11 **Abstract**

12 Current models of human fear learning processes emphasize a primary contribution of the
13 ventromedial prefrontal cortex (vmPFC) to fear inhibition (i.e., fear extinction). Here, we discuss
14 crucial findings from recent brain imaging studies that highlight the role of vmPFC and its
15 subregions in how fear is acquired (i.e., fear conditioning).

16 Since the dawn of psychology, fear conditioning paradigms have been successfully used to reveal
17 the psychological processes that govern the acquisition and expression of emotional memories and
18 their neurobiological underpinnings. From an evolutionary perspective, learned fear serves to
19 activate defensive behaviours in anticipation of harm, thus supporting an organisms' chances of
20 survival and well-being. Fear conditioning has moved beyond the realm of associative learning
21 theory to become a framework of substantial interest in the neuroscience of learning, memory, and
22 emotion. Neural circuits have been mapped, synaptic plasticity in these circuits has been identified,
23 and biochemical and genetic investigations are beginning to disentangle the molecular mechanisms
24 responsible for the storage and expression of fear memories. It is anticipated that these advances
25 will improve our understanding of common mental health conditions characterized by pathological
26 fear and lead to future optimized treatments. However, despite a century of research, the neural
27 circuitry underlying human fear-learning is still a matter of debate. One important issue in this
28 regard relates to the contribution of the ventromedial prefrontal cortex (vmPFC) and its subregions.
29 Specifically, while the predominant view of vmPFC function is that it underlies successful *fear*
30 *extinction* [1, 2], recent work suggests that it may also play a major role in *fear conditioning* [3–5],
31 as processed within its posterior subregion [6].

32 In 2020, Battaglia et al. provided direct evidence that naturally occurring bilateral lesions
33 centred on the human vmPFC compromised fear conditioning as measured via skin conductance
34 responses [3]. In this study, patients showed impaired fear conditioning (similar responses to

35 conditional (CS+) and non-conditional (CS-) stimuli), when compared to patients with a lesion
36 outside of the vmPFC and healthy participants. Furthermore, impaired fear conditioning was found
37 to be selectively correlated with vmPFC damage in a mid-posterior subregion corresponding with
38 Brodmann area (BA) 11 (see Figure 1A). Although classical studies have shown abnormal SCR
39 generation following a similar brain injury [7], vmPFC lesions in the Battaglia study were not found
40 to compromise unconditional responses. This study demonstrated on a psychophysiological level
41 that fear conditioning was impaired due to the patient's brain injury and thus, provided potential
42 causal evidence of a crucial role of the mid-posterior vmPFC in the *acquisition* of fear. Importantly,
43 this recent evidence finds support in the meta-analysis of Fullana et al. (2016), which summarized
44 27 independent functional MRI human fear conditioning experiments [4]. Specifically, in a sub-
45 analysis that compared early and late phases of fear conditioning (threat vs safety, CS+ vs CS-)
46 across several studies, greater activation of the posterior vmPFC (BA11) was prominently observed
47 during *late conditioning* (see Figure 1B).

48 These recent observations, which support a facilitatory role of the posterior vmPFC in fear
49 conditioning, have emerged in comparison to broader evidence linking the vmPFC to fear
50 regulatory processes, including fear extinction and safety learning. In the Fullana et al., fear
51 conditioning meta-analysis, it was shown that the anterior vmPFC, in particular, was consistently
52 activated during safety vs threat (CS- vs CS+) presentations, adding to earlier imaging findings [1]
53 (see Figure 1C). Separately, earlier evidence from brain imaging studies suggests that vmPFC
54 activity is *negatively* correlated with sympathetic arousal [2]. However, recent evidence has
55 identified *positive* associations between these variables [2, 8]. These conflicting findings suggest
56 potentially distinct contributions of anterior vs posterior subregions of the vmPFC to affective
57 processes. On the specific topic of fear and safety learning, Tashjian and colleagues have recently
58 hypothesized that fear (i.e., threat) and safety computations can be reliably parsed along a gradient
59 of function that spans posterior-to-anterior vmPFC [6]. In support of this claim, Tashjian and
60 colleagues marshal evidence – synthesized broadly across imaging studies – to suggest that
61 posterior vmPFC activity prepares organisms for anticipated threat, but that the anterior vmPFC, a
62 region with distinct functional connectivity from its posterior counterpart, cues safety both in the
63 presence and absence of threat. Noting that the anterior vmPFC is a central hub of metacognition
64 and the default mode network (DMN), the authors suggest that its role in “safety-seeking” may
65 represent an attempt to restore equilibrium [6]. This hypothesis has been previously advanced in
66 Harrison et al. (2017), which demonstrated that greater anterior vmPFC activation in response to a
67 safety signal (CS-) (see Figure 1D) correlated with increased ratings of positive affect towards it –

68 suggesting that anterior vmPFC, as a core region of the DMN, likely computes the self-oriented
69 value or meaning of safety signals [5].

70 Together, these recent findings suggest a broader model of vmPFC function in fear learning
71 and call for a greater focus on studying the contribution of vmPFC subregions [3–6]. The results of
72 these studies might change not only how the neurobiology of human fear learning is characterized
73 but also help refine existing clinical translational models of aberrant fear learning neural processes.
74 In these efforts, it will be important to understand more precisely the computational neural
75 dynamics through which vmPFC subregions underlie fear learning processes, as well as their
76 principal interactions with extended subcortical and cortical components of the brain’s so-called
77 ‘fear circuit’. Methodological innovation will be key in this endeavour [9], but keeping in mind the
78 need for reproducibility and replication – a noted area of concern in this field of research [10].
79 Other approaches (e.g., conditioned fear inhibition) are likely to be important for understanding
80 more discrete fear learning neural processes, including the characterization of excitatory versus
81 inhibitory mechanisms. Clinical hypotheses could be tested. For example, lesions of vmPFC
82 subregions could be associated with an increase or decrease in fear acquisition (i.e., fear symptoms
83 after a traumatic experience) depending on the location of the lesion (i.e., posterior vs anterior).

84 In conclusion, a necessary effort still needs to be made to understand the unclear functional
85 interplay within the vmPFC sub-regions as well as with the other brain structures implicated in
86 human fear learning. Thus, the challenge of the upcoming decade for research in this theoretical
87 framework must be to provide more causal-direct evidence of specific functional-contribution of
88 vmPFC to processing safety-threat information or their relative value, and how specifically vmPFC
89 orchestrates the acquisition of fear.
