17 Highlights

- 18 Optimal LED light intensity for lettuce and basil indoor growing is addressed;
- 19 Maximum yield and leaf area is achieved at 250 μ mol m⁻² s⁻¹;
- 20 $250 \mu mol m^{-2} s^{-1}$ increased chlorophyll and improved stomatal functions in leaves;
- 21 In lettuce, PPFD \geq 200 µmol m⁻² s⁻¹ raised antioxidant capacity, phenolics and flavonoids;
- 22 Water, energy and light use efficiencies were optimized at 250 μ mol m⁻² s⁻¹;

24 Abstract

25 Indoor plant cultivation systems are gaining increasing popularity because of their ability to meet the needs of 26 producing food in unfavourable climatic contexts and in urban environments, allowing high yield, high quality, 27 and great efficiency in the use of resources such as water and nutrients. While light is one of the most important 28 environmental factors affecting plant development and morphology, electricity costs can limit the widespread 29 adoption of indoor plant cultivation systems at a commercial scale. LED lighting technologies for plant 30 cultivation are also rapidly evolving, and lamps for indoor cultivation are often designed to optimize their light 31 emissions in the photosynthetically active spectrum (i.e. red and blue), in order to reduce energetic requirements 32 for satisfactory yield. Under these light regimens, however, little information is available in literature about 33 minimum photosynthetic photon flux density (PPFD) for indoor production of leafy vegetables and herbs, while 34 existing literature often adopts light intensities from 100 to 300 µmol m⁻² s⁻¹. This study aims at defining the 35 optimal PPFD for indoor cultivation of basil (Ocimum basilicum L.) and lettuce (Lactuca sativa L.), by linking 36 resource use efficiency to physiological responses and biomass production under different light intensities. Basil 37 and lettuce plants were cultivated at 24°C and 450 µmol mol⁻¹ CO₂ under red and blue light (with red:blue ratio 38 of 3) and a photoperiod of 16 h d⁻¹ of light in growth chambers using five PPFD (100, 150, 200, 250 and 300 39 µmol m⁻² s⁻¹, resulting in daily light integrals, DLI, of 5.8, 8.6, 11.5, 14.4 and 17.3 mol m⁻² d⁻¹, respectively). A progressive increase of biomass production for both lettuce and basil up to a PPFD of 250 µmol m⁻² s⁻¹ was 40 41 observed, whereas no further yield increases were associated with higher PPFD (300 µmol m⁻² s⁻¹). Despite the highest stomatal conductance associated to a PPFD of 250 µmol m⁻² s⁻¹ in lettuce and to a PPFD ≥200 µmol m⁻² 42 s⁻¹ in basil, water use efficiency was maximized under a PPFD \geq 200 µmol m⁻² s⁻¹ in lettuce and PPFD \geq 250 µmol 43 44 m⁻² s⁻¹ in basil. Energy and light use efficiencies were increased under a PPFD of 200 and 250 µmol m⁻² s⁻¹ in lettuce and under a PPFD of 250 µmol m⁻² s⁻¹ in basil. Furthermore, in lettuce grown under 250 µmol m⁻² s⁻¹ 45 46 antioxidant capacity, phenolics and flavonoids were higher as compared with plants supplied with PPFD <150 µmol m⁻² s⁻¹. Accordingly, a PPFD of 250 µmol m⁻² s⁻¹ seems suitable for optimizing yield and resource use 47 48 efficiency in red and blue LED lighting for indoor cultivation of lettuce and basil under the prevailing conditions 49 of the used indoor farming set-up.

54 1 INTRODUCTION

55 Indoor farming systems supplied with artificial lighting are claimed to substantially decrease the pressure on 56 natural resources, with specific potentialities in reducing water used for food production (Graamans et al., 2018). 57 Thanks to the use of hydroponics, the improved photosynthetic efficiency under the stable lighting and climatic 58 conditions provided by the indoor environment and the possibilities for transpiration water recovery through air 59 dehumidification, indoor cultivation may enhance water use efficiency (WUE, commonly expressed as grams 60 of fresh biomass produced per liter of water consumed) up to 50 times in comparison with current greenhouse 61 systems (Kozai and Niu, 2020). On the other hand, in indoor farming, the efficiency of light assimilation is 62 crucial not only for plant growth performances, but since it overall dramatically affects the environmental and 63 economic sustainability of the production system (Kozai, 2015). Vegetable and aromatic crops have been 64 extensively to date studied for their response to artificial lighting, with most promising results being associated 65 with LED lights, which allow to maximise electricity use efficiency and reduce production costs as compared 66 to other lighting technologies (Benke and Tomkins, 2017). Moreover, through the use of coloured diodes 67 targeting specific regions of the light spectrum, it is possible to concentrate the light within the chlorophyll 68 absorption peaks, which are respectively found within the red (600-700 nm) and the blue (400-500 nm) spectral 69 regions, allowing for further improvements in the efficiency of converting electricity into photosynthetic gains 70 (Yeh and Chung, 2009). Lettuce (Lactuca sativa L.) stands amongst the most studied species for indoor 71 cultivation under LED lights (Pennisi et al., 2019a). To date, most of the research work has focused on the 72 comparison between LED and alternative light sources (Kozai, 2016) or the comparison between 73 monochromatic and combined colours of LED lights (Rehman et al., 2017). Energy use efficiency (EUE, 74 expressed as grams of fresh biomass produced per kWh), was shown to increase by up to 2.5-folds when moving 75 from fluorescent (15.9 g FW kWh⁻¹) to LED light (40.6 g FW kWh⁻¹) in lettuce (Zhang et al., 2018). More recently, EUE values up to 80 g FW kWh⁻¹ were reported for lettuce grown under LED (Yan et al., 2020). Also, 76 77 the role of red:blue (RB) ratio in the spectral composition used for indoor lettuce cultivation was targeted, 78 showing that RB=3 would allow for maximum yield and resource-use efficiency (Pennisi et al., 2019a). 79 Similarly to lettuce, the aromatic herb sweet basil (Ocimum basilicum L.) is a widely studied crop species for 80 indoor cultivation. Growth of basil under LED lighting has been compared with other light sources, including

high pressure sodium (Hammock, 2018) or cool fluorescent lighting (Frąszczak et al., 2014; Piovene et al.,
2015). It was recently demonstrated (Pennisi et al., 2019b) that similar to lettuce the optimal red and blue spectral
composition for basil cultivation and resources use efficiency stands on RB=3. Another study (Pennisi et al.,
2019c) confirmed that the normalized environmental impact (based on a life cycle assessment) was reduced
when RB=3 or RB≥2 were used respectively for lettuce and basil.

