18 **Abstract**

19 Nitrogen (N) is often applied to soil surface during the grapevine cycle, increases N
20 losses. One way to reduce N losses lies on its application method, however how N dose
21 and application mode impact on grapevines remain poorly investigated. The aim of this
22 study is to evaluate the root growth, as well as grape must yield and composition, in a
23 sandy soil and subjected to different N application doses and modes under subtropical
24 climate conditions. Grapevines were implanted in 2011 and, since 2014, they were
25 subjected to surface (N-Surf), and fertigation (N-Fert) N application, at rates of 0, 40

26 and 100 kg N ha⁻¹ year⁻¹. Leaf N concentration, yield, must quality parameters and root
27 system morphology were evaluated in the 2016/2017 and 2017/2018 seasons. The
28 application of N in both rates (40 and 100 kg N ha⁻¹ year⁻¹), in the N-Surf and N-Fert
29 methods, increased the surface area of root, number of living roots and root production.
30 The application of N rates, in both N application modes, provided adequate N supply to
31 the soil and increased root system development, which contributed to the increase of
32 soil N uptake by plants, higher N concentration in leaves and greater grape yield.
33 However, N supply decreased the quality of the must, as observed in decreased TSS and
34 total anthocyanins values and in increased total titratable acidity values, which are not
35 desirable for red wine making processes.

39

40 **Introduction**

41 Grapevines are grown worldwide in sandy soils that often have low organic
42 matter (OM) content, a fact that leads to low nitrogen (N) availability in the soil
43 (Gustavo Brunetto et al., 2016, 2014; Lorensini et al., 2017). Thus, applications of N
44 fertilizer are necessary to increase soil mineral N availability, *i.e.* nitrate (NO₃⁻) and
45 ammonium (NH₄⁺) forms, which are the ones uptake by plants. Soil surface (without
46 incorporation) N applications are often recommended, however this approach may
47 increase N losses, mainly due to volatilization (Lorensini et al., 2012; Viero, Bayer,
48 Mara Vieira Fontoura, Paulo de Moraes, & Professor, 2014), and decrease grapevines N
49 uptake (Gustavo Brunetto et al., 2016; Gustavo Brunetto, Kaminski, Melo, Brunning, &
50 Mallmann, 2006). Therefore, it is necessary adopting alternative ways of supplying N to

51 decrease losses and increase N use efficiency. Fertigation is one of these alternatives; it
52 enables urea solubilization and hydrolysis reaction, decreases losses caused by
53 volatilization, since it favors the migration of NO_3^- and NH_4^+ in soil profile (Comas,
54 Bauerle, & Eissenstat, 2010).

55 Increased mineral N contents in soil subsurface layers can contribute plant root
56 system growth and development (Centinari, Heuvel, Goebel, Smith, & Bauerle, 2016;
57 Comas et al., 2010; Zhou, Yang, Ren, Huang, & An, 2014). Increased NO_3^- and NH_4^+
58 concentrations in soil solution activates NO_3^- (NRTs) and NH_4^+ (AMTs) transporters
59 and, consequently, contributes for N uptake (Pii, Aldrighetti, Valentinuzzi, Mimmo, &
60 Cesco, 2019; Tomasi, Monte, Varanini, Cesco, & Pinton, 2015; Xu, Fan, & Miller,
61 2012) and for the increase of grapevine root emission and root surface area (Krouk et
62 al., 2010; Remans et al., 2006). In addition, high NO_3^- concentrations can inhibit auxin
63 transport in the root system due to competition at the NRT1.1 transporter site; thus,
64 auxin accumulates in plant roots and leads to an increase of lateral root growth in sites
65 presenting high NO_3^- concentrations (Mounier, Pervent, Ljung, Gojon, & Nacry, 2014).
66 On the other hand, high N doses can decrease soil pH due to NH_4^+ nitrification into
67 NO_3^- . This phenomenon, which is often seen in vineyards (Lorensini et al., 2017), can
68 solubilize minerals in the soil and release aluminum (Al^{+3}) into soil solution;
69 consequently, Al^{+3} can be uptake by plant roots and lead to root length shortening and to
70 root diameter increase (Inostroza-Blancheteau, Aquea, Reyes-Díaz, Alberdi, & Arce-
71 Johnson, 2011; Riaz et al., 2018; Zhou et al., 2014). This outcome is undesirable
72 because it reduces the volume of soil explored by the root system, as well as the
73 absorption of water and nutrients (Riaz et al., 2018).

74 Mineral N provided by N fertilization can be uptake and transported to plant
75 shoot, increasing N content in the leaves. This process occurs mainly in stages of

76 intense root growth, such as at flowering, when the increased root volume contributes to
77 great N uptake (Radville et al., 2016). Increased leaf N content can lead to an increased
78 photosynthetic rate and CO₂ fixation, since RuBisCo corresponds to 50% of soluble
79 proteins in the leaves of C3 plants (Stefano, Agyei, Njoku, & Udenigwe, 2018). This
80 outcome favors cell division and elongation conditions in plant tissues and increases
81 vegetative growth (Blank, Tittmann, Ghozlen, & Stoll, 2018; Moriwaki et al., 2019) in
82 grape clusters, resulting in greater crop yield (Gustavo Brunetto et al., 2009a; Yu et al.,
83 2012).

