages of maturation of their locomotor behavior and towards the age of 6 they acquire the mature bipedal gait typical of adults. In the early phases of toddling (i.e., between the ages of 1 and 2 years), children lean on a wide base of support, abducting their thigh and flexing their hip and knee. They point toes outwards and strike the ground with a plantigrade foot (McGraw, 1940; Forssberg, 1985; Hallemans et al., 2003; Hallemans et al., 2006a, b). As a result of a flexed hip and knee, the torso tends to lean forward causing the hip (contralateral to the standing leg) to lift during the swing phase and the pelvis to tilt from side to side (Hallemans et al., 2004; Cowgill et al., 2010). This early form of walking is typically conducted at a

slow pace, with small and jerky steps performed in bursts at irregular intervals (Hallemans et al., 2006a). Children at age 3 usually engage in a more mature toddling pattern, with improved gait, narrower and longer steps, and a loading pattern of an initial heel-strike which sees the beginning of the stride with the center of pressure under the calcaneus (Adolph et al., 2003; Ivanenko et al., 2004; Hallemans et al., 2006b; Zeininger et al., 2018; Swan et al., 2020). Finally, around age 6 (on average), a mature, stable, and efficient gait is fully acquired, as a result of the progressive increase in the femoral bicondylar angle (that adducts the knee, positioning the joint under the body's center of gravity) which leads to the correction of the *genu varum* typical of toddlers (Tardieu and Trinkaus, 1994; Swan et al., 2020).

From the locomotor behavior illustrated above, during growth, it can be deduced that the GM and SOL muscles begin to play an important role towards the end of the first year of life, i.e., when the infant begins to be able to stand and take their first steps independently. GM and SOL control respectively hip flexion and dorsiflexion during standing. The GM is certainly involved even within the first year for precursory locomotor movements such as supine kicking, dependent/independent crawling and scooting, or even during phases of assisted locomotion while holding on to objects or caregivers (Thelen and Fisher, 1982; Thelen et al., 1984; Bly, 1994; Adolph et al., 1998). On the contrary, we are not aware that the SOL (with the plantar flexion movement) plays any relevant role among the precursory locomotor movements. However, it is reasonable to think that GM and SOL begin to make a significant contribution only when external supports for locomotion disappear, and even more so when a mature and efficient bipedal locomotion is acquired around the age of 6.

Since all the entheses respond directly to the biomechanical stimuli imparted by muscle activity we believe it is very important to take the locomotor development into account as a potential etiological agent of any enthesal modifications in subadults.

125

126 **2. Materials and Methods**

In this work we examine the morphometric variability of the femoral insertion of the *gluteus maximus* muscle (GM) and tibial origin of the *soleus* muscle (SOL). Both entheses are fibrous (Havelková and Villotte, 2007; Villotte, 2009; Mann and Hunt, 2012, p. 204; Weiss, 2015; Milella et al., 2020; Villotte and Santos, 2022. entheses).

The sample consists of 119 skeletons of juvenile individuals aged from birth to 30 years (Table 1) belonging to the Documented Human Skeletal Collection of the "Certosa" Cemetery of Bologna (Italy), for which the personal data are known from the cemeterial records (Belcastro et al., 2017, 2022). A subsample of young adults was included in order to observe the morphological variation of the entheses with respect to the last stages of skeletal maturation. Only well-preserved individuals

were included in this research, discarding all those where it was impossible to evaluate at least one enthesis on a femur or tibia (i.e., due to taphonomic alterations). Furthermore, the enthesis was considered recordable if at least 50% of its surface was not damaged. Individuals whose femurs or tibiae showed evidence of pathologic conditions (e.g., presence of abundant woven bone, deformations of the diaphysis) were also discarded. The individuals analyzed in this study were divided into 7 age classes (Table 1), where the first two age classes were designated considering the information present in the literature about the early stages of acquiring bipedal gait:

- **Age class 1 (<1 years):** bipedal locomotion is absent (Thelen and Fisher, 1982; Thelen et al., 1984; Bly, 1994; Adolph et al., 1998).
- **Age class 2 (1-5.9 years):** bipedal locomotion is present but still immature (toddling). This is therefore a long transitory phase that goes from a rudimental and still dependent locomotion to a mature gait (McGraw, 1940; Forssberg, 1985; Adolph et al., 2003; Hallemans et al., 2003, 2004; Ivanenko et al., 2004; Hallemans et al., 2006a, b; Cowgill et al., 2010; Zeininger et al., 2018; Swan et al., 2020; Pietrobelli et al., 2022a).
- **Age class 3 (6-10.9 years), 4 (11-15.9 years), 5 (16-20.9 years), 6 (21-25.9 years), 7 (26-30 years):** even though from the age of 6 a bipedal gait is already completely acquired, the remaining individuals have also been divided into quinquennial classes, (except for the last one which covers 4 years) to identify any possible morphological changes in entheses in relation to bone lengthening (classes 3-5) and enthesal “settlement” once the definitive stature has been reached (classes 6-7).

We examined juvenile femurs and tibiae without considering the age *a priori*. The variation observed at the GM was subdivided into 3 morphological classes, whereas variation at the SOL was subdivided into 4 morphological classes, as described in Table 2 and depicted in Figures 1-7. At each morphological class we arbitrarily assigned a number that is not in a predefined order. The assessment of ECs on GM and SOL in juvenile individuals was therefore performed following a new descriptive and photographic standard we created for this purpose (Table 2; Figures 1-7). For each morphological class, photographs of four entheses belonging to four different individuals were provided to better illustrate the variability within the single morphological classes (Figures 1-7). The entheses which were completely covered by *mineralized tissue formations*, in particular characterized by *diffuse cortical irregularities* and *longitudinal protrusions* (typical features of adult individuals) have been assessed with Mariotti et al. (2007) method for enthesal robusticity.

We proceeded taking the linear dimensions of the entheses with a digital sliding caliper (resolution: 0.001 mm):

- The **enthesal length** was taken by measuring the distance between the most proximal and most distal extremities, following the longitudinal axis of the enthesis, regardless of its relative

170 orientation to the bone length. In the case of GM, a possible third trochanter must be included in the
171 measurement, as part of the enthesis. Both extremities must be clearly visible, otherwise the
172 measurement must be considered non-recordable.

173 • The **enthesal width** was measured at maximum width, therefore according to the transversal
174 axis of the enthesis. Regarding the GM, it is essential that the proximal half of the enthesis is intact,
175 as in this area the gluteal tuberosity is very often wider and more evident. If not, the width must be
176 considered non-recordable. Concerning the SOL, at least the 50% of the enthesis must be intact,
177 regardless of whether it is proximal or distal, as the enthesis does not appear to have significant
178 variations in width along its attachment.

179 The stage of development of femurs and tibiae was assessed by determining of the degree of
180 epiphyseal closure and bone size. The degree of epiphyseal closure was assessed following the
181 Belcastro et al. (2019) method, which provides a five-degree assessment standard. For statistical
182 convenience, the different degrees of closure of the epiphyses evaluated with this method were
183 reduced to three: 0 corresponds to not fused (equivalent to grade 0), 1 corresponds to partially fused
184 (equivalent to grades 1 and 2) and 2 corresponds to totally merged (equivalent to grades 3 and 4).
185 This adaptation was then extended to the whole bones to assign an overall assessment of its state of
186 maturation: in grade 0 none of the epiphyses are fused, in grade 1 at least one epiphysis is at closure
187 stage 1 or 2, and in grade 2 all bone epiphyses must be fully fused (grade 3 and 4).

188 Linear measurements of maximum length and transverse diameter at midshaft were taken
189 following the protocols provided by Martin and Saller (1957). Immature bones were instead measured
190 according to Fazekas and Kósa's (1978) protocol. The measurements were considered non-recordable
191 if the cortical bone at the landmarks was damaged.

192 All statistical analyses were performed in R v.4.2.2. To test the validity of this method to
193 morphometrically assess the GM and SOL entheses, intra- and inter-observer errors were evaluated
194 calculating the Cohen kappa coefficient (κ – Cohen, 1960, 1968) and the accuracy for qualitative
195 variables (i.e., the morphological standards), while the intraclass correlation coefficient (ICC – Fisher,
196 1954) was opted for the quantitative variables (i.e., all the linear enthesal measurements). The author
197 who executed the inter-observer error had no previous experience on the study of ECs of GM and
198 SOL in juvenile individuals.