86 In indoor grown basil and lettuce, a range of optimal light intensities, ranging from 50-150 μmol m⁻² s⁻¹ (Shiga

87 et al., 2009), to 150-250 μmol m⁻² s⁻¹ (Žukauskas et al., 2011; Cha et al., 2012; Tarakanov et al., 2012; Muneer

88 et al., 2014; Piovene et al., 2015; Pennisi et al., 2019a, 2019b), or even above 250 (Li and Kubota, 2009;

89 Samuoliene et al., 2009; Stutte et al., 2009; Johkan et al., 2010; Johkan et al., 2012) has been suggested.

90 Similarly, a model for supplemental lighting in greenhouse grown lettuce adopted intensities ranging 100 to 200

91 μ mol m⁻² s⁻¹ (Albright and Both, 2000).

92 However, it appears that studies targeting the amelioration of light intensity from productive, qualitative and 93 resource efficiency perspectives in leafy vegetables and herbs under combined red-blue LED lighting are still 94 lacking, while the selection of the optimal light intensity for indoor cultivation of these species still relies on 95 other lamp typologies (e.g. fluorescent or incandescent lights, Beaman et al., 2009).

96 A meta-analysis of plant responses to light intensity suggests that light intensity may have strong effects on 97 nutritional properties of plants (Poorter et al., 2019). For instance, Brazaityte et al. (2015), found that in 98 microgreens of Brassicaceae (including mustard, red pak choi and tatsoi) grown under mixed red and blue LED 99 lights, the accumulation of antioxidant compounds was stimulated by increasing the photosynthetic photon flux 100 density (PPFD) from 110 to 440 µmol m⁻² s⁻¹, though their concentration decreased as light intensity was further 101 augmented to 545 µmol m⁻² s⁻¹. In coriander (Coriandrum sativum L.), total phenolics and antioxidant capacity 102 were increased as the intensity of a combined LED light (featuring red, white and far red LEDs) was progressively enhanced from 100 to 300 µmol m⁻² s⁻¹ (Nguyen et al., 2019). In lettuce, total carotenoids were 103 increased as PPFD increased from 60 to 140 µmol m⁻² s⁻¹, but decreased when PPFD reached 220 µmol m⁻² s⁻¹ 104 105 (Fu et al., 2017), although information on the spectral properties of the light source were not reported in the study. Vitamin C content in lettuce leaves was highest at 140 µmol m⁻² s⁻¹, as compared with 220 and 60 µmol 106

107 $m^{-2} s^{-1}$ (Fu et al., 2017), while another study reported an increase in vitamin C content in lettuce in response to 108 PPFD from 120 to 150 µmol $m^{-2} s^{-1}$ (Lin et al., 2018). However, under red and white LED lights (RB=1.2) and 109 a photoperiod of 16 h d⁻¹, it was also shown that vitamin C content was higher at PPFD of 200 as compared with 110 250 µmol $m^{-2} s^{-1}$ (Yan et al., 2019), overall confirming an optimum response curve. On the other hand, in basil, 111 the effect of artificial light intensity was only studied by using cool fluorescent lamps. Similarly to the previously 112 cited studies on LEDs, antioxidant capacity was shown to increase when the PPFD was enhanced from 160 113 µmol $m^{-2} s^{-1}$ to 290 µmol $m^{-2} s^{-1}$ (Dou et al., 2018).

It emerges that LED lighting technologies for plant cultivation are rapidly evolving, and lamps for indoor cultivation are often designed to optimise their light emissions in the photosynthetically active spectrum (i.e. red and blue), in order to reduce energetic requirements for satisfactory yield. Under these light regimens, however, little information is available in literature about minimum PPFD for indoor production of leafy vegetables and herbs. The aim of this paper is to assess the effects of different light intensities (e.g. ranging from 100 to 300 μ mol m⁻² s⁻¹) on plant growth, physiological response and product quality, as well as on the overall crop resource use efficiency.

121

122 **2 MATERIALS AND METHODS**

123 **2.1. Plant material and growth conditions**

124 The plants were grown in five separate compartments (0.64 m² surface and 0.4 m³ volume) in a climate-125 controlled growth chamber (day temperature 26°C, night temperature 22°C, 55-70% relative humidity and 450 µmol mol⁻¹ CO₂) at the University of Bologna (Italy) (Choi et al., 2000). Each compartment was insulated by 126 127 using light opaque white walls, and equipped with fans constantly replacing internal air (hourly replacing 200 128 times the volume of the chamber). Lettuce plants belonging to the green typology Gentilina, commonly adopted 129 for baby-leaf production (Lactuca sativa L. cv. Rebelina, Gautier, Eyragues, France), and basil plants belonging 130 to the typology "Genovese" (Ocimum basilicum L. cv. Superbo, Sais seeds, Cesena, Italy) were grown. Three 131 independent experiments were conducted for each species. A planting density of 100 plants m⁻² and a crop cycle length of 21 days from transplant to harvest for both lettuce and basil experiments were adopted, as for previous
experiments (Saha et al., 2016; Pennisi et al., 2019a, 2019b, 2019c).

134 Seeds were germinated in polystyrene containers filled with a mixture of peat (70%) and vermiculite (30%), under cool-white fluorescent lamps (TL-D90 De Luxe 950, Philips), providing a PPFD of 215 µmol m⁻² s⁻¹ and 135 136 a photoperiod of 16 h d^{-1} of light. When plants reached a two true leaf stage (14 and 21 days after sowing - DAS 137 - respectively for lettuce and basil), roots were washed and plantlets were transplanted into individual 138 hydroponic systems (Pennisi et al. 2019a). Each single-plant hydroponic unit consisted of plastic jars (1 L of 139 volume, see image in Supplementary material S1 and further details in Pennisi et al., 2019c), filled with 140 nutrient solution (EC = 1.6, pH = 6.5) with the following composition: N-NO₃: 14 mM; N-NH₄: 4.4 mM; P: 1.0 141 mM; K: 5.0 mM; S: 2.0 mM; Ca: 1.2 mM; Mg: 5.2 mM; Fe: 17.9 µM, Cu: 2.0 µM, Zn: 3.8 µM, B: 11.6 µM, 142 Mn:18.2 µM, Mo: 0.5 µM. The nutrient solution was constantly aerated through air pumps (Airline 3, Haquoss, Turin, Italy, air exchange rate of 0.25 L min⁻¹ pot⁻¹). At 14 Days After start of light Treatment (DAT), pots were 143 144 replenished with 0.25 L of fresh nutrient solution.