84 In addition to increased crop yield, there may be changes in oenological
85 parameters associated with wine quality; these changes may be due to total
86 anthocyanins and total soluble solids (TSS) dilution, as well as to increase in total
87 titratable acidity values (Gustavo Brunetto et al., 2009a; Janjanin et al., 2016; Kelly et
88 al., 2017; Spayd, Nagel, & Edwards, 1995). Thus, it is recommended adopting
89 strategies, such as N doses and application modes, to stimulate root system growth in
90 order to increase water and nutrient absorption by plants, as well as to increase crop
91 yield without decreasing the quality of must. The aim of the current study was to
92 investigate whether N rates and modes of application can change root system
93 morphology, yield and the composition of grape must in grapevines (*Vitis vinifera* L.)
94 grown in sandy soil under subtropical climate conditions.

95

96 **Materials and Methods**

97 **Experimental site description**

98 The experiment was conducted in a vineyard established in 2011, in Santana do
99 Livramento County, Rio Grande do Sul State (RS), Southern Brazil (30° 48' 31" S; 55°
100 22' 33" W). Alicante Bouschet (*Vitis vinifera* L. grafted onto Paulsen 1103 rootstock)

101 was the adopted cultivar. Plant density was 2,976 hectare⁻¹ (2.8 m between rows × 1.2
102 m between plants), based on the espalier system. Soil in the experimental site was
103 classified as Typic Hapludalf (Soil Survey Staff, 2014); the main chemical properties of
104 the 0.0-0.20 m layer before the experiment are shown in Table 1.

105 Based on Köppen classification, the climate in the region is subtropical humid
106 (Cfa); it is featured by mild temperatures and rainfall rates, with little variation
107 throughout the year. Mean annual rainfall is 1,600 mm, whereas mean temperature is
108 23.8° C in the warmest month (January) and 12.4° C in the coldest month (July)
109 (Alvares, Stape, Sentelhas, De Moraes Gonçalves, & Sparovek, 2013). Annual
110 insolation reaches approximately 2,500 hours; the site presents gently undulating
111 terrain. Two crop production cycles, 2016/17 and 2017/18, were evaluated. According
112 to data from the National Institute of Meteorology (INMET), the experimental area
113 recorded 513.2 mm and 189.6 mm of rainfall from November 2016 to February 2017
114 and from November 2017 to February 2018 (period between treatment application and
115 harvest), respectively (Fig. 1).

116 Weeds in the grapevine row were desiccated with two to four sequential
117 applications of 2 L ha⁻¹ y⁻¹ of non-selective systemic herbicide (*i.e.*, glyphosate),
118 depending on cover plant development. Inter-row cover plants were cut near the soil
119 surface, five times throughout each crop season and the residues were deposited on soil
120 surface between rows. Grapevines were subjected to four applications of 45 kg P₂O₅ ha⁻¹
121 year⁻¹ and 45 kg K₂O ha⁻¹ year⁻¹ prior to experiment installation (CQFS-RS/SC, 2016).
122 Triple superphosphate (42% P) and KCl (60% K) were used as P and K sources,
123 respectively. Nitrogen fertilizers were applied to the crop based on each treatment.

124

125

126 **Experimental design and treatments**

127 Starting from September 2014, two N application methods: surface (N-Surf) and
128 fertigation (N-Fert) and three rates 0, 40 and 100 kg N ha⁻¹ year⁻¹ were evaluated. The
129 experiment followed a complete randomized block experimental design with three
130 repetitions (plot) with 2 x 3 factorial arrangement (*i.e.*, two N application modes and
131 three N rates). Each plot consisted of five plants were only the three central plants were
132 used for data collection. In both application methods, urea was employed as N source
133 (45% N); in N-Surf treatment, N was applied on the surface of the soil, within plant
134 canopy projection, without incorporation. Every year, N application was performed
135 during flowering (Gustavo Brunetto et al., 2009a). In N-Fert treatment, N was applied
136 via drip irrigation (Netafim™ 132 Dripnet PC AS 16250), at a flow rate of 1.6 L h⁻¹;
137 drippers were spaced 0.6 m a part along the tree row, within canopy projection. The
138 applications were performed at four different times, at 7-day intervals, according to the
139 following procedure: 10 minutes of water; 10 minutes of water + N; and 10 minutes of
140 water. Applications N-Fert provided 6.4 L of water per plant per crop season.