199 Chi-squared tests (X^2) (Pearson, 1900) were performed to test differences in sex and age
200 distribution within the sample and a t-test (Student, 1908) was calculated to evaluate a possible
201 asymmetry between the left and the right side. Descriptive statistics (mean, standard deviation,
202 median, minimum and maximum values) were calculated for each measurement and grouped by age
203 class and sex. The distribution of the morphological classes of GM and SOL by age and sex was

represented through boxplots. Normality distribution was assessed with a Shapiro-Wilk normality test (Shapiro and Wilk, 1965). Fisher's exact tests of independence (Fisher, 1934) were calculated to study the distribution of the morphological classes of entheses by sex, by age classes and by sex within the single age classes. Wilcoxon rank-sum tests (Wilcoxon, 1945) were performed to analyze the linear measurements in relation to sex within the age classes. The data were also investigated for possible correlations performing Spearman's tests (Spearman, 1904) between the morphological classes of the entheses and age, linear measurements and epiphyseal closure degree; linear regression models have also been developed for these same variables. The data were finally analyzed performing a Factor Analysis of Mixed Data (i.e., FAMD) using the "FactoMineR" (Lê et al., 2008) and "factoextra" (Kassambara and Mundt, 2020) packages. Specifically, the following variables were included in the FAMD: sex, age, age classes, enthesal morphological classes, linear measurements of the bones and entheses and degree of epiphyseal closure. For this purpose, missing data were replaced with each variable's median value for linear measurements, calculated for each age class and sex.

3. Results

No significant differences were found in the distribution of the sexes by age ($X^2 = 59$; p -value > 0.05), but differences were detected in the distribution of individuals among the age classes ($X^2 = 82.6$; p -value < 0.0001). In fact, age class 1 is largely the most represented (especially by males), while age classes 3, 4 and 7 are the least represented. In age class 4 the females are totally absent (Table 1). No differences were found between left and right limb, therefore all the following statistical analyzes were performed only on the left limb. Since not all variables followed a normal distribution or were homoscedastic, nonparametric tests were chosen for the univariate and bivariate statistical analyzes.

The results of the intra- and inter-observer errors are shown in Table 3. The intra-observer results show a high reliability, both concerning the morphological standards and the linear enthesal measurements. The inter-observer results, instead, show very reliable results concerning SOL_morph and all the linear enthesal measurements of GM, while a poorer but still fair/moderate reliability (Landis and Koch, 1977; Koo and Li, 2016) resulted regarding GM_morph, SOL_length and SOL_width.

The most represented morphological classes of GM are GM1, GM2a and GM2b, with a way larger male contribution in class GM2a; regarding the SOL, the most represented morphological class is SOL3 (Table 4). For both GM and SOL, statistically significant differences were only found among age classes. Within age classes significant differences between sexes emerged only in GM in age class 1 (Table 4). Figure 8 shows for both sexes that as the age increases, morphological classes

238 GM2a, GM2b, GM1 and GM3 follow one another almost without overlapping. A similar pattern can
239 be seen for SOL, where SOL1+SOL2, SOL3 and SOL4 seem to follow one another, even though
240 there does not appear to be a clear separation between SOL1 and SOL2.

241 Table 5 and Table S1 (i.e., the extended version of Table 5) show the descriptive statistics for
242 linear measurements of bones and entheses by sex and age classes and the results of the Wilcoxon
243 rank-sum test performed by sex within the age classes for each continuous variable; the results of the
244 age classes 3, 4 and 7 and the result of the enthesal length of SOL (SOL_length) in class 1 were not
245 reported due to the small number of observations. By and large females show comparable
246 measurements to males during growth, except for the bone diameters in age class 1
247 (Femoral_diameter and Tibial_diameter). A more marked sexual dimorphism begins to appear from
248 age class 5. In general, all measurements tend to increase with age.