145

146 **2.2. Light treatments**

147 Lettuce and basil plants were grown under dimmable LED lamps (Flytech s.r.l., Belluno, Italy) featuring red 148 (peak at 669 nm) and blue (peak at 465 nm) emitting diodes. The lamps were set to supply a spectral composition 149 with a red:blue ratio of 3 (RB=3), such ratio being calculated by the relative spectral areas within the red (600– 150 700 nm) and the blue (400–500 nm) regions (Singh et al., 2015). The spectral distribution was measured using 151 an illuminance spectrophotometer (CL-500A, Konica Minolta, Chiyoda, Tokyo, Japan). A photosynthetic 152 photon flux sensor (with equal sensitivity to red and blue radiation), model QSO (Apogee instruments, Logan, 153 UT, USA) connected with a ProCheck handheld reader (Decagon Devices Inc., Pullman, WA, USA) was used to set PPFD (µmol m⁻² s⁻¹) over the plant canopy. Daily Light Integrals (DLI) were calculated by multiplying 154 the PPFD (μ mol m⁻² s⁻¹) by the photoperiod (s), and expressed as mol m⁻² d⁻¹. In order to define the lamp's 155 156 efficacy of electricity-to-light conversion, the PPFD:electricity ratio (µmol J⁻¹) was estimated through flat plane 157 integration technique as the ratio of the incident PPFD (µmol m⁻² s⁻¹) at a set distance (40 cm, equal to the

- distance of the lamp from the top of the canopy during the experiments) and the light electricity power
 consumption (LEPC W m⁻², Pennisi et al., 2019a).
- 160 After transplant, 5 LED light treatments were applied, one per each compartment. Light treatments consisted of
- 161 five different PPDF values of 100 (DLI: 5.8 mol m⁻² d⁻¹, LEPC: 70 W m⁻², PPFD:electricity ratio: 1.44 μmol J⁻
- 162 ¹), 150 (DLI: 8.6 mol m⁻² d⁻¹, LEPC: 98 W m⁻², PPFD:electricity ratio: 1.53 μmol J⁻¹), 200 (DLI: 11.5 mol m⁻²
- 163 d⁻¹, LEPC: 132 W m⁻², PPFD:electricity ratio: 1.51 μmol J⁻¹), 250 (DLI: 14.4 mol m⁻² d⁻¹, LEPC: 164 W m⁻²,
- 164 PPFD:electricity ratio: 1.52 μ mol J⁻¹) and 300 (DLI: 17.3 mol m⁻² d⁻¹, LEPC: 197 W m⁻², PPFD:electricity ratio:
- $165 \qquad 1.52 \; \mu mol \; J^{\text{-}1}) \; \mu mol \; m^{\text{-}2} \; s^{\text{-}1} \; (\text{Fig. 1}).$

In each experiment, a new full randomisation of light treatments was applied. Each compartment hosted 40 plants at planting density of 100 plants m⁻², resembling common densities in indoor farming environments (Cha et al., 2012), and measurements were taken on the central 12 plants. Final measurements were taken 21 DAT, meaning 35 DAS for lettuce and 42 DAS for basil, at which stage the plants reached commercial harvest.

170

171 **2.3.** Growth analysis and resource use efficiency

At harvest (21 DAT), fresh weight (FW) of shoot and root was measured and dry weight was quantified after drying samples at 60°C for 72 hours. Root:shoot ratio (R:S ratio) was determined as the ratio of root dry weight to shoot dry weight. Leaf number was counted (leaves longer than 2 cm) and leaf area was determined using a leaf area meter (LI-3100C, LI-COR, Lincoln, Nebraska, USA). Specific leaf area (SLA) was calculated as the ratio between plant leaf area and leaf dry weight. For basil plants, also plant height was measured.

Water use was individually quantified for each plant during each experiment and water use efficiency (WUE) was determined as the ratio between final fresh weight of the shoot and the volume of water used, and expressed as g FW L⁻¹ H₂O. Lighting energy use efficiency (EUE) was determined according to the crop cycle length and the final fresh weight of the shoot, related to the lamps' cumulated electricity absorption and expressed as g FW kWh⁻¹. Light use efficiency (LUE, g DW mol⁻¹) was calculated as the ratio of shoot dry weight production per unit surface of cultivation (g DW m⁻²) and the light integral (mol m⁻²), obtained by multiplying DLI values by the number of days between transplanting and harvest. 184

185 **2.4. Stomatal size and density**

186 Measurements of stomatal size and density were performed using a nail polish print of leaf abaxial sides. 187 Imprints were taken from the middle portion of the blade between the midrib and the leaf margin, on the fourth 188 fully expanded leaf from five plants per treatment per experiment at 14 DAT. Each imprint was placed on a 189 microscope slide and covered with a cover slip. Image data were acquired using a brightfield biological 190 microscope (MT4300H, Meiji Techno, Saitama, Japan) equipped with a digital camera (UK1175-C QXGA 191 color, ABS GmbH, Jena, Germany). From each imprint, five pictures were taken in different locations. Pictures 192 were analysed using ImageJ software (version 1.48 v, NIH, USA). For each picture, stomata number was 193 counted and stomata size was estimated by the area of the rectangle encasing the stomata (Jensen et al., 2018).

194

195 **2.5. Stomatal conductance**

196 Measurements of stomatal conductance (mmol m⁻² s⁻¹) were performed on the third fully expanded leaf using a 197 leaf porometer (Δ P4, Delta-T Devices, Cambridge, UK) at 14 DAT in each experiment.

198

199 **2.6. Leaf chlorophyll content**

200 Content of chlorophyll in leaves was estimated during each experiment at 14 DAT through a leaf chlorophyll 201 meter (YARA N-Tester, Oslo, Norway) on the third fully expanded leaf. The tool provides a numeric three-digit 202 dimensionless value that is commonly expressed as N-Tester value and was previously used for leaf chlorophyll 203 estimation in lettuce (Orsini et al., 2018).