141

142 **Minirhizotron installation**

143 Minirhizotron tubes (Supplementary material 1) were installed in the ground of
144 four plants per treatment in May 2016 to enable scanning the grapevine root system *in*
145 *situ*. For each assessed grapevine plant, a hole was made with a spiral drill (70 mm
146 diameter and 1,500 mm length), pulled by motorized ground driller (Branco, Bps 52),
147 0.5 m away from the trunk, inside the canopy projection. Each individual hole was
148 made at an angle of 45° to soil surface and a clear acrylic tube (70 mm x 1050 mm) was
149 inserted. Three images were taken along each tube, referring to the soil layers: 0-20;
150 40; and 40-60 cm deep. Each image had fixed dimensions of 216 mm × 196 mm. A

151 flexible, lightweight, waterproof and non-toxic plastic polyethylene rod (CID Bio-
152 Science, Inc. Camas, WA, USA) internally protected the tubes. PVC pipes (100 mm
153 diameter) were used to protect the external part of the tubes from damage caused by
154 weather, handling or pest attacks. Soil disturbance during the hole drilling process made
155 it necessary waiting eight months for soil-plant-tube system stabilization, before the
156 beginning of the scanning activities.

157

158 **Image collection and measurements of root morphological parameters**

159 Root images were taken at grapevine flowering stage (in October) in the 2016/17
160 and 2017/18 crop seasons. This phenological stage was selected because it coincides
161 with a period of intense root growth and nutrient absorption, as reported in several
162 studies (Comas, Anderson, Dunst, Lakso, & Eissenstat, 2005; Radville et al., 2016).
163 Images of the root system were generated *in situ* with a CI-600™ cylindrical scanner
164 (CID Bio-Science, Inc. Camas, WA, USA).

165 Subsequently, images were captured at different soil layers (0-20, 20-40 and 40-
166 60 cm deep) and individually analyzed. The CI-600 scanner was connected to a
167 computer by USB cable. Images captured in TIFF format (600 dpi resolution) were
168 analyzed in the RootSnap!® CI-690 software version 1.3.2.25 (CID Bio-Science, Inc.
169 Camas, WA, USA), which enables seeing the fine roots (≤ 2 mm). Parameters evaluated
170 in each tube based on generated images were (i) root surface area ($\text{mm}^2 \text{tube}^{-1}$); (ii)
171 mean root diameter (mm tube^{-1}); (iii) number of living roots; (iv) number of dead roots;
172 and (v) root production as the difference between the total length of living and dead
173 roots (mm tube^{-1}).

174

175 **Leaf collection for nitrogen analysis**

176 Six fully expanded leaves located in the opposite direction of the grape clusters,
177 in the middle third of the annual branches, were collected at flowering (October 2016
178 and 2017) and at berry veraison (December 2016 and 2017). According to CQFS-
179 RS/SC (2016), these leaves are the diagnostic organ used to assess the nutritional status
180 of grapevines. Leaves were washed in distilled water and dried in forced-air-circulation
181 oven at 65 °C, until they reached constant weight. Then, they were milled in Wiley mill
182 and sieved through 2-mm mesh. Subsequently, the leaf tissue was prepared and
183 subjected to sulfuric digestion (Tedesco, Gianello, Bissani, Bohnen, & Volkweiss,
184 1995). Total N concentration was determined in Kjeldahl semi-micro steam distiller
185 (Tecnal, TE-0363, Brazil).

186

187 **Grape yield**

188 The number of grape clusters per plant was counted in the 2016/17 and 2017/18
189 grape harvests. All grape clusters were harvested and weighed in a portable electronic
190 scale (WalMur, 50 K, Brazil), to measure grape yield (Mg ha^{-1}). Berries were collected
191 at the upper, middle and lower third of the grape clusters, thus totaling 100 berries per
192 repetition and 9 repetitions per treatment. They were weighed in scale (Bel Engineering,
193 Precision Scale L, Brazil) to determine the weight of 100 berries, before storing for
194 chemical analysis (in triplicate) of the must.

195

196 **Chemical analysis of the must**

197 The stored berries were peeled and only the pulp and seeds were analyzed. A
198 benchtop refractometer (Cosmo, Type K - 32) was used to determine the total soluble
199 solids (TSS) based on standards set by AOAC (2005). Total titratable acidity was
200 determined by transferring 10 mL of extract to a 100 mL volumetric flask, whose

201 volume was completed with distilled water. For the titration of the resulting solution 0.1
 202 mol L⁻¹ of sodium hydroxide (NaOH) was used (IAL, 2008).

203 Berry peel was used to determine total anthocyanin contents through a contact
 204 with a 70:30 acidified (1% HCl) ethanolic solution (Ju and Howard 2003) at
 205 peel/solution ratio of 1:3 (m/v) and crushed in a blender (Arno, Clic Lav Top, Brazil) at
 206 low (1500 RPM) and high speed (3500 RPM) for 40 seconds each. The solution
 207 resulting from the aforementioned extraction was placed in a 250 mL beaker and left to
 208 rest for 30 minutes at room temperature (20 ± 1 °C) before it was centrifuged at 3500
 209 RPM for 5 minutes. Extract supernatant was removed and stored in amber bottle, which
 210 was placed in refrigerator (4-10°C). Subsequently, triplicate readings of these extracts
 211 were performed.