249 Table 6 shows the results of the Spearman correlation and linear regression performed
250 between the enthesal morphological classes and age and other variables inherently correlated with
251 age (linear measurements of bones and entheses and epiphyseal closure), both with the distinction
252 between the sexes and together. To perform correlation and linear regressions, it was necessary to
253 convert the morphological classes into ranks. Since the descriptive statistics relating to the
254 morphological classes of GM, more specifically in Figure 8, showed a clear sequence in relation to
255 the age of morphologies GM2a, GM2b, GM1, GM3 and Mariotti subclasses, it was preferred to assign
256 the ranks consistently with this pattern. Regarding the morphological classes of SOL, the rank
257 conversion was performed following the original sequence (SOL1, SOL2, SOL3, SOL4, Mariotti
258 subclasses), as it did not show big discrepancies compared to the pattern shown in the Figure 8. In all
259 the cases, all the considered variables resulted strongly and positively correlated with the
260 morphological classes assigned to the two entheses. Most of the linear regressions show a good
261 predictive power ($r^2 > 0.5$), except for all the linear measurements of tibia and SOL.

262 Two FAMDs were calculated, one for the GM and all the variables regarding the femur and
263 one for SOL and all the variables regarding the tibia (Figures 9 and S1). In the FAMD calculated for
264 GM morphological classes and related variables, Dim1 explains the 34% of the variance of the
265 dataset, while Dim2 explains the 9% (Figure 9a, b; Figures S1a and S2a). In the FAMD for SOL
266 morphological classes and related variables, instead, Dim1 explains the 37.5% of the variance of the
267 dataset, while Dim2 explains the 9.2% (Figure 9c, d; Figures S1b and S2d). In both cases, Dim1 is
268 mostly driven by age classes, age, all linear measurements, degree of epiphyseal closure and
269 morphological classes (Figure S2b, e); age classes, morphological classes and the degree of
270 epiphyseal closure highly contribute to Dim 2 too (Figure S2c, f). In both cases sex contributed very
271 little (Figures S1a, b and S2b, c, e, f). As far as the GM and femoral variables are concerned (Figures

9a, b and S1a), Dim 1 clearly separates GM2 and GM3+Mariotti subclasses while GM1 encompasses almost all the variability along Dim1, but only considering its confidence interval. A pattern is thus visible (especially by observing the points), which sees a succession among the morphological classes GM2a, GM2b, GM1 and GM3. Dim2 explains the separation between GM1+GM2 and Mariotti subclasses, while GM3 overlaps with Mariotti for higher values and with GM1+GM2 for lower values of Dim2 (Figure 9a). The age classes follow the same pattern, where age classes 1, 2, 3, 4 and 5 plot close to morphologies GM2a, GM2b and GM1, while age classes 6 and 7 are closer to GM3 and the Mariotti subclasses (Figure 9a). Figure 9b shows a complete separation along Dim1 between the individuals who present unfused femoral epiphyses and who present a partial or total state of closure. Morphological classes GM2a and GM2b are strongly associated to unfused femoral epiphyses, GM1 is associated to both unfused and partially/totally fused epiphyses, GM3 is associated to both partially and totally fused epiphyses, and Mariotti subclasses are all associated to totally fused epiphyses. Regarding the SOL and tibial variables (Figure 9c, d; S1b), the morphological classes SOL1+SOL2, SOL3 and SOL4 separate from one another along Dim1, while the separation among SOL4 and the Mariotti subclasses is better explained by Dim 2, although they are still largely overlapped, especially in the negative values of Dim2 (Figure 9d). The confidence intervals of SOL1 and SOL2 do not separate neither along Dim1 nor along Dim2, resulting largely overlapped (Figure 9c); furthermore, SOL1 and SOL2 morphologies fall entirely within the confidence interval of SOL3 (for more negative values), however, the overlap between the points is minimal. The age classes follow the same pattern, where age classes 1, 2, and 5 plot closer to morphologies SOL1, SOL2, SOL3 and SOL4, while age classes 6 and 7 result closer to the Mariotti subclasses (Figure 9c). Figure 9d shows a complete separation along Dim1 between the individuals who present unfused tibial epiphyses and who present a partial or total state of closure. Morphological classes SOL1, SOL2 and SOL3 are strongly associated to unfused femoral epiphyses, while class SOL4 and Mariotti subclasses are associated to partially and totally fused epiphyses. The packages FactoMineR and factoextra excluded the age classes 3 and 4 from the calculation of this FAMD because some variables were not represented in these age classes (i.e., SOL_length in both age classes 3 and 4, SOL_width as regards the females of age class 4).

