**Abstract**

How atmospheric and oceanic processes control North American precipitation variability has been extensively investigated, and yet debates remain. Here we address this question in a 50km-resolution flux-adjusted global climate model. The high spatial resolution and flux adjustment greatly improve the model’s ability to realistically simulate North American precipitation, the relevant tropical and midlatitude variability and their teleconnections. Comparing two millennium-long simulations with and without an interactive ocean, we find that the leading modes of North American precipitation variability on seasonal and longer timescales exhibit nearly identical spatial and spectral characteristics, explained fraction of total variance and associated atmospheric circulation. This finding suggests that these leading modes arise from internal atmospheric dynamics and atmosphere-land coupling. However, in the fully coupled simulation, North American precipitation variability still correlates significantly with tropical ocean variability, consistent with observations and prior literature. We find that tropical ocean variability does not create its own type of atmospheric variability but excites internal atmospheric modes of variability in midlatitudes. This oceanic impact on North American precipitation is secondary to atmospheric impacts based on correlation. However, relative to the simulation without an interactive ocean, the fully coupled simulation amplifies precipitation variance over southwest North America (SWNA) during late spring to summer by up to 90%. The amplification is caused by a stronger variability in atmospheric moisture content that is attributed to tropical Pacific sea surface temperature variability. Enhanced atmospheric moisture variations over the tropical Pacific are transported by seasonal mean southwesterly winds into SWNA, resulting in larger precipitation variance.

43       **1. Introduction**

44           Precipitation over North America, a region prone to frequent large-scale droughts  
45       persisting from a season to multiple decades (e.g., Seager and Ting 2017), has been extensively  
46       studied over the past forty years with a goal to assess its predictability and improve predictions.  
47       Most of the efforts have been focused on the physical understanding of North American  
48       precipitation variability. Processes underlying North American (or any regional) precipitation  
49       variability can be categorized into two types, external radiative forcing and internal climate  
50       dynamics. In this work we focus on the latter, which consists of processes internal to, and  
51       interactions among, atmosphere, land, cryosphere and ocean, on seasonal and longer timescales.

52           Precipitation is a meteorological phenomenon and the earliest studies are, as expected,  
53       atmosphere-oriented. The most prominent large-scale atmosphere circulation variability that  
54       have been identified to affect North American precipitation includes the Pacific North America  
55       (PNA) pattern (Wallace and Gutzler 1981) and the North Pacific Oscillation (NPO) pattern  
56       (Walker 1924). Both patterns represent variations of background mean flow over the North  
57       Pacific/America sector. The PNA depicts planetary-scale coherent strengthening or weakening of  
58       a trough in the central North Pacific, a ridge over the Rocky Mountains and a trough over  
59       southeast North America, while the NPO delineates the meridional movements of the Asian-  
60       Pacific jet. The PNA and NPO affect North American precipitation by modulating the Pacific  
61       storm track and moisture transport into North America (e.g., Leathers et al. 1991; Linkin and  
62       Nigam 2008; Liu et al. 2017; Chen et al. 2018; references therein). Although the PNA and NPO  
63       are often portrayed as atmosphere circulation variability, they especially the PNA can also be  
64       triggered by ocean variability (e.g., Horel and Wallace 1981) and act as a teleconnection to link  
65       remote ocean impacts to North American precipitation variability (Liu et al. 2017).

66           The tropical ocean's role in North American precipitation variability began to be noticed  
67       and understood first by Bjerknes (1966, 1969) and then in the late 1970s and early 1980s, when  
68       the now-well-established Rossby wave and teleconnection dynamics were theorized (Hoskins  
69       and Karoly 1981) and applied to link the tropical Pacific El Niño-Southern Oscillation (ENSO)  
70       to meteorological anomalies over North America (Rasmusson and Wallace 1983). Rossby waves  
71       excited by ENSO-induced rainfall anomalies in the tropical Pacific propagate poleward and  
72       eastward along a great circle of the Earth and generate alternating cyclonic and anticyclonic  
73       circulation anomalies that are quasi-stationary and akin to the PNA pattern, with centers of