212 Total anthocyanin content was determined based on the pH difference method
 213 (Giusti and Wrolstad 2001), according to which samples were dissolved in two buffer
 214 systems: 0.025 mol L⁻¹ potassium chloride at pH 1.0 and 0.4 mol L⁻¹ sodium acetate at
 215 pH 4.5. Maximum absorption readings were taken at 515 nm and 700 nm, with the aid
 216 of a UV-visible spectrophotometer (FEMTO, 600 plus, Brazil). Absorbance was
 217 calculated through equation (1):

$$218 \quad A = (A_{515vis} - A_{700nm})_{pH1.0} - (A_{515vis} - A_{700nm})_{pH4.5} \quad (1)$$

219 Pigment concentration in the extract was calculated and represented in cyanidine-3-
 220 glycoside through equation (2).

$$221 \quad Anthocyanins (mg\ 100\ mL^{-1}) = (A \times MM \times DF \times 10000) / (\varepsilon \times 1) \quad (2)$$

222 wherein: A = absorbance; MM = molecular mass; DF = dilution factor; and ε = molar
 223 absorptivity.

224

225

226 **Statistical analysis**

227 Data were subjected to analysis of variance by the R Studio software (R Core
228 Team, 2019); whenever the analysis of variance showed a significant effect, means
229 were compared through Scott-Knott test, at 5% significance level ($P < 0.05$). In
230 addition, data were subjected to multivariate principal component analysis (PCA) in the
231 R software (R Core Team, 2019) in order to investigate correlation effects between
232 response variables and treatments' distribution along the evaluated crop seasons.

233

234 **Results**

235 **Root morphological parameters**

236 In the 2016/17 crop season, the highest root surface areas, recorded in the 0-20
237 cm layer, were observed in grapevines subjected to the application of 40 kg N ha⁻¹ year⁻¹
238 ¹ as N-Surf and of 100 kg N ha⁻¹ year⁻¹ as N-Fert (Fig. 2a). As for the 2017/18 crop
239 season, the highest root surface areas were observed in grapevines subjected to the
240 application of 40 kg N ha⁻¹ year⁻¹ as N-Surf and of 100 kg N ha⁻¹ year⁻¹ as N-Surf and
241 N-Fert (Fig. 2b). In the 2016/17 crop season, the highest root surface area, recorded in
242 the 20-40 cm and 40-60 cm layers was observed in grapevines subjected to the
243 application of 40 kg N ha⁻¹ year⁻¹ as N-Surf (Fig. 2a); whereas in the 2017/18 crop
244 season, the highest values recorded were observed in grapevines subjected to
245 application of 100 kg N ha⁻¹ year⁻¹ and 40 kg N ha⁻¹ year⁻¹ as N-Fert and N-Surf,
246 respectively (Fig. 2b).

247 In the 2016/17 crop season, the highest mean root diameters, recorded in the 0-
248 20 cm layer were observed at rate of 0 kg N ha⁻¹ year⁻¹ and 100 kg N ha⁻¹ year⁻¹, as N-
249 Surf and N-Fert, respectively (Fig. 2c). On the other hand, the highest root diameters,
250 recorded in the 20-40 cm and 40-60 cm layers in the 2016/17 crop season, were

251 observed in grapevines subjected to all N rates (0, 40 and 100 kg N ha⁻¹ year⁻¹) applied
252 as N-Surf. In the 2017/18 crop season, the highest root diameters in the three soil layers
253 were observed in plants subjected to 40 kg N ha⁻¹ year⁻¹ in the N-Surf mode and to 100
254 kg N ha⁻¹ year⁻¹ as N-Fert mode (Fig. 2d).

255

256 **Root production and mortality**

257 In 2016/17 and 2017/18 crop seasons, the highest number of living roots,
258 recorded in the 0-20 cm layer, were observed in plants subjected to 40 kg N ha⁻¹ year⁻¹
259 as N-Surf and to 100 kg N ha⁻¹ year⁻¹ as N-Fert mode (Fig. 3a, b). In the 2016/17 crop
260 season, the highest number of living roots, recorded in the 20-40 cm and 40-60 cm
261 layers, were observed in grapevines subjected to 40 kg N ha⁻¹ year⁻¹ as N-Surf and N-
262 Fert modes (Fig. 3a). In the 2017/18 crop season, the highest number of living roots,
263 recorded in the 20-40 cm layer were observed in grapevines subjected to 100 kg N ha⁻¹
264 year⁻¹ as N-Surf and N-Fert (Fig. 3b). In 40-60 cm layer, the highest number of living
265 roots was in the 100 kg N ha⁻¹ year⁻¹ as N-Fert (Fig. 3b).