4. Discussion

Our work sheds light on the variability of ECs during growth highlighting the influence of age, sex and locomotor development.

The results concerning the calculation of the errors (Table 3) showed an overall lower agreement on the inter-observer error, especially on the morphological standard of GM (GM_morph),

306 enthesal length of SOL (SOL_length) and width (SOL_width). As far as concerns GM_morph, the
307 disagreement was almost entirely caused by a difficulty in recognizing the GM1 morphology,
308 specifically, the second observer tended to recognize as GM3 the entheses that the first observer,
309 creator of the standard, recognized as GM1. The discrepancy observed for SOL_length and
310 SOL_width is likely due to the fact that this enthesis is often discontinuous and not well-defined,
311 especially in its proximal extremity. The potential difficulty in identifying clear boundaries in
312 entheses has already been raised in the past (Zumwalt, 2005), however, it was not an obstacle to the
313 research as the most uncertain measures were removed from the analysis.

314 The morphological variability observed on entheses is continuous, it is self-evident that it is
315 very difficult to divide it into discrete categories and therefore to grasp recurring characteristics.
316 fssStudies on enthesis are generally affected by the experience of the observer (Wilczak et al.,
317 2017), however, the protocol here proposed has the advantage of being easily usable, with acceptable
318 levels of repeatability, and of allowing the evaluation of numerous samples without the need of
319 expensive equipment.

320 Remarkable **sex differences** emerged neither in the univariate nor in the multivariate statistics
321 (Table 4; Figure S1a, b). The distribution of morphological classes of both GM and SOL do not differ
322 between the sexes, except for a slightly significant difference within age class 1 in GM (Table 4),
323 probably related to the imbalance of the *sex ratio* present in this age class: firstly, because there are
324 way more males than females (Table 1), secondly, because the youngest individuals of age class 1
325 are male, while the oldest are mostly female (10 females vs 25 males in the first 6 months, and 10
326 females vs 3 males in the last 6 months). It is likely that this imbalance is also responsible for the
327 significance that emerged in the same age class as regards the transverse diameter at midshaft of the
328 femur (Femoral_diameter) and tibia (Tibial_diameter), which sees higher dimensions in females
329 rather than males (Tables 5 and S1). Apart from the differences just mentioned, we did not observe
330 significant sex differences in measurements in the first three age classes (i.e., from birth to 10.9 years
331 of age), contrary to what reported in literature for other metric variables (e.g., Malina and Johnston,
332 1967; Humphrey, 1998; Stull and Godde, 2012; Stull et al., 2017; Luna et al., 2017; Marino et al.,
333 2020). The present study also disagrees with Gonen Aydin et al. (2021), who observed differences
334 between sexes in the gait cycle pattern.

335 Fisher's exact test of independence (Table 4), Spearman correlation tests and linear
336 regressions (Table 6) and the FAMDs (Figure 9 and S2) reveal the significant role of **age** in explaining
337 variation among the morphological classes of both GM and SOL. Indeed, several studies conducted
338 on adults highlighted a strong relationship between enthesal morphological features and age
339 (Hawkey and Merbs, 1995; Peterson, 1998; Robb, 1998; Eshed et al., 2004; Mariotti et al., 2007;