74 action over the North Pacific, western Canada and the southeastern United States. These  
75 circulation anomalies affect the strength and position of the subtropical jet stream over the North  
76 Pacific (stronger and further equatorward during warm El Niño events and vice versa during cold  
77 La Niña events), which then change the associated storminess, moisture transport and  
78 precipitation over North America. This dynamical mechanism has been tested in models (e.g.,  
79 Palmer and Mansfield 1984, 1986; Suarez 1985) and invoked to explain the observed  
80 precipitation variations over North America during major ENSO events (e.g., Ropelewski and  
81 Halpert 1986; Trenberth et al. 1988; Palmer and Branković 1989; Trenberth and Branstator 1992;  
82 Trenberth and Guillemot 1996; Hoerling and Kumar 2003; Schubert et al. 2009). It has also been  
83 shown to operate during non-ENSO seasons such as boreal summer, although the associated  
84 atmosphere teleconnection pattern changes with seasonal mean circulation (e.g., Castro et al.  
85 2001; and references therein).

86         The ENSO teleconnection mechanism has been expanded by Seager et al. (2003, 2005).  
87 They use observations and models to show that ENSO drives a prominent zonally and  
88 hemispherically symmetric component of precipitation variability in the midlatitudes. El Niño  
89 events warm the entire tropical troposphere, which strengthens the subtropical jets in both  
90 hemispheres and pulls them equatorward (opposite for La Niña events). These changes in the  
91 subtropical jets influence the transient eddy momentum fluxes and the eddy-driven mean  
92 meridional circulation, resulting in ascent and more precipitation in the midlatitudes especially  
93 over North America (Seager et al. 2005a).

94         On decadal to multidecadal time scales, in the early 2000s, tropical Pacific low-frequency  
95 variability was found to affect North American precipitation (e.g., McCabe et al. 2004; Schubert  
96 et al. 2004a, b; Seager et al. 2005b). Over the past two decades, tremendous progress has been  
97 made, particularly on decadal droughts over North America (see two review papers by Seager  
98 and Hoerling 2014; Seager and Ting 2017; and the references therein). The dynamical  
99 mechanisms on low-frequency timescales are essentially the same as those on seasonal and  
100 interannual timescales as discussed above.

101         In addition to the tropical Pacific, tropical North Atlantic variability also influences North  
102 American precipitation on seasonal to multidecadal timescales (e.g., Enfield et al. 2001; Sutton  
103 and Hodson 2005, 2007; Wang et al. 2008; Kushnir et al. 2010; Ruprich-Robert et al. 2016,  
104 2018; Johnson et al. 2020). The associated mechanisms are insensitive to timescales (as for the

105 tropical Pacific), but seasonally dependent (Kushnir et al. 2010). In warm seasons, variations in  
106 tropical North Atlantic sea surface temperature (SST) change the strength of the North Atlantic  
107 subtropical high (warmer SSTs lead to a weaker high), which influences the associated  
108 northward moisture transport on its west flank from the Gulf of Mexico and thus precipitation  
109 over North America (mainly the United States and northern Mexico). In cold seasons, the above  
110 warm-season mechanism still operates; in addition, tropical North Atlantic SST variations also  
111 modify the convection over the equatorial Pacific, which then affects North American  
112 precipitation in a way similar to the ENSO teleconnection but with a weaker amplitude. Overall,  
113 the impacts of tropical North Atlantic on North American precipitation are considerably weaker  
114 than those from the tropical Pacific.

115         Despite the significant progress on the physical understanding of North American  
116 precipitation variability, debates still remain. For example, the argument that the 1988 summer  
117 North American drought was caused by the La Niña event that year (Trenberth et al. 1988;  
118 Palmer and Branković 1989) has been refuted by others arguing a fundamental role for remote  
119 diabatic heating over the western North Pacific as well as local land feedbacks and atmosphere  
120 dynamics (Lyon and Dole 1995; Liu et al. 1998; Chen and Newman 1998; Bates et al. 2001,  
121 Seager and Hoerling 2014). The attribution of the infamous 1930s Dust Bowl to the persistent  
122 cold tropical Pacific and warm tropical North Atlantic (Schubert et al. 2004a, b; Seager et al.  
123 2005b; Herweijer et al. 2006) has been augmented by studies arguing for an indispensable role  
124 for human-induced land changes and dust aerosol feedbacks in the persistence, intensification  
125 and spatial expansion of the drought (Cook et al. 2009, 2011) and a fundamental role for  
126 atmosphere random processes in the onset of the drought (Hoerling et al. 2009). At the core of  
127 these debates is a lack of agreement on the relative contributions to North American precipitation  
128 of the tropical oceans and internal atmosphere dynamics—processes internal or intrinsic to the  
129 atmosphere and independent of other components of the earth system.