266 In the 2016/17 crop season, the highest number of dead roots, recorded in the 0-
267 20 cm layer were observed in grapevines subjected to 40 kg N ha⁻¹ year⁻¹ as N-Surf
268 mode and to 100 kg N ha⁻¹ year⁻¹ as N-Fert mode (Fig. 3c). In the 2017/18 crop season,
269 the highest number of dead roots, recorded in the 0-20 cm layer, were observed in
270 grapevines subjected to 100 kg N ha⁻¹ year⁻¹ as N-Fert and to 0 kg N ha⁻¹ year⁻¹ and 40
271 kg N ha⁻¹ year⁻¹ as N-Surf (Fig. 3d). In the 2016/17 crop season, the highest number of
272 dead roots, recorded in the 20-40 cm layer were observed in plants subjected to 40 kg N
273 ha⁻¹ year⁻¹ as N-Surf and N-Fert and to 0 kg N ha⁻¹ year⁻¹ and 100 kg N ha⁻¹ year⁻¹ as N-
274 Surf mode (Fig. 3c). In the 2017/18 crop season, the highest number of dead roots,
275 recorded in the 20-40 cm layer, were observed in grapevines grown in control soil (0 kg

276 N ha⁻¹ year⁻¹) N-Fert and in soil subjected to the application of 40 kg N ha⁻¹ year⁻¹ as N-
277 Surf mode (Fig. 3d). In the 2016/17 crop season, the largest total number of dead roots
278 recorded in the 40-60 cm layer, was observed in grapevines grown in the control soil N-
279 Fert and N-Surf (Fig. 3c). In the 2017/18 crop season, the highest number of dead roots
280 recorded were observed in grapevines subjected to 100 kg N ha⁻¹ year⁻¹ as N-Fert and to
281 40 kg N ha⁻¹ year⁻¹ as N-Surf (Fig. 3d).

282 In the 2016/17 crop season, the highest root production, recorded in the 0-20 cm
283 layer, was observed in grapevines grown in soil subjected to the application of 40 kg N
284 ha⁻¹ year⁻¹ as N-Surf and to 100 kg N ha⁻¹ year⁻¹ as N-Fert (Fig. 4a). In the 2017/18 crop
285 season, the highest root production, recorded in the 0-20 cm, 20-40 cm and 40-60 cm
286 layers, were observed in grapevines subjected to 100 kg N ha⁻¹ year⁻¹ as N-Surf and N-
287 Fert (Fig. 4b).

288

289 **Leaf N concentration**

290 In the 2016/17 crop season, the highest N concentrations, in leaves collected at
291 flowering and at berry veraison were observed in grapevines subjected to application of
292 40 kg N ha⁻¹ year⁻¹ as N-Surf and N-Fert (Fig. 5a, c). In the 2016/17 crop season, N
293 concentration in leaves, collected at flowering were significant difference between N
294 supply methods, except for rate of 100 kg N ha⁻¹ year⁻¹, and at veraison there was a
295 significant difference between the N supply methods for 0 kg N ha⁻¹ year⁻¹. In the
296 2017/18 crop season, the highest N concentration in leaves collected at flowering and at
297 veraison was observed in grapevines grown in soil subjected to 100 kg N ha⁻¹ year⁻¹ as
298 N-Fert (Fig. 5b, d). In 2017/18 crop season, N concentrations in leaves collected at
299 flowering and at berries veraison in grapevines subjected to N-Surf did not show
300 significant difference among N rates (Fig. 5b, d).

301

302 Yield and its components

303 In the 2016/17 crop season, the lowest weight of 100 berries was observed in
304 grapevines grown in soil subjected to the application of 0 and 100 kg N ha⁻¹ year⁻¹, than
305 40 kg N ha⁻¹ year⁻¹, as N-Fert (Fig. 6a). The weight of 100 berries recorded for
306 grapevines subjected to N-Surf in the 2016/17 crop season did not statistically differ
307 with N doses (Supplementary material 2). In the 2017/18 crop season, the weight of 100
308 berries did not show statistically significant difference among N doses and modes (Fig.
309 6b).

310 In 2016/17 crop season, the largest number of grape clusters per plant fertilized
311 as N-Fert was observed at the rate of 100 kg N ha⁻¹ year⁻¹ (Fig. 6c). The number of
312 grape clusters per plant fertilized as N-Surf were not affected by N application rates
313 (Supplementary material 2). In 2017/18 crop season, the smallest numbers of grape
314 clusters per plant were observed in control grapevines (Fig. 6d). In the two crop seasons
315 - 2016/17 and 2017/18, the number of grape clusters per plant did not statistically differ
316 between N supply modes (Supplementary material 2).