Alves Cardoso and Henderson, 2010; Milella et al., 2012). This is immediately evident in the descriptive statistics (Figure 8), where the different morphologies follow one another in order of age and characterize well-defined age intervals, especially as regards the GM morphological classes. This pattern and the close relationship with age tends to be less clear considering the Mariotti subclasses (we remind that Mariotti and colleagues' assessment method is applicable on adult individuals only, in this case on long bones with fully closed epiphyses). The FAMD divided by morphological class of the GM (Figure 9a) shows a pattern that sees a distancing between the new morphological classes (i.e., GM2a, GM2b, GM1 and GM3) along Dim1, where age and related variables play a predominant role (Figure S2b), despite a partial overlapping of the confidence intervals. A similar pattern can be seen in the FAMD divided by the morphological classes of the SOL (Figure 9c): the new morphological classes (i.e., SOL1, SOL2, SOL3 and SOL4) result divided along Dim1, with the exception, however, of classes SOL1 and SOL2, whose centroids are very close to each other. On the other hand, for both GM and SOL, the variability of individuals associated with the Mariotti subclasses is best explained by Dim2, where the linear dimensions of bones and entheses play a secondary role (Figure S2c, f), as growth has ceased. Furthermore, the confidence intervals of the single Mariotti subclasses do not separate considerably: this result is not surprising, as there were very few individuals with an enthesis characterized by a complete *mineralized tissue formation* (and therefore detectable with the method developed on adult samples by Mariotti et al., 2007), moreover, 5 morphological subclasses were considered, which are a lot compared to the few individuals.

As regards the relationships between enthesal morphology and **locomotor** milestones, we here consider the EC patterns observable within the first two age classes, as the child acquires a mature locomotor behavior by the age of six (i.e., by the end of age class 2) with the correction of the *genu varum* (Tardieu and Trinkaus, 1994; Swan et al., 2020). For the GM, the GM2a morphology seems to uniquely characterize age class 1, while morphology GM2b characterizes age classes 1 and 2, but with a greater frequency in age class 2. This morphological switch may reflect a locomotor pattern, in fact, just at the end of the first year of life (i.e., age class 1) the infant begins to take their first steps independently (Bly, 1994); therefore, we hypothesize that this new stimulus may represent the cause of this morphological change. Until the age of six, toddlers present a poorly accentuated bicondylar angle of the femur, which causes poor medio-lateral control during locomotion (Tardieu and Trinkaus, 1994; Swan et al., 2020). This skeletal feature causes a “waddling” gait (Cowgill et al., 2010) which we suppose could affect the GM enthesal morphology in this phase. The hypothesis that morphology GM2b may be determined by an immature locomotor behavior is supported by the fact that from age class 3, when the child has fully acquired a complete bipedal locomotion, morphology GM2b disappears, leaving room for morphology GM1 only, characterized by a fine

374 porosity and a much smoother surface. The overlap between GM2a and GM2b in class 1 and between
375 GM2b and GM1 can reflect variability among children in the maturation of their locomotor skills
376 (Bly, 1994). The close relationship between gait biomechanics and age here proposed is also
377 supported by Froehle et al. (2013) and Liu et al. (2022).

378 The relationship between the morphology of the entheses and locomotor milestones is not
379 clear for SOL instead: age class 1 is characterized by morphology SOL1, SOL2, but above all by
380 SOL3, which is present up to age class 5 (Table 4). Probably these morphologies are not associated
381 to a particular locomotor pattern. One reason that can explain this big difference between the two
382 entheses is that the stimulus imparted from the two entheses on the bones can differ for several
383 reasons. Firstly, the SOL enthesis is an origin, moreover, shared with another bone (i.e., the fibula);
384 on the other hand, the GM enthesis is an insertion, which consequently has to bear a much greater
385 effort since it is located on the bone that performs the movement. Firstly, the SOL enthesis serves as
386 an origin (with another end originating from the fibula). In contrast, the GM enthesis functions as an
387 insertion and is therefore subject to a significantly greater effort due to its location on the bone
388 responsible for the movement. This anatomo-functional difference could also explain why the
389 insertion of the GM on the femur is always visible and much more defined than the tibial origin of
390 the SOL. Moreover, the GM muscle seems to activate before the SOL muscle during life, in fact, it
391 seems to be already involved in the precursory locomotor movements, while the SOL does not seem
392 to have any noteworthy role before the acquisition of an upright posture (Bly, 1994).