130         The role of internal atmosphere dynamics in North American precipitation variability on  
131 seasonal and longer time scales has been emphasized by a few studies (e.g., Hoerling and Kumar  
132 1997; Hoerling et al. 2009; Seager and Hoerling 2014; Stevenson et al. 2014; Seager and Ting  
133 2017; Kumar and Chen 2020). On seasonal to interannual time scales, North American  
134 precipitation anomalies during El Niño events differ significantly from event to event  
135 (Rasmusson and Wallace 1983), and most of these differences have been attributed to internal

136 atmosphere variability (Hoerling and Kumar 1997). On decadal time scales, Stevenson et al.  
137 (2017) explore the causes of North American megadroughts by comparing a fully coupled  
138 simulation with an atmosphere-only simulation driven by climatological SSTs from the coupled  
139 simulation. They find similar intensity and frequency of megadroughts between the two  
140 simulations and suggest that the atmosphere alone (still coupled with the land) is able to generate  
141 North American megadroughts. A recent review paper by Seager and Ting (2017) conclude that  
142 the ocean's role in North American decadal droughts is influential, but not paramount, with  
143 atmosphere internal variability explaining up to three quarters of the low-frequency precipitation  
144 variability. In all of these studies except Stevenson et al., the role of internal atmosphere  
145 dynamics is not explicitly assessed, but inferred as a residual between the total precipitation  
146 variations and the ocean contributions that are explicitly assessed (often by averaging ensembles  
147 of atmosphere-only simulations driven by observed monthly SSTs). Even in Stevenson et al.,  
148 internal atmosphere dynamics are only assessed as a whole in terms of the statistics of North  
149 American megadroughts. It remains unclear how exactly internal atmosphere dynamics work  
150 together with ocean variability to generate North American precipitation variability, especially  
151 on seasonal and longer timescales.

152 In this work, we aim to fill this gap by (1) investigating the specific role of internal  
153 atmosphere dynamics in North American precipitation variability on seasonal and longer time  
154 scales and (2) assessing how atmospheric and oceanic processes play out in the context of North  
155 American precipitation variability, that is, how different or comparable the atmosphere-induced  
156 and ocean-induced precipitation variability are. We will not only demonstrate the fundamental  
157 role of internal atmospheric dynamics and coupling with land in shaping the spatial and spectral  
158 characteristics of the leading modes of variability in North American precipitation, but also  
159 present a new physical mechanism whereby the tropical oceans affect North American  
160 precipitation variability.

161

## 162 **2. Methods**

### 163 2.1 Model and experiments

164 In order to cleanly separate the contributions of atmospheric and oceanic processes,  
165 analyzing observations alone is not enough and we have to use climate models. The model in this  
166 work is the Forecast-oriented Low Ocean Resolution (FLOR) flux-adjusted model developed at

167 the Geophysical Fluid Dynamics Laboratory (Vecchi et al. 2014). FLOR has a high horizontal  
168 resolution of approximately 50km for the atmosphere (AM2.5) and land (LM3) components and  
169 a horizontal resolution of 1° (telescoping to 0.333° near the equator) for the ocean (MOM4) and  
170 sea ice (Sea Ice Simulator) components. It has a standard freely coupled version and a flux-  
171 adjusted version. The flux-adjustment in FLOR imposes fixed anomalous enthalpy, momentum  
172 and fresh water fluxes to the ocean to correct biases in the climatological seasonal cycle of SST,  
173 sea surface salinity and wind stress (against 1979-2012 observations). We use the flux-adjusted  
174 FLOR because of its much-improved mean climate and variability (see the next section).