317 In the 2016/17 crop season, the lowest yield of N-Fert plant was observed in
318 control (12.49 Mg ha⁻¹) (Fig. 6e), whereas yield in N-Surf plants was not affected by
319 application rates. In the 2017/18 crop season, the highest yields recorded were observed
320 in grapevines grown in soil subjected to the application of 100 kg N ha⁻¹ year⁻¹ as N-
321 Surf and N-Fert (29.77 and 27.86 Mg ha⁻¹, respectively) (Fig. 6f). In the 2016/17 and
322 2017/18 seasons, crop yield was not statistically affected by N application modes
323 (Supplementary material 2).

324

325 Chemical parameters of the must

326 In the 2016/17 crop season, the highest total titratable acidity was observed in
327 grape musts subjected to the application of $100 \text{ kg N ha}^{-1} \text{ year}^{-1}$ as N-Fert (Fig. 7a),
328 whereas in the 2017/18 crop season, the highest total titratable acidity was recorded in
329 grape musts subjected to the application of the same N dose, in both N-Fert and N-Surf
330 modes (Fig. 7b). In the 2016/17 and 2017/18 crop seasons, the highest TSS values in
331 must were observed in grapevines that were not fertilized ($0 \text{ kg N ha}^{-1} \text{ year}^{-1}$) (Fig. 7c,
332 d). In the 2016/17 crop season, the highest total anthocyanin were observed in grape
333 that were not fertilized (Fig. 7e), whereas in the 2017/18 crop season, the highest total
334 anthocyanin values recorded were observed in grapevines subjected to the application of
335 $0 \text{ kg N ha}^{-1} \text{ year}^{-1}$ and $40 \text{ kg N ha}^{-1} \text{ year}^{-1}$, for both N application modes (N-Surf and N-
336 Fert modes) (Fig. 7f).

337

338 **Principal Component Analysis (PCA)**

339 The sum of components PC1 and PC2 explained 54.18% of original data
340 variability (Fig. 8). The PC1 explained 32.22% of data variability and enabled
341 observing treatment trends to show repeated behavior throughout crop seasons, a fact
342 that was evidenced by the constant position of the $0 \text{ kg N ha}^{-1} \text{ year}^{-1}$ dose (at the right
343 side) in the spatial distribution. These results differed from those recorded for N doses
344 of $40 \text{ kg N ha}^{-1} \text{ year}^{-1}$ and $100 \text{ kg N ha}^{-1} \text{ year}^{-1}$, which alternated in the most productive
345 position between crop seasons and always headed left in the spatial distribution.

346 The PC2 explained 21.96% data variability and it was efficient in separating
347 grapevines' productive behavior in each crop season, which was delimited by different
348 ellipses. Thus, plants subjected to the application of $40 \text{ kg N ha}^{-1} \text{ year}^{-1}$ and 100 kg N
349 $\text{ha}^{-1} \text{ year}^{-1}$ were mostly influenced by production variables such as yield, number of
350 grape clusters and weight of 100 berries; as well as by several root parameters such as

351 surface area, diameter, number of living roots and root production, which were
352 positively correlated to each other. On the other hand, grapevines that were not
353 subjected to N application mainly showed the influence of variables on quality
354 parameters such as total anthocyanins and TSS. This variable of quality parameters also
355 showed negative linear correlation to grape yield.

356

357 **Discussion**

358 The increased root surface area observed in plants subjected to N application
359 may have happened due to increased content of mineral N forms (*i.e.* NH_4^+ and NO_3^-) in
360 the soil which derived from the applied urea (Radville et al., 2016; Yan et al., 2017).
361 Nitrogen application as fertigation probably promoted the movement of NO_3^- , a form of
362 N common in subtropical soils (Barlow, Bond, Holzapfel, Smith, & Hutton, 2009; G.
363 Brunetto et al., 2017), through to deeper soil layers and, consequently, reduced N losses
364 due to volatilization. This outcome most likely resulted from the downward flow of
365 water deriving from fertigation (Castellanosa et al., 2013), considering that the
366 investigated soil was sandy with low OM content, a fact that facilitates the ion
367 approximation through mass flow until the outer surface of the root system (Comas et
368 al., 2010).

369 Increased NO_3^- concentration in soil solution stimulates the development of
370 plant root system components, such as root diameter and surface area, two components
371 sensitive to NO_3^- concentrations in the soil (Othman and Leskovar 2019). It also enables
372 activating transporters, such as NRT1.1, in the root system, a fact that increases the
373 amount of NO_3^- uptake by plants (Krouk et al., 2010; Pii et al., 2013; Remans et al.,
374 2006). This NO_3^- root transporter is also capable of transporting auxin, under the control
375 of NO_3^- in root-growth medium. Roots grown at high NO_3^- concentrations shows the

376 preference for transporting NO_3^- over auxin, which accumulates in the roots and favors
377 root growth (Mounier et al., 2014). Increased NO_3^- concentrations in root tissues also
378 increases cytokinins metabolism rates (Silva and Delatorre 2009); cytokinines are
379 important cell division regulators that lead to increased root system surface area
380 (Centinari et al., 2016; Comas et al., 2010).