393 Regarding the relationships between enthesal morphology and **epiphyseal closure**, in both
394 the entheses here analyzed, a single morphology dominates in age class 3 (6-10.9 years of age), which
395 are morphological classes GM1 and SOL3 (Table 4). In the following phases, the entheses seem then
396 to evolve into forms characterized by a *mineralized tissue formation* typical of adults (Villotte et al.,
397 2016). In both entheses, however, this shift from a “juvenile-like” to an “adult-like” morphology does
398 not seem to be sudden, in fact, it goes through a sort of “transitional” phase in which a coexistence of
399 typically adult (raised areas) and juvenile (porotic or furrowed zones) characteristics is observed:
400 these are respectively morphology GM3 (Table 4; Figures 3, 8 and 9a) and morphology SOL4 (Table
401 4; Figures 7, 8 and 9c). This relevant morphological change, or rather at this point, this maturation
402 process of the enthesis, could be triggered by the closure of the epiphyses, that marks the end of the
403 long bone lengthening and thus the “migration” of the enthesis along the diaphysis (Hoyte and Enlow,
404 1966; Dörfl, 1980a, 1980b; Hurov, 1986). This hypothesis may be supported by the results of the
405 FAMD divided by the degree of epiphyseal closure (Figures 9b, d). In Figure 9b, relating to the
406 enthesis of the GM, morphology GM3 and the Mariotti subclasses (typical of adults) are strongly
407 associated with individuals who present partially or totally fused epiphyses. GM1 instead appears to

be associated with all closure degrees, but more commonly with unfused and partially fused epiphyses, while morphological classes GM2a and GM2b are exclusively associated with unfused epiphyses. Given the observed pattern, considering the close correlation between morphologies and age (Table 6) and the division between morphologies observed in Figure 9a, it can be hypothesized that morphology GM1 remains for a short period when the epiphyses begin to fuse, after which a process of gradual mineralization of the enthesis begins and finally leads to a complete ridge.

The enthesis of SOL shows the same pattern (Figure 9d): the “transitional” morphology SOL4 and the Mariotti subclasses for SOL (typical of adults) are strongly associated with individuals who present at least partially fused tibial epiphyses, in which, therefore, bone lengthening has already ceased. Morphological class SOL3, although associated much more with unfused epiphyses, is also present in several individuals with partially fused ones, while morphological classes SOL1 and SOL2 are only associated with unfused epiphyses. The same conclusions drawn for the GM can reasonably be applied on the SOL as well, so considering the close correlation between morphologies and age (Table 6) and the division between morphologies observed in Figure 9c, it can be hypothesized that morphology SOL3 remains for a short period when the epiphyses begin to fuse, after which a process of gradual mineralization of the enthesis begins, finally leading to a complete ridge.

These transformations observed in GM and SOL entheses are attested by the possible presence of woven bone in the “transitional” morphologies GM3 and SOL4 (Table 2, Figures 3 and 7), which may be an indicator of ongoing mineralization (White et al., 2012; Cunningham et al., 2016, pp: 26–29, 34–35).

To sum up, we saw a transformation from a very irregular appearance typical of subadults to a *mineralized tissue formation* in variable degrees of expression (Mariotti et al., 2007). The porotic or furrowed surface of juvenile entheses could therefore be symptoms of a strong bone remodeling due to the migratory process, as Hoyte and Enlow (1966), Dörfl (1980a, 1980b) and Hurov (1986) proposed, which prevents the mineralization of the bone-tendon interface.

5. Conclusions

The present work sheds light on aspects never explored before, providing new important insights into the variability of ECs in modern juvenile individuals. In particular, we gathered more consistent data than before (cf. Belcastro et al., 2020) on the modern juvenile morphological variability. It would be interesting to enlarge the small sample of Neanderthal adult and juvenile entheses to perform more consistent comparisons between the intrapopulation variability of these different human populations.

Through the application of our morphometric recording standard for modern juvenile individuals, we highlight a very clear relationship between the morphometric changes affecting the

entheses of GM and SOL muscles and age. For the GM, also a relationship between the morphological ECs and locomotor milestones seems to be observed. Another interesting perspective of this study is the possibility of using these features in subadult-young adult age estimation, with possible applications in bioarcheological and forensic fields. In fact, these methods would permit to estimate the age of juvenile individuals, even from fragmented bones, provided that the enthesis is preserved.