175 Experiments are summarized in Table 1. We first introduce two long control simulations,  
176 one conducted with the fully coupled FLOR for 3500 years and the other with the uncoupled  
177 AM2.5 for 1000 years (note in AM2.5, the atmosphere is still coupled with the land). For  
178 simplicity, these control simulations are referred to as FLOR and AM2.5, respectively. Both  
179 simulations are driven by preindustrial level atmospheric composition and radiative forcing. In  
180 AM2.5, the boundary forcing is prescribed as the climatological annual cycle of monthly mean  
181 SST and sea ice (concentration and thickness) derived from the last 1000 years of FLOR. This  
182 1000-year FLOR simulation is compared with AM2.5. FLOR and AM2.5 share the same  
183 radiative forcing and the same climatology at the surface, but differ in that the ocean (including  
184 sea ice) is fully active in FLOR but is replaced with an imposed climatological seasonal cycle of  
185 SST and sea ice in AM2.5. Precipitation variability in AM2.5 (excluding seasonal cycle) thus  
186 arises purely from internal atmosphere processes and coupling with land, while that in FLOR  
187 also includes contributions from the ocean (specifically, SST and sea ice variability). He et al.  
188 (2018a) showed that the ocean and atmosphere induced precipitation variability is linearly  
189 additive and that variability internal to the atmosphere (and land) can be cleanly extracted using  
190 atmosphere-only simulations with prescribed climatological SSTs. Analyzing and comparing the  
191 millennium-long fully coupled and atmosphere-only simulations allows for a physically clean  
192 and statistically robust assessment of the relative contributions of internal atmosphere processes  
193 and coupling with land versus the ocean in North American precipitation variability.

194 The remaining simulations are summarized in Table 1 and will be introduced later. We  
195 first examine the performance of the FLOR model in simulating North American precipitation  
196 and the associated climate variability in the tropics and midlatitudes, in order to build confidence

197 in using the model for investigating North American precipitation variability and the underlying  
198 atmospheric and oceanic processes.

## 199 2.2 Model performance

200 Precipitation biases over North America, especially over the western mountains, are a  
201 common problem in the current generation of climate models (Mejia et al. 2018). The FLOR  
202 model, however, substantially reduces these biases owing partly to its high resolution and flux  
203 adjustment. A recent paper by Johnson et al. (2020) has explained that the flux adjustment in  
204 FLOR reduces SST biases in the tropical Pacific and Atlantic, which improves the climatology  
205 of North American precipitation through atmosphere teleconnection mechanisms (including the  
206 ENSO teleconnection and those proposed by Kushnir et al. (2010)). Here we highlight the  
207 precipitation biases that remain in the flux-adjusted FLOR, against two observational products at  
208  $0.5^\circ$  resolution, the Climatic Research Unit timeseries (CRU) datasets version 3.24.01 (Harris et  
209 al. 2014) and the Global Precipitation Climatology Centre (GPCC) version 2018 (Schneider et al.  
210 2011). Fig. 1b shows that the flux-adjusted FLOR still has significant biases over most of North  
211 America, with too much precipitation over the Pacific Northwest and the monsoon region and  
212 too little precipitation over central to southeast North America. These positive biases are  
213 simulated throughout the year while the negative biases occur mainly during early summer to fall  
214 (Fig. 17 in appendix). Compared to the climatology, precipitation variability is better simulated  
215 in FLOR (Fig. 1c and Fig. 18 in appendix, indicated by more stippling). As will be shown later in  
216 the Results section, FLOR realistically simulates the leading modes of North American  
217 precipitation variability on seasonal and longer (up to the sampling length) time scales.

218 Tropical climate variability is assessed by comparing FLOR with the Met Office Hadley  
219 Centre's sea ice and sea surface temperature dataset (HadISST) version 1.1 (Rayner 2003).  
220 FLOR realistically simulates the spatial pattern and amplitude of tropical SST variability,  
221 although the ENSO variability is excessively strong in FLOR (Fig. 2a-b). This bias over the  
222 Niño3.4 occurs during February to June, while during the rest of the year FLOR simulates a very  
223 realistic Niño3.4 variability (Fig. 2c). FLOR also realistically simulates the ENSO spectrum,  
224 with a broad interannual peak consistent with observations (Fig. 2d) but seemingly too weak  
225 decadal variability.