204

205 2.7 Total phenolic, flavonoids and antioxidant capacity

In all experiments, leaf samples were collected at harvest (21 DAT), immersed in liquid N₂ and kept at -80°C. One gram of frozen plant tissue was extracted in a methanol:water:acetone (6:3:1, v:v:v) (Pennisi et al., 2019b). Total antioxidant capacity, phenolic and flavonoid compounds were determined on the resulting extract. The total antioxidant capacity, measured by the ferric reducing antioxidant power (FRAP) assay, was expressed as mmol Fe²⁺ kg⁻¹ FW (Aaby et al., 2007). Phenolic compounds and flavonoids were quantified by Folin-Ciocalteu and aluminium chloride assays, and expressed as gallic acid and catechin equivalents, respectively (Zhishen et
al., 1999; Waterhouse, 2002).

213

214 2.7. Statistical analysis

Measurements were conducted on twelve plants per light treatment (unless otherwise stated), which were surrounded by border plants. Data were analysed by one-way ANOVA considering experiments as replicates and the means were compared by Tukey's Honestly Significant Difference (HSD) test, at 5% significance level. Regression analysis was conducted on the correlation between total antioxidant capacity and phenolics and between total antioxidant capacity and total flavonoid concentration, at 5% significance level. For all statistical analyses, software used included Microsoft Excel® and SPSS package.

221

222 **3 RESULTS**

223 **3.1. Effects of light intensity on lettuce and basil growth**

224 In both lettuce and basil (Table 1), light intensity increased fresh (FW) and dry (DW) weights up to 250 µmol 225 m^{-2} s⁻¹, while further increase of light intensity led to a reduction (in lettuce) or no further increase (in basil) of 226 FW and DW. Dry matter content (DM) of lettuce plants increased with increasing PPFD, while no further change 227 occurred when PPFD increased from 200 to 300 µmol m⁻² s⁻¹. In basil plants, the lowest DM value was associated to the lowest light intensity level (e.g. 100 μ mol m⁻² s⁻¹), while the other treatments did not present statistically 228 229 significant differences. The R:S ratio, on a dry weight basis, was not affected by light intensity in basil, whereas 230 in lettuce it was progressively increased, reaching highest values at 250 µmol m⁻² s⁻¹, without statistically 231 significant differences from plants exposed to 200 µmol m⁻² s⁻¹. The leaf number was not affected by light 232 intensity in lettuce, whereas it reached the highest values at 250 µmol m⁻² s⁻¹ in basil, while the highest values 233 of basil plant height was achieved under a PPFD \geq 200 µmol m⁻² s⁻¹. Finally, the plant leaf area was higher in 234 lettuce at PPFD>200 μ mol m⁻² s⁻¹ and in basil at PPFD>250 μ mol m⁻² s⁻¹, whereas the specific leaf area (SLA, expressed as cm² g⁻¹ DW) was maximised at PPFD of 100 µmol m⁻² s⁻¹ in lettuce and of 100 and 150 µmol m⁻² 235 s⁻¹ in basil (**Table 1**). 236

237

238 **3.2.** Effect of light intensity on leaf physiological functionality and anatomy

In both lettuce (**Fig. 2A**) and basil (**Fig. 2E**), light intensity increased leaf chlorophyll content up to a PPFD of 250 μ mol m⁻² s⁻¹, whereas further increases did not result in higher values of chlorophyll. Similarly, in lettuce, also stomatal conductance was positively correlated with light intensity up to 250 μ mol m⁻² s⁻¹, while a significant reduction of was observed at 300 μ mol m⁻² s⁻¹ (**Fig. 2B**). In basil plants, stomatal conductance was lowest at PPFD≤150 μ mol m⁻² s⁻¹ as compared with PPFD≥200 μ mol m⁻² s⁻¹ (**Fig. 2F**). In lettuce, stomatal density (**Fig. 2C**) was the lowest at 100 and 150 μ mol m⁻² s⁻¹ and reached the highest values at both 200 and 250 μ mol m⁻² s⁻¹. Stomatal size (**Fig. 2D**) resulted higher at 250 and 300 μ mol m⁻² s⁻¹.

In basil, stomatal density (Fig. 2G) reached the highest values at 200 and 250 μ mol m⁻² s⁻¹. Stomatal size (Fig. 2H) was the lowest at 100 μ mol m⁻² s⁻¹ and the highest at 250 μ mol m⁻² s⁻¹.

248

249 **3.3.** Effect of light intensity on antioxidant properties

In basil, no differences in total antioxidant capacity (P=0.97), phenolics (P=0.83) and total flavonoid (P=0.66) concentrations were observed as a function of imposed light intensity (data not shown). On the other hand, total antioxidant capacity, phenolic compounds and flavonoids in lettuce were higher when PPFD \geq 200 µmol m⁻² s⁻¹ was supplied (**Table 2**). A significant correlation between antioxidant capacity and total flavonoids content was observed in lettuce (P=0.00025) and basil (P=0.00239), whereas no significant correlation was observed between total antioxidant capacity and phenolics (data not shown).

256

257 **3.4.** Effect of light intensity on light, water and energy use efficiency

Water use presented a similar trend in both lettuce and basil plants. In lettuce, water use was increased from 0.48 L plant⁻¹ (100 μ mol m⁻² s⁻¹) to 0.66 L plant⁻¹ (150 μ mol m⁻² s⁻¹), and was the highest at PPFD \geq 200 μ mol m⁻² 2 s⁻¹, featuring 0.95 L plant⁻¹ as mean value (data not shown). Similarly, in basil, water use grew from 0.38 L plant⁻¹ (100 and 150 μ mol m⁻² s⁻¹, mean value) to 0.54 L plant⁻¹ (200 and 300 μ mol m⁻² s⁻¹, mean value) and up to 0.69 L plant⁻¹ under 250 μ mol m⁻² s⁻¹. Water Use Efficiency (WUE) was progressively increased in lettuce

(Fig. 3A) as PPFD was augmented from 100 µmol m⁻² s⁻¹ to 200 µmol m⁻² s⁻¹, without any further significant 263 increase for PPFD≥200 µmol m⁻² s⁻¹. In basil (Fig. 3D) plants, the highest values of WUE were obtained in 264 plants grown under PPFD 250 µmol m⁻² s⁻¹. The highest energy use efficiency (EUE) values in lettuce were 265 266 associated with 150, 200 and 250 µmol m⁻² s⁻¹ (Fig. 3B). In basil, energy use efficiency was the highest at 250 267 µmol m⁻² s⁻¹ (Fig. 3E). Light use efficiency was maximised in lettuce when PPFD was equal to 200 and 250 μ mol m⁻² s⁻¹ (**Fig. 3C**), whereas lower values were observed at PPFD \leq 150 or above 250 μ mol m⁻² s⁻¹. In basil, 268 269 LUE values were generally lower than those observed in lettuce (Fig. 3F), and resulted the highest at PPFD=250 umol $m^{-2} s^{-1}$, as compared to all other treatments. 270