A future goal will certainly be to test our protocol on other documented juvenile skeletal collections, especially enlarging the sample in less represented age classes in this study, in order to deepen the understanding of the relationship between enthesal morphometric changes and development, also in an evolutive perspective.

Table 2. Morphological standard for GM (**top**) and SOL (**bottom**) entheses.

GM_morph ¹	Description
GM1	The enthesis is defined by a diffuse dense <i>fine porosity</i> (Figure 1).
GM2	The enthesis is defined by a <i>furrowed surface</i> (Figure 2). If the enthesis is mainly characterized (for more than 50% of its surface) by furrows arranged neatly between each other and oriented longitudinally with respect to the length of the diaphysis, assign the morphological subclass GM2a (Figure 2, top); if, on the other hand, the enthesis is characterized mainly (for more than 50% of its surface) by regions in which the furrows have a disordered disposition, then assign the subclass GM2b (Figure 2, bottom). In cases where a mixed morphology occurs, neatly oriented furrows are usually found proximally, while messily oriented furrows are more commonly found distally.
GM3	The enthesis is characterized by a mixed morphology: the same enthesis shows regions with <i>diffuse cortical irregularity</i> and/or a <i>longitudinal protrusion</i> and others with a rather smooth surface defined by a <i>fine porosity</i> or smooth <i>furrows</i> . The <i>mineralized tissue formations</i> can generally be found from the proximal border and along the medial border of the enthesis, while the finely porous smooth surface is generally prevalent at the distal and lateral border, thus tracing a proximal-distal pattern. The <i>mineralized tissue formations</i> can be covered by a layer of <i>woven bone</i> , either continuously or discontinuously (Figure 3).

SOL_morph ²	Description
SOL1	The enthesis is totally indistinguishable, there is no type of morphological discontinuity between the enthesal area and the surrounding bone (Figure 4).
SOL2	The inferolateral border of the triangular surface covered by the <i>popliteus</i> muscle is sharply defined by the soleal line, which separates an area of porous-looking bone (i.e., the triangular “popliteal” surface – Cunningham et al., 2016, pp: 415–416) from the cortical surface distal to it. The enthesis appears only as a line with no width (Figure 5).
SOL3	The enthesis is defined by <i>furrowed surface</i> with short and shallow furrows. The furrows may enclose oval-shaped pores (Figure 6).
SOL4	The enthesis is characterized by a mixed morphology: the same enthesis shows regions with <i>diffuse cortical irregularity</i> and/or a <i>longitudinal protrusion</i> and others with a <i>finely porous/furrowed surface</i> . The two morphologies coexist on the same enthesis and can appear discontinuously along it, but the <i>mineralized tissue formations</i> occur more frequently in the distal portion of the enthesis, while the porotic/furrowed surface proximally, thus tracing a distal-proximal pattern. The <i>mineralized tissue formations</i> can be covered by a layer of <i>woven bone</i> , either continuously or discontinuously (Figure 7).

Note. If more more than 50% of the enthesal surface is damaged the evaluation must be considered nonrecordable (NR).

¹: All juvenile GM morphologies can be either on a flat surface or in a fossa; in some cases, especially when the enthesis presents a fossa, the borders of the enthesis can be angled and well evident and should not be confused with a longitudinal protrusion. In GM3 the *mineralized tissue formations* never affect the entire surface of the enthesis, and this distinguishes this morphology from those typical of adults (Mariotti et al., 2007).

²: The trace of the SOL enthesis is often discontinuous and there are areas where the trace is totally absent, most often in its proximal half. In younger individuals, the proximal portion of the enthesis can be indistinguishable among the porosity that characterizes the popliteal surface. In these cases, the morphologic assessment must necessarily be performed in its visible portion. In morphological classes SOL2, SOL3 and SOL4 a fossa can be present, which can be constituted by a single or more different sunken areas on the same enthesis.

Abbreviations: GM_morph, morphological classes of *gluteus maximus*; SOL_morph, morphological classes of *soleus*.