226 To evaluate how FLOR simulates the ENSO teleconnection and impacts on North  
227 American precipitation, we compute the correlation coefficients between the Niño3.4 index and

228 SST, land precipitation and 200mb geopotential height (GHT200) during December to February  
229 (DJF). Observational fields include SST from HadISST, precipitation from CRU and  
230 geopotential height from the NOAA-CIRES-DOE Twentieth Century Reanalysis (20CR) version  
231 2 (Compo et al. 2011) during 1901-2012. Fig. 3 shows that FLOR simulates the observed global  
232 ENSO teleconnection very well, indicated by the similar Rossby wave trains emanating from the  
233 tropical Pacific. Over the Pacific/North America sector, FLOR realistically simulates the  
234 observed PNA-like upper tropospheric circulation (GHT200) associated with ENSO (Fig. 3a vs  
235 3c). In particular, observed correlations between North American precipitation and ENSO are  
236 realistically captured in FLOR, with a pattern of positive/negative correlations over  
237 southern/northern North America, respectively (Fig. 3b vs 3d). We note that the correlations  
238 appear a bit weaker in FLOR than in observations, which can be partly attributed to the  
239 uncertainty in the observed teleconnection patterns due to the insufficient sampling lengths (112  
240 years, (Deser et al. 2017)).

241 To evaluate FLOR's performance in simulating midlatitude variability over the  
242 Pacific/North America sector (20°N-80°N, 100°E-50°W), we conduct an empirical orthogonal  
243 function (EOF) decomposition of monthly mean sea level pressure (SLP) variability and  
244 compare the leading modes between FLOR and the 20CR dataset (Fig. 4, top two rows). Clearly,  
245 FLOR faithfully simulates the top three EOF modes in terms of the spatial pattern and the  
246 explained variance. Accounting for about 24% of total variance in both FLOR and 20CR, the  
247 first EOF mode (EOF1) features three centers of action over the Aleutian Low, the Arctic Ocean  
248 and the Gulf Stream, respectively and likely reflects the surface expression of the PNA (which in  
249 literature is defined by middle to upper tropospheric geopotential heights). Note that EOF1 is  
250 nearly identical to the ENSO teleconnection pattern in SLP (black contours in Fig. 4 upper left  
251 two panels), suggesting that EOF1 is related to the ENSO variability. However, this EOF mode  
252 does not owe its existence to ENSO, because it also appears as the first EOF mode in AM2.5  
253 without the interactive varying ocean (Fig. 4 bottom left) and explains a similar amount of  
254 monthly SLP variance, 22.7% in AM2.5 vs 24.2% in FLOR. This result supports the familiar  
255 concept that ENSO affects the extratropics by projecting onto internal modes of atmospheric  
256 variability (e.g., Simmons et al. 1983; Palmer and Mansfield 1984; Geisler et al. 1985; Palmer  
257 1993; Lau and Nath 1994; Saravanan 1998; Hoerling and Kumar 2002; Barsugli and  
258 Sardeshmukh 2002; Dai et al. 2017; Henderson et al. 2020). A similar story holds true for the

259 second and third EOF modes, with EOF2 being the North Pacific Oscillation (Walker 1924) and  
260 EOF3 being an east-west seesaw pattern over the Aleutian Islands. Both are realistically  
261 simulated in FLOR.

262 In summary, as shown by Johnson et al. (2020), the flux-adjusted high-resolution FLOR  
263 model substantially improves the simulation of North American precipitation climatology  
264 compared to its standard version and other peer models. Here we demonstrate that FLOR also  
265 realistically simulates climate variability both in the tropical oceans and midlatitudes as well as  
266 the ENSO teleconnection. Next, we move on to the focus of this work—North American  
267 precipitation variability on seasonal and longer time scales, evaluate how it is simulated in FLOR  
268 and investigate how it is shaped by atmospheric and oceanic processes.