271

4 DISCUSSION

4.1. A PPFD of 250 μmol m⁻² s⁻¹ is needed for improved yield in indoor grown lettuce and basil supplied with RB=3.

275 Plant biomass production in response to light intensity often follows an optimum function, which reaches its 276 maximum when light stress begins to occur (Kang et al., 2013; He et al., 2019). However, optimum light 277 intensity for fresh biomass production in lettuce was shown to vary among cultivars (Lee et al., 2019; Viršilė et 278 al., 2019). Also, when both temperature (e.g. from 20 to 25° C) and light intensity (from 150 to 200 μ mol m⁻² s⁻ ¹ from red and blue LEDs with RB=3, respectively supplying DLI of 8.6 to 11.5 mol m⁻² d⁻¹) were simultaneously 279 280 increased, an increase in fresh biomass of lettuce was observed. Such an increase was not visible when 281 temperature or light intensity alone were augmented (Okazaki and Yamashita, 2019). Similarly, the response of 282 lettuce biomass to light intensity (400 or 700 µmol m⁻² s⁻¹, resulting in DLI of 20.2 and 35.3 mol m⁻² d⁻¹) was 283 also altered by the atmospheric CO₂ (400 and 700 µmol mol⁻¹ CO₂) availability (Pérez-López et al., 2013). While 284 a synergistic effect on the promotion of biomass in two cultivars (red and green) was observed when elevate 285 light intensity (700 µmol m⁻² s⁻¹) and CO₂ (700 µmol mol⁻¹) were supplied, at ambient CO₂ (400 µmol mol⁻¹), 286 elevate light intensity (700 µmol m⁻² s⁻¹) only increased growth in green lettuce, but not in the red cultivar (Pérez-287 López et al., 2013). It was also shown that when photoperiod was reduced from 16 to 14 h d⁻¹ of light (at 288 T=22/18°C and 800 µmol mol⁻¹ CO₂), the optimum light intensity for fresh biomass production was increased

289 from 200 to 250 µmol m⁻² s⁻¹ under red and blue LED (with both RB=1.2 and RB=2.2) (Yan et al., 2019). 290 Looking at daily light integrals, it was observed that under RB=1.2 higher biomass was associated with DLI≥12.6 mol m⁻² d⁻¹, whereas under RB=2.2, biomass production decreased when DLI≥11.5 mol m⁻² d⁻¹ were 291 292 adopted (Yan et al., 2019). When comparing 60, 140 and 220 µmol m⁻² s⁻¹ (DLI respectively of 3.4, 8.1 and 12.7 mol m⁻² d⁻¹) supplied by mixed red and blue LED (RB=4), Fu et al. (2017) concluded that 220 µmol m⁻² s⁻¹ was 293 294 the PPFD value allowing for the greatest lettuce growth at 23°C and 16 h d⁻¹ of light. However, the lack of higher 295 PPFD values in their study, does not allow to further define the crop growth-response function to PPFD. In basil, the highest fresh biomass was previously achieved when supplying 224 μ mol m⁻² s⁻¹ (DLI=12.9 mol m⁻² d⁻¹) 296 297 through a fluorescent white light (Dou et al., 2018), although no further increase was reported when the PPFD was raised up to 310 µmol m⁻² s⁻¹ (DLI=17.8 mol m⁻² d⁻¹). The observed biomass increases were associated with 298 299 enhancement of leaf photosynthetic rates when PPFD was raised from 160 to 224 µmol m⁻² s⁻¹, albeit no leaf 300 photosynthetic changes were observed among treatments in which plants were grown with PPFD> 224 umol m⁻ ² s⁻¹ (Dou et al., 2018). From the results of hereby presented research, it could be advanced that the adopted 301 302 environmental (including light spectrum, photoperiod and CO₂) and plant growing (including plant density and cultivar used) features resulted in an optimum PPFD of 250 µmol m⁻² s⁻¹ (DLI=14.4 mol m⁻² d⁻¹) (Table 1), 303 304 while higher PPFD values (e.g. 300 µmol m⁻² s⁻¹, DLI=17.3 mol m⁻² d⁻¹) resulted in reduced growth in lettuce. 305 The detrimental effects on lettuce yield associated with too elevate DLI were previously observed by Zhang et 306 al. (2018), in experiments where an optimal DLI (when plants were grown under LED with RB=2.2 and photoperiod of 12 h d⁻¹ of light) for fresh biomass accumulation was found at 10.8 mol m⁻² d⁻¹ as compared with 307 308 13.0 mol m⁻² d⁻¹. It results that the definition of optimal light intensity is a complex scenario that can only be 309 defined building on the combined and synergistic effects of a number of environmental and crop factors. 310 Dry weight production in lettuce increased when light intensity was augmented from 120 to 150 µmol m⁻² s⁻¹

(DLI respectively of 6.9 and 8.6 mol m⁻² d⁻¹) (Lin et al., 2018) and from 60 to 220 μ mol m⁻² s⁻¹ (DLI from 3.4 to 12.7 mol m⁻² d⁻¹) (Fu et al., 2017). Contrarily, Yan et al. (2019) reported highest dry biomass in lettuce seedlings grown under LED (featuring mixed red, green and blue light with RB of 1.2 or 2.2, photoperiod 16 h d⁻¹) light supplying 200 μ mol m⁻² s⁻¹ (DLI=11.5 mol m⁻² d⁻¹) as compared with those experiencing 250 μ mol m⁻ 2 s⁻¹ (DLI=14.4 mol m⁻² d⁻¹). Nevertheless, when photoperiod was of 14 h d⁻¹, the light intensity did not result in changes in dry biomass accumulation (Yan et al., 2019). In basil, grown under fluorescent lamps, dry weight was augmented from 160 up to 290 µmol m⁻² s⁻¹ (DLI respectively from 9.3 to 16.5 mol m⁻² d⁻¹), while higher PPFD values did not result in a further increase (Dou et al., 2018).