381 In the present study, the increased mineral N availability in the soil contributed
382 to increase the mean root diameter in grapevines grown in soil subjected to N
383 application rate of 40 and 100 kg N ha⁻¹ year⁻¹. It may have happened due to decreased
384 soil pH values, which reduced cell division and elongation (Barlow et al., 2009; Yan et
385 al., 2017). Such process often takes place because H^+ is released during nitrification and
386 stimulates the solubilization of Al^{+3} from soil native minerals (Miotto et al., 2019).
387 Released Al^{+3} can bind to carboxylic groups and to pectic materials in the cell wall.
388 This process increases the stiffness and decreases the extensibility of root cell walls;
389 consequently, it can lead to disorganized cell division, which impairs root elongation
390 and enables larger root diameter (Riaz et al., 2018; Zhou et al., 2014).

391 Nitrogen applications increased mineral N contents in the soil, a fact that
392 stimulated root emission, as observed in the total number of living roots in grapevines
393 subjected to N addition in both application modes. Roots preferentially grow in soil
394 regions presenting the highest nutrient contents (Centinari et al., 2016), including
395 mineral N (Lima, Kojima, Takahashi, & von Wirén, 2010). This because NO_3^- available
396 in the soil acts as a signaling molecule that can regulate the expression of genes
397 involved in plant hormonal balance (Lee et al., 2016; Xuan, Beeckman, & Xu, 2017).
398 This process contributes to the production and development of new roots, mainly in soil
399 regions where NO_3^- is available (Krouk et al., 2010; Remans et al., 2006).

400 The increased production and number of living roots in grapevines subjected to
401 the highest N dose application ($100 \text{ kg N ha}^{-1} \text{ year}^{-1}$) can also be associated with
402 strategies adopted by plants to uptake and accumulate N, such as amino acids and
403 proteins, in perennial organs (Ortiz-Lopez, Chang, & Bush, 2000). The increased N
404 availability in the soil increases the likelihood of nutrient uptake; however, in addition
405 to N supply, root emission and renewal processes also depend on the internal carbon (C)
406 balance of grapevines (Jagodzinski and Kalucka 2011; Yan et al. 2017). In periods of
407 higher metabolic activity, such as intense annual plant growth, part of N can be
408 redistributed to shoots and leaves, in order to enable biochemical and physiological
409 processes in grapevines (Gustavo Brunetto et al., 2016; Zambrosi et al., 2012).
410 However, senescence is expected to happen in part of the roots when most of the C
411 found in plants is allocated to the shoot, as it happens in vegetative growth periods
412 (Kou, Chen, et al., 2015; Kou, Guo, Yang, Gao, & Li, 2015). This was observed in
413 grapevines subjected to $40 \text{ kg N ha}^{-1} \text{ year}^{-1}$ as N-Surf mode and to $100 \text{ kg N ha}^{-1} \text{ year}^{-1}$
414 as N-Fert mode, in the two evaluated crop seasons.

415 Increased N concentrations in leaves collected at flowering and at berry veraison
416 can be attributed to increased mineral N content in the soil, in grapevines subjected to N
417 applications. Part of N uptake by plants can be incorporated into C skeletons, such as
418 amino acids, amines and proteins, which can be transported to leaves, which undergo
419 intense cell division and elongation processes (Radville et al., 2016; Yu et al., 2012).
420 This phenomenon, in association with the application of higher N rates such as 100 kg
421 $\text{N ha}^{-1} \text{ year}^{-1}$, led to increase of N concentrations in leaves of plants subjected to this
422 treatment. In addition, large rainfall volumes recorded in concomitance of N
423 applications, as observed in the 2016/17 crop season (Fig. 1), have stimulated NO_3^-
424 movement in the soil solution, since NO_3^- links itself to reactive particles in the soil by

425 means of external sphere complex (Comas et al., 2010; Li, Wang, & Stewart, 2013;
426 Lorensini et al., 2012). This process may have stimulated the emission of new in-depth
427 roots and increased grapevine N uptake (Gustavo Brunetto et al., 2016).

428 The increased number of grape clusters per plant and yield of grapevines
429 subjected to the highest N application (100 kg N ha⁻¹ year⁻¹) might be associated to a
430 higher mineral N availability in the soil (Brunetto et al., 2016; Steenwerth and Belina,
431 2010), a fact that stimulated root growth to 60 cm. On the one hand, increased N
432 concentrations in plant leaves stimulated photosynthetic processes, since higher
433 concentrations of chlorophylls and chloroplast proteins, such as RuBisCO, enabled
434 increased CO₂ fixation in leaf tissues, as well as increased plant growth (Blank et al.,
435 2018; Moriwaki et al., 2019). On the other hand, plants needed to be photosynthetically
436 active in order to enable NO₃⁻ uptake and reduction. Therefore, higher rates of
437 photosynthesis can also favor the uptake of N to be increased, since enzymes
438 responsible for reducing N were regulated by light, whereas the energy used in this
439 process derived from chloroplasts (Krouk et al., 2010).