269

### 270 **3. Results**

#### 271 3.1 Dominant modes of variability in North American precipitation

272 To examine North American precipitation variability on seasonal and longer time scales,  
273 we focus on the dominant modes of variability in monthly precipitation calculated from an EOF  
274 decomposition. Note that the mean annual cycle has been removed from precipitation prior to the  
275 EOF decomposition. In observations and FLOR, the top two EOF modes are significantly  
276 separated from each other (and also other modes) based on the North test (North et al. 1982) and  
277 reflect the strong precipitation over the southeastern United States and the Pacific Northwest,  
278 respectively (recall Fig. 1a). In Fig. 5, for the first matching EOFs, both the observed and FLOR  
279 modes have the largest loading over the southeastern United States and explain about 9.0% and  
280 7.8% of their total variance over North America, respectively. In Fig. 6, for the second matching  
281 EOFs, the observed and FLOR modes are dominated by two largest loadings along the Pacific  
282 Northwest and explains about 6.4% of the variance in observations and 8.8% in FLOR. The  
283 pattern correlation between observations and FLOR is 0.77 for the EOF modes in Fig. 5 and 0.87  
284 in Fig. 6. Note that the order of the two modes is reversed between observations and FLOR, with  
285 the first (second) mode in observations being the second (first) mode in FLOR. The reversed  
286 order in FLOR is due to the relatively large biases in regions of strong precipitation, namely, the  
287 Pacific Northwest (more precipitation and larger variance, thus EOF 1) and the southeastern  
288 United States (less precipitation and weaker variance, thus EOF 2) (recall Fig. 1c). In addition to  
289 the spatial pattern, the principal components (PC) associated with these two EOF modes also

290 share similar behavior between observations and FLOR: their auto-correlation function decreases  
291 to almost zero at the 1-month lag (little or no persistence) and their spectrum is basically flat,  
292 both of which are characteristic of a white noise process. Overall, FLOR realistically simulates  
293 the spatial and spectral characteristics of the observed dominant modes of variability in monthly  
294 mean precipitation over North America. The reversed order of the two leading modes in FLOR  
295 and observations suggests that the relative contributions of the two leading modes to total  
296 precipitation variability are also reversed, which should be kept in mind for the rest of the paper.

297 AM2.5 without the interactive ocean simulates virtually the same top two EOF modes as  
298 the fully coupled FLOR (Fig. 5 and 6). For both EOF modes, the spatial structure is nearly  
299 identical between AM2.5 and FLOR with a pattern correlation of 0.99. The percentage of total  
300 variance explained by each EOF mode is also very similar, 8.5% (AM2.5) vs 8.8% (FLOR) for  
301 EOF 1 and 7.7% (AM2.5) vs 7.8% (FLOR) for EOF 2. The associated PCs exhibit little or no  
302 persistence and have a white-noise spectrum. These similarities suggest that the spatial and  
303 spectral characteristics of the two dominant modes of variability in monthly precipitation over  
304 North America are not sensitive to the ocean in the FLOR model and are determined by internal  
305 atmospheric dynamics and coupling with land.

306 In addition to monthly precipitation, we have conducted the same EOF decomposition on  
307 seasonal mean precipitation and low-pass-filtered monthly precipitation with various cutoff  
308 periods (1, 3 and 5 years) and also over various sub-regions of North America. These results are  
309 not shown but summarized here. Overall, the spatial pattern of leading EOF modes follows the  
310 pattern of strong precipitation (as expected, because strong precipitation implies strong variance  
311 and the EOF decomposition by design maximizes the variance explained by the leading modes).  
312 The main quantitative difference from the results based on monthly precipitation is in the  
313 percentage of explained variance, which increases by various extents depending on the season  
314 and the sub-region. However, regardless of seasons and sub-regions, the leading EOF modes of  
315 FLOR and AM2.5 still share very similar spatial patterns and white-noise behavior. These  
316 similarities further suggest that internal atmospheric dynamics and coupling with land dominate  
317 the spatial and spectral characteristics of the leading modes of precipitation variability over  
318 North America not only on high-frequency time scales (in monthly precipitation) but also on  
319 low-frequency (interannual to decadal) time scales. Next, we return to monthly fields and present  
320 the physical processes associated with the two leading EOF modes.

321 To examine the large-scale atmosphere circulation and possible SST anomalies  
322 associated with the top two EOF modes, we calculate the correlation coefficients between the  
323 associated PCs and SLP, GHT200 and surface temperature. For the EOF mode with a strong  
324 loading over the southeastern United States (Fig. 5), the associated large-scale atmosphere  
325 circulation is very similar over North America (where the EOF analysis is performed, indicated  
326 by the magenta box in each panel) among observations, FLOR and AM2.5. In Fig. 7, the large-  
327 scale pattern of SLP correlation (contours in top row) includes two anticyclones centered around  
328 east of the Caribbean and off the Canada-Alaska coast and one cyclone in between over the U.S..  
329 The GHT200 correlation (shading in bottom row) exhibits a similar pattern (but slightly tilted  
330 westward), suggesting an equivalent barotropic structure for the associated circulation over  
331 North America. The implied geostrophic winds and moisture advection are consistent with the  
332 EOF precipitation anomalies. In particular, the moist southerlies from the Gulf of Mexico  
333 support the strong precipitation over the southeastern United States, while the wet-dry dipole  
334 along the Pacific Northwest (weak in observations but strong in the model simulations) agrees  
335 with the wet oceanic southerlies and dry inland northerlies that straddle the anticyclone there.