319 The absence of univocal recommendations on the optimal PPFD may be associated to the elevate variability 320 among the lighting technologies and spectral properties and overall environmental conditions used in the cited 321 literature. In the present study an optimized LED spectral composition (RB=3) was used, and a PPFD of 250 µmol m⁻² s⁻¹ (DLI=14.4 mol m⁻² d⁻¹) in lettuce and of 250 and 300 µmol m⁻² s⁻¹ (DLI of 14.4 mol m⁻² d⁻¹ and 17.3 322 mol m⁻² d⁻¹, respectively) in basil allowed for maximum fresh and dry yields (Table 1). The increase in dry 323 324 biomass production in response to augmented light intensity was previously associated to increased 325 photosynthate accumulation (Kang et al., 2013; Lin et al., 2018), as a consequence of larger photosynthetic rates 326 (Fu et al., 2017; Dou et al., 2018). Similarly, higher values of shoot fresh and dry weight (g plant⁻¹) upon PPFD of 250 μ mol m⁻² s⁻¹ (DLI=14.4 mol m⁻² d⁻¹) and dry matter content upon PPFD \geq 200 μ mol m⁻² s⁻¹ (DLI \geq 11.5 mol 327 328 $m^{-2} d^{-1}$) were observed in lettuce (**Table 1**). Similar trend was also observed in basil shoots for both fresh and 329 dry biomass production with higher values being found in plants grown upon PPFD≥250 µmol m⁻² s⁻¹ (DLI≥14.4 330 mol m⁻² d⁻¹), although significant differences in dry matter content could only be found between PPFD≤150 331 μ mol m⁻² s⁻¹ and PPFD \geq 150 μ mol m⁻² s⁻¹ (**Table 1**).

332 The greater plant growth at 250 µmol m⁻² s⁻¹ (DLI=14.4 mol m⁻² d⁻¹) was also consistent with a larger leaf area 333 in both crops and, in basil, also to increased plant height and leaf number (Table 1). Increased leaf area and 334 number were previously observed in lettuce plants, when PPFD was increased from 260 to 290 μ mol m⁻² s⁻¹ 335 (DLI from 16.8 to 18.8 mol m⁻² d⁻¹) from LED featuring mixed red, blue and white light (RB=8) (Kang et al., 336 2013). Similarly, in basil, an increase in leaf area and plant height were also observed after 21 days of light treatment when PPFD≥224 µmol m⁻² s⁻¹ (DLI=12.9 mol m⁻² d⁻¹) was supplied (Dou et al., 2018). Despite the 337 338 higher shoot biomass in response to growing PPFD, functional changes in dry biomass partitioning to roots were 339 also observed, overall altering the plant R:S ratio in lettuce (Table 1). In some other studies on lettuce, R:S ratio 340 was either reported to increase or not to change (Fu et al., 2017) or even decrease (Lin et al., 2018) in response

341 to growing PPFD. Possibly, an optimum function may be hereby demonstrated (Table 1), with 200 and 250 µmol m⁻² s⁻¹ resulting in the highest R:S ratio. In a previous study on lettuce, the R:S ratio was shown to increase 342 343 as light intensity increased, when moving from 200 (DLI=13.0 mol m⁻² d⁻¹, R:S ratio=0.15) to 230 umol m⁻² s⁻¹ (DLI=14.9 mol m⁻² d⁻¹, R:S ratio=0.21), but then decrease as light intensity reached 260 µmol m⁻² s⁻¹ (DLI=16.8 344 345 mol m⁻² d⁻¹, R:S ratio=0.18) (Kang et al., 2013). According to the functional equilibrium hypothesis, as 346 irradiance increases, plants fix larger amounts of carbon in photosynthesis and show higher allocation to roots 347 at the expenses of shoots, while as light leads to stress in leaves the R:S ratio will not increase anymore (Poorter 348 et al., 2012).

The changes in leaf area and plant dry biomass production in response to varying light intensity regimes also altered the leaf structure. The observed reduction of SLA (**Table 1**) in response to increased PPFD was previously associated in basil with more compact mesophyll cells (higher dry matter content) and thicker and larger leaves (**Dou et al.**, 2018). Besides, light intensity may also result in functional adaptations of leaf anatomy and physiology as described in the following section.

354

355 4.2. Leaf adaptation mechanisms to increased PPFD.

356 Light intensity was previously shown to alter leaf anatomical and physiological features in both basil and lettuce 357 grown in greenhouse (Orsini et al., 2018) and indoor farming (Dou et al., 2018; Kang et al., 2013) environments. Leaf chlorophyll content was reported to be lower in basil plants grown under PPFD 224 µmol m⁻² s⁻¹ 358 (DLI>12.9 mol m⁻² d⁻¹) as compared with those grown under PPFD<200 μ mol m⁻² s⁻¹ (DLI<11.5 mol m⁻² d⁻¹) 359 360 (Dou et al., 2018). However, in the same work, leaf chlorophyll was not reported to vary between plants grown under 224 (DLI=12.9 mol m⁻² d⁻¹) and 310 µmol m⁻² s⁻¹ (DLI=17.8 mol m⁻² d⁻¹). Similarly, in lettuce, no 361 362 differences in chlorophyll content could be observed in plants grown under PPFD ranging 200 to 290 µmol m⁻² 363 s⁻¹ (DLI from 13.0 to 18.8 mol m⁻² d⁻¹) (Kang et al., 2013) or when plants were grown under either 150 to 200 364 umol m⁻² s⁻¹ (DLI respectively of 8.6 and 11.5 mol m⁻² d⁻¹) (Okazaki and Yamashita, 2019). The observed 365 behaviour (Fig. 2A and 2E) is consistent with the hypothesis that under either non-optimal radiation intensity, 366 leaf chlorophyll content is reduced, as previously described in lettuce (Fu et al., 2012; Orsini et al., 2018). It should be noted that such a reduction in chlorophyll may also result in lighter green colour of the leaves, a trait
that was previously associated with reduced consumer preference in fresh vegetable products (Rouphael et al.,
2012).