440 The highest total titratable acidity in the must of grapevines grown in soil
441 subjected to the highest N applications may be explained by the inverse relationship
442 between the total titratable acidity in the must and the vegetative growth of grapevine
443 shoots. Increased leaf yield also increases the shading of clusters inside plants, which, in
444 its turn, delays the ripening of grapes and decreases organic acid degradation in berries
445 (Centinari et al., 2016; Vilanova, Fandiño, Frutos-Puerto, & Cancela, 2019). Decreased
446 TSS values observed in the must of grapevines grown in soil subjected to the
447 application of higher N doses resulted from the increased number of grape clusters per
448 plant and, mainly, from the increased grape yield, which contributed to dilute the sugars
449 in the berries (Guilpart, Metay, & Gary, 2014). In addition, decreased TSS levels in the

450 must may have resulted from increased leaf area in grapevines subjected to higher N
451 applications, since excessive leaf growth reduces direct sunlight incidence on berries, a
452 fact that leads to lower sugars concentration (Sadras and Moran 2012). Nitrogen
453 applications at the highest dose ($100 \text{ kg N ha}^{-1} \text{ year}^{-1}$) and N supply modes (N-Surf and
454 N-Fert) led to TSS values lower than 14 °Brix, which are not appropriate for
455 winemaking processes (Chiarotti, Guerios, Cuquel, & Biasi, 2011). The application of
456 40 and $100 \text{ kg N ha}^{-1} \text{ year}^{-1}$, in both N supply methods, also reduced total anthocyanin
457 values in grape must. This outcome may be associated with increased number of grape
458 clusters per plant and with grape yield, which is often associated with increased berry
459 size and pulp/peel ratio. Thus, the concentration of important compounds, such as total
460 anthocyanins in the must, which account for the reddish color of the must and,
461 consequently, of the wine, gets diluted (Brunetto et al. 2009b; Sadras and Moran, 2012;
462 Sofo et al. 2012). In addition, as plants' vegetative growth increases, part of the
463 anthocyanins found in the clusters may have been redistributed to other growth sites and
464 had their contents decreased in berries (Terrier, Poncet-Legrand, & Cheynier, 2009).

465 Results of the principal component analysis showed intrinsic climate variation in
466 each crop season, which resulted in plants' productive response to the application of
467 different treatments. It also showed annual variations in fruit yield and nutritional status.
468 It happened because fruit plant species have a cyclical dynamics of C allocation to
469 different organs that can favor yield in a given year and species maintenance in the
470 following year, due to reserve accumulation in organs that require more energy for
471 protein synthesis, mainly in plants subjected to N applications (Ceccon et al. 2016;
472 Artacho and Bonomelli 2017). The PCA enabled a better understanding of the positive
473 relationship among root system, plants yield, N application rates and modes. These
474 results showed that as photoassimilates accumulated in grapevines roots, water and

475 nutrient intake increased, a fact that improved crop yield (Antolín et al., 2003; Barlow et
476 al., 2009; Comas et al., 2010). In addition to this process, there was a decrease in the
477 oenological quality of the must, which was diagnosed based on decreased total
478 anthocyanins and total soluble solids values, as well as on increased total acidity values.
479

480 **Conclusion**

481 The application of 40 kg N ha⁻¹ year⁻¹, as N-Surf mode, provided adequate N
482 supply to the soil and increased root system development, which enabled larger root
483 surface area, larger number of living roots and greater root production. This process
484 enabled an increase of soil N uptake by plants, higher N concentration in leaves and
485 greater grape yield. However, N supply decreased the quality of the must, as observed
486 in decreased TSS and total anthocyanins values and in increased total titratable acidity
487 values, which are not desirable for red wine making processes.

 811 of the root system (total surface area of roots (a), average diameter of roots (d), total number of living
 812 roots (living), total number of dead roots (dead) and root production (prodR) in 0-20, 20-40 and 40-60 cm
 813 soil layers), leaf N concentration (leaf N concentration at flowering (N flowering) and leaf N
 814 concentration at veraison (N veraison)), grape yield parameters (grape yield (Yield), number of cluster
 815 per plant (n cluster), weight of 100 berries (100b)) and chemical parameters of the must (total
 816 anthocyanins (Anthocyanins), total soluble solids (TSS), total titratable acidity (TTA)) of 'Alicante
 817 Bouschet' (*Vitis vinifera* L.) grapevine subjected to different N doses and application modes

818

819

820 **Supplementary material 1.** Schematic representation of the imaging system from minirizotron tubes
821 installed in the vineyard of the experimental area; *in situ* image capture high resolution (600 dpi) from a
822 cylindrical scanner (Root Imager – CI600®).

823 **Supplementary material 2.** Analysis of variance of the roots parameters, leaf N concentration, grape
 824 yield and chemical of the must of 'Alicante Bouschet' (*Vitis vinifera* L.) grapevine subjected to different
 825 N doses and application modes.