336 For the correlation with surface temperature, the local patterns over North America are  
337 also very similar among observations, FLOR and AM2.5, and largely consistent with the  
338 anomalous advection of mean surface temperature (that is, southerlies lead to warming and vice  
339 visa). Remotely over the ocean, the pattern of SST correlation is similar between observations  
340 and FLOR (AM2.5 has no SST variability by design). In particular, the EOF mode shown in Fig.  
341 5 is accompanied with positive SST (also increased GHT200 aloft) anomalies over the tropical  
342 Pacific and Indian Ocean, suggesting a role for the tropical oceans. However, the weak  
343 magnitude of the correlation implies that the role of the tropical oceans is very limited for the  
344 variability in monthly precipitation over North America. AM2.5 without the interactive ocean  
345 simulates the associated surface temperature and atmospheric circulation over North America  
346 (and actually has opposite sign GHT200 anomalies in the tropics), suggesting that the physical  
347 processes underlying the precipitation EOF mode shown in Fig. 5 can arise solely from internal  
348 atmosphere dynamics and coupling with land.

349 Similar conclusions are found for the EOF mode shown in Fig. 6 reflecting strong  
350 precipitation anomalies over the Pacific coast of North America. In Fig. 8, the associated  
351 atmosphere circulation over North America features a strong equivalent-barotropic anticyclone

352 over the Pacific Northwest in observations, FLOR and AM2.5. To the west of the anticyclone,  
353 the associated geostrophic southerlies bring warm moist air from the ocean to British Columbia  
354 and Alaska. To the south of the anticyclone geostrophic easterlies bring cold dry air from inland  
355 to the US west coast. This results in the dipole pattern in both surface temperature (Fig. 8,  
356 shading in top row) and precipitation (Fig. 6). Note that the anticyclone is part of an anomalous  
357 circulation that reflects changes in the strength of midlatitude stationary eddies (Fig. 8, contours  
358 in bottom row). This EOF mode also exhibits some positive but weak correlations with tropical  
359 SSTs, mostly in FLOR. We note that the large-scale atmosphere circulation associated with the  
360 two leading EOF modes has three centers of actions over the North Pacific/American sector.  
361 These centers of action resemble but are shifted relative to those of the PNA (the upper left two  
362 panels in Fig. 4). This difference in atmosphere circulation is consistent with the fact that both of  
363 the leading EOF modes in precipitation are different from the precipitation pattern associated  
364 with the PNA (not shown but is nearly identical to the ENSO teleconnection pattern in Fig. 3).

365 Overall, despite the reversed order of the two leading EOF modes, FLOR faithfully  
366 reproduces the spatial and spectral features of the observed dominant variability in monthly  
367 precipitation over North America and the associated large-scale atmosphere circulation and  
368 surface temperature. Comparing the fully coupled FLOR and AM2.5 without the interactive  
369 ocean, we find that their dominant modes of monthly (and seasonal) precipitation variability over  
370 North America have nearly identical spatial structures, explained fraction of total variance,  
371 spectral behavior (no persistence and white-noise spectrum) and the associated large-scale  
372 atmosphere circulation and local surface temperature anomalies. These similarities suggest that  
373 the dominant variability in North American precipitation arises from internal atmosphere  
374 dynamics and coupling with land, and does not require SST variability to exist. However, SST  
375 variability, particularly in the tropics, still affects North American precipitation, as demonstrated  
376 in the literature and indicated here by the positive correlation with tropical SSTs in FLOR and  
377 observations. The weak magnitude of correlation suggests that the impacts of the tropical oceans  
378 are very limited. The results that the ocean does not change the spatial and spectral  
379 characteristics of North American precipitation leading modes of variability suggest that SST  
380 variability does not create its own modes of atmosphere variability but rather excites modes of  
381 variability that already exist in the atmosphere. This interpretation is also supported by the  
382 results in Fig. 4, where the leading mode of midlatitude variability in AM2.5 without the