370 Alongside with the role played by leaf chlorophyll content, photosynthesis in leaves is regulated by stomatal 371 features, as evidenced in basil (Mancarella et al., 2016). Stomatal opening is a general response of plants to high 372 light intensity, facilitating both CO₂ uptake for photosynthesis and evaporative cooling of the leaf undergoing 373 elevate radiative heat loads (Matsuda, 2016). Two mechanisms are mainly associated with the light-induced 374 stomatal response (Shimazaki et al., 2007), one of them supposedly driven by the photosynthetic activity of both 375 guard and mesophyll cells, the other induced by blue light triggering the response of the photoreceptor 376 phototropin (Hiyama et al., 2017). Accordingly, the light spectral composition was shown not only to alter 377 biomass growth, but also to modify stomatal functionality and overall water use in both lettuce and basil plants 378 (Pennisi et al., 2019a and 2019b). Stomatal conductance was previously reported to increase in lettuce when PPFD was raised from 60 to 220 µmol m⁻² s⁻¹ (DLI from 3.4 to 12.7 mol m⁻² d⁻¹) (Fu et al., 2017) or from 200 to 379 230 µmol m⁻² s⁻¹ (DLI from 13.0 to 14.9 mol m⁻² d⁻¹) (Kang et al., 2013), while was decreased at higher PPFD 380 381 values (Kang et al., 2013). Similarly, in basil, Dou et al. (2018) reported stomatal conductance to increase from 382 160 (DLI=9.3 mol m⁻² d⁻¹) up to 224 µmol m⁻² s⁻¹ (DLI=12.9 mol m⁻² d⁻¹), while becoming stable upon higher 383 PPFD. Accordingly, in the hereby presented study, in lettuce plants stomatal conductance reached the highest values at 250 μ mol m⁻² s⁻¹ (DLI=14.4 mol m⁻² d⁻¹), and then decreased for greater values of light intensity (Fig. 384 385 **2B**), while in basil plants stomatal conductance resulted stable in plants grown under PPFD \geq 200 µmol m⁻² s⁻¹ 386 (DLI≥11.5 mol m⁻² d⁻¹) (Fig. 2F). Changes in stomatal conductance were previously associated with 387 modifications in stomatal size and/or density in both lettuce (Pennisi et al., 2019a) and basil (Barbieri et al., 388 2012). Similarly, stomatal density followed an optimum function showing higher values at 200 and 250 µmol 389 m⁻² s⁻¹ (DLI of 11.5 and 14.4 mol m⁻² d⁻¹, respectively) in both lettuce and basil (Fig. 2C and 2G). Moreover, stomatal size resulted to be increased by growing PPFD up to 250 μ mol m⁻² s⁻¹, in both species (Fig. 2D and 390 391 **2H**). These changes in stomatal size and density were also consistent with the response in stomatal conductance 392 (Fig. 2B and 2F), which was highest at PPFD=250 and PPFD \geq 200 µmol m⁻² s⁻¹, in lettuce and basil, respectively. 393 The observed changes in leaf morphology and physiology are likely responsible of the overall plant water 394 relations and secondary metabolism, as targeted in the following sections.

395

396 4.3. In lettuce, PPFD affects antioxidant capacity

The content of flavonoid compounds and the overall antioxidant capacity of lettuce and basil (**Table 2** and data not shown) were closely related, suggesting that flavonoids may be the main compounds responsible for radical scavenging in these species. Despite the large variety of commercial cultivars among basil and lettuce species (presenting different secondary metabolite concentrations and responsiveness to environmental cues), the role of flavonoids on radical-scavenging is a well-established assumption (Ouzounis et al, 2015).

In basil, red wavelengths (Piovene et al., 2015; Pennisi et al., 2019b) have also been implicated in the increased biosynthesis of phenolic and flavonoid compounds, while light shading is probably responsible for their reduced content (Stagnari et al., 2018). However, in this work, light intensity did not affect antioxidant capacity, phenolics and total flavonoid concentration in basil (data not shown), suggesting that the spectral composition and/or the intensity of radiation at wavelength not considered here (e.g. UV), but not light intensity *per se*, may underlie the stimulation of antioxidants biosynthesis in this crop.

408 In contrast, lettuce responded to light intensity, showing the highest antioxidant activity and concentrations of 409 phenolics and flavonoids between 200 and 300 µmol m⁻² s⁻¹ PPFD (Table 2), resembling previously reported 410 values for the same crop species (Msilini et al., 2013; Ouhibi et al., 2014) and confirming the hypothesis of a 411 PPFD-related effect on the plant antioxidant profile (Poorter et al., 2019). The finding of an optimum intensity 412 value, rather than a proportional relation, suggests that antioxidant capacity and both flavonoids and phenolics 413 concentrations may be determined as a trade-off between different processes with opposite effects. For instance, 414 the finding of a lower stomatal conductance (i.e., potentially higher accumulation of O_2) at 300 vs 250 μ mol m⁻ 415 ² s⁻¹ PPFD, associated with comparable chlorophyll contents, suggests a higher risk of oxygen radical formation 416 as a result of electron leakage from photosynthetic machinery (Anjum et al., 2011).

417

418 **4.4.** Toward efficient resource use in indoor lettuce and basil cultivation: the role of light intensity.

419 Reducing water use while preserving satisfactory yield is a target priority for agricultural production (Fernández 420 et al., 2018). The increased yield associated with 250 µmol m⁻² s⁻¹ PPFD (DLI=14.4 mol m⁻² d⁻¹) in lettuce and 421 with PPFD \geq 250 µmol m⁻² s⁻¹ (DLI \geq 14.4 mol m⁻² d⁻¹) in basil (**Table 1**), compensated for the increase in stomatal 422 conductance (Fig. 2B and 2F), overall leading to greater water use efficiency (WUE, Fig. 3A and 3D). The 423 observed values for WUE (reaching up to 60 g FW L⁻¹ H₂O and 38 g FW L⁻¹ H₂O, respectively in lettuce and 424 basil, Fig. 3A and 3D), are extremely impressive when compared with reported values for traditional cultivation. 425 Accordingly, from data on open-field and greenhouse cultivation, WUE of lettuce was respectively defined at 4 g FW L⁻¹ H₂O and 50 g FW L⁻¹ H₂O (Barbosa et al., 2015), whereas basil respectively performed 3 g FW L⁻¹ 426 427 H₂O and 22 g FW L⁻¹ H₂O in open-field (Ekren et al., 2012) and greenhouse (Montesano et al., 2018) systems. 428 Similarly, the balance between increased electricity needs at growing PPFD and greater plant biomass achieved 429 in response to higher light intensities, altered the crop Energy Use Efficiency (Fig. 3B and 3E). From such 430 equilibrium, maximum EUE was achieved under 200 to 250 µmol m⁻² s⁻¹ PPFD (corresponding to DLI of 11.5 431 and 14.4 mol m⁻² d⁻¹, respectively) in lettuce and at 250 µmol m⁻² s⁻¹ PPFD (DLI=14.4 mol m⁻² d⁻¹) in basil. The 432 achieved EUE values under 250 µmol m⁻² s⁻¹ PPFD (110 and 45 g FW kWh⁻¹, in lettuce and basil, respectively) 433 are already higher than those reached under comparable environmental conditions at lower intensities (215 µmol 434 m⁻² s⁻¹ PPFD and DLI=12.4 mol m⁻² d⁻¹) in both lettuce (91 g FW kWh⁻¹, Pennisi et al., 2019a) and basil (33 g 435 FW kWh⁻¹, Pennisi et al., 2019b).

In the hereby presented experiments, LUE was highest respectively at 200 and 250 µmol m⁻² s⁻¹ (DLI of 11.5 436 437 and 14.4 mol m⁻² d⁻¹, respectively) in lettuce (LUE=1.03 g DW mol⁻¹, Fig. 3C) and at 250 µmol m⁻² s⁻¹ in basil 438 (LUE=0.70 g DW mol⁻¹, Fig. 3F), as compared with all other light intensities. Janssen et al. (2019) reported 439 values of LUE ranging from 15 to 30 g FW mol⁻¹ in lettuce (around 0.75-1.50 g DW mol⁻¹ considering 5% of 440 dry matter content) and from 8 to 12 g FW mol⁻¹ in basil (around 0.60-0.96 g DW mol⁻¹ considering 8% of dry 441 matter content) in indoor systems with artificial lighting, in a range of experiments where they tested the effects 442 of temperature (ranging 22 to 30°C), CO₂ supply (400 to 1600 µmol mol⁻¹), photoperiod (14 to 18 h d⁻¹ of light) 443 and light intensity (180 to 400 µmol m⁻² s⁻¹). Graamans et al. (2018) simulated a LUE of 0.37 g DW mol⁻¹ for lettuce production in a plant factory (PPFD=500 µmol m⁻² s⁻¹, photoperiod=16 h d⁻¹, DLI=28.8 mol m⁻² d⁻¹, 444

445 $CO_2=1200 \ \mu mol \ mol^{-1}$). In lettuce plants grown in a growth chamber under HPS lamps (PPFD=420 \ \mumol mol^{-2} s^{-1} 446 ¹, photoperiod=16 h d⁻¹, DLI=24.2 mol m⁻² d⁻¹, CO_2=370-410 \ \mumol mol^{-1}), lower values of LUE were reported 447 (0.15-0.18 g DW mol⁻¹, El-Nachel et al., 2019). In greenhouses, however, reported LUE values were even lower 448 and ranged 0.33-1.39 g DW MJ⁻¹, which would correspond (considering a conversion factor of 4.6 mol MJ⁻¹) to 449 LUE value as little as 0.07 g DW mol⁻¹ (Wheeler et al., 1993). When greenhouse values were referred to the 450 actually absorbed PAR instead, De Pinheiro Henriques and Marcelis (2000) reported LUE to range 3.5 to 4.9 g 451 DW MJ⁻¹, which would correspond to 0.8 to 1.1 g DW mol⁻¹.

452

453 **5 CONCLUSIONS**

454 The research confirmed that an optimum response curve exists between light intensity and plant growth, with 250 µmol m⁻² s⁻¹ (DLI=14.4 mol m⁻² d⁻¹) resulting in improved fresh and dry biomass production as well as 455 456 larger plant leaf area under the prevailing conditions of red and blue light (RB=3), a photoperiod of 16 h d⁻¹ of 457 light, 24° C, $450 \,\mu$ mol mol⁻¹CO₂ and a plant density of 100 plants m⁻². At this light intensity regime and following 458 the functional equilibrium hypothesis, an increased R:S ratio was also observed, altogether with reductions in 459 SLA, possibly as a consequence of functional leaf adaptations. Consistently, leaves of plants grown under 250 μ mol m⁻² s⁻¹ (DLI=14.4 mol m⁻² d⁻¹) presented denser and larger stomata, which allowed for improved stomatal 460 461 conductance and higher leaf chlorophyll content. On the contrary, lower light intensities reduced leaf 462 functionality (in terms of stomatal features and chlorophyll content), which also resulted in reduced nutritional 463 content in lettuce, where antioxidant capacity, phenolics and flavonoids concentrations were lower.

464 Despite the higher water requirements and the higher electricity needs experienced when a PPFD of 250 μ mol 465 m⁻² s⁻¹ was supplied as compared with lower light intensities, the yield gain allowed for improved water (WUE), 466 energy (EUE) and light (LUE) use efficiencies. On the other hand, additional light intensity (e.g. up to 300 μ mol 467 m⁻² s⁻¹) did not allow for additional yield and therefore WUE, EUE and LUE were not further improved. From 468 the study it may be concluded that under a mixed red and blue LED light (featuring RB=3) and a photoperiod 469 of 16 h d⁻¹ of light, indoor cultivation of both lettuce and basil may be improved when DLI=14.4 mol m⁻² d⁻¹ and 470 PPFD=250 μ mol m⁻² s⁻¹ are supplied. The novelty proposed therefore stands in the optimization of radiation 471 intensity in a specific spectral environment (RB=3) that was recently shown to improve productivity and 472 resource use efficiency in basil and lettuce (Pennisi et al., 2019a, b). The research also elaborates on 473 physiological changes associated with stomatal response to light, that result in viable strategies for maximising 474 water, energy and light use efficiencies in the studied crops.

475

476 Author Contributions

Giuseppina Pennisi designed and performed all experiments and drafted the manuscript. Alessandro Pistillo managed the experiments and performed measurements. Francesco Orsini and Leo Marcelis contributed to the experimental design and the drafting of the manuscript. Francesco Spinelli and Antonio Cellini performed the analyses of antioxidant compounds and contributed to the manuscript preparation. Andrea Crepaldi coordinated the manufacturing of the lamps used in the experiment. Silvana Nicola, Juan Fernandez and Giorgio Gianquinto supervised the research and critically revised the manuscript.

Figure 3. Water Use Efficiency (WUE), Energy Use Efficiency (EUE) and Light Use Efficiency (LUE) of lettuce (A, B and C) and basil (D, E and F) plants grown under different DLI (obtained by changing light intensity from 100 to 300 μ mol m⁻² s⁻¹) at 21 DAT. Each value is the mean of 36 independent measures. Vertical bars represent standard errors. Different letters indicate significant differences at P \leq 0.05.