383 interactive ocean is nearly identical to the ENSO teleconnection pattern in the fully coupled  
384 FLOR and observations. Note that these results are consistent with the familiar concept that SST  
385 variability affects the atmosphere by projecting onto internal modes of atmospheric variability.  
386 We emphasize here that SST variability does not significantly change the basic characteristics of  
387 the large-scale atmospheric variability and its influence only accounts for a small portion of the  
388 total North America precipitation variability. Despite its limited impacts, SST variability is still  
389 the main source of long-term predictability for North American precipitation variability beyond  
390 the time scales of internal atmosphere dynamics.

### 391 3.2 Precipitation variance over SWNA

392 To quantify the impacts of the ocean on year-to-year variance of precipitation over North  
393 America, we compute the fractional change of monthly precipitation standard deviation at each  
394 grid point for each calendar month between FLOR and AM2.5 by

$$395 \frac{STD_{FLOR} - STD_{AM2.5}}{STD_{FLOR}} \times 100\%,$$

396 where  $STD_{FLOR}$  and  $STD_{AM2.5}$  are the year-to-year standard deviation of monthly precipitation  
397 evaluated at the same grid point for the same calendar month in FLOR and AM2.5, respectively.  
398 In Fig. 9, the impacts of the ocean on precipitation variance are not significant (at 1% level) for  
399 most of North America throughout the year. The largest significant fractional increase of  
400 precipitation variance due to the ocean occurs over southwest North America (SWNA) during  
401 May to about September, with magnitudes up to 90% over parts of SWNA especially the North  
402 American monsoon region during June and July. In contrast, during winter (November to  
403 February) when ENSO variability peaks (recall Fig. 2c), the fractional increase of precipitation  
404 variance is relatively weak and only significant over smaller areas of SWNA.

405 How does the ocean amplify precipitation variance over SWNA during the late spring  
406 through summer? To answer this question, we examine the factors that affect precipitation  
407 variability, including evaporation and atmospheric moisture convergence. The latter depends on  
408 circulation and moisture variability, which we will focus on. Similar to precipitation, we  
409 compute the fractional change in year-to-year standard deviation of these two factors between  
410 FLOR and AM2.5. The metrics used are monthly 500mb pressure velocity (Omega500) and  
411 column-integrated water vapor (CWV) content. Over SWNA, no systematic significant changes  
412 are found in the standard deviation of monthly Omega500 between FLOR and AM2.5  
413 throughout the year (Fig. 10), which suggests that the interactive ocean in FLOR does not

414 significantly affect the variance of atmosphere divergent circulation over SWNA. In contrast, the  
415 standard deviation in CWV is significantly enhanced over SWNA during May to about October  
416 (Fig. 11), similar to the changes in precipitation standard deviation (Fig. 9). Together these  
417 results suggest that the amplified precipitation variance over SWNA in FLOR relative to AM2.5  
418 is caused by the enhanced variability in atmosphere moisture content.

419         How does the interactive ocean enhance CWV variability over SWNA and why is this  
420 enhancement mainly during late spring to summer but not winter? Our interpretation is that the  
421 seasonal mean atmosphere circulation is transporting enhanced CWV anomalies from  
422 surrounding oceans into SWNA. This is supported in FLOR by the vertically-integrated fluxes of  
423 specific humidity standard deviation by mean winds,  $\int \bar{\vec{u}} \cdot STD(q') dp$ , where  $\bar{\vec{u}}$  is climatological  
424 monthly winds,  $STD(q')$  is the standard deviation of monthly specific humidity anomalies and  
425 the integral is done for the entire atmosphere. This quantity can also be interpreted as the  
426 vertically-integrated mean circulation weighted by moisture variability and thus reflects the  
427 mean circulation of the lower troposphere where most of the moisture is. During late spring to  
428 early fall (around May to October), CWV variability is significantly enhanced by SST variability  
429 over the tropical to midlatitude North Pacific, which extends northeastward into the SWNA  
430 region following the mean southwesterly winds (see vectors in Fig. 11). In contrast, during  
431 winter (around December to March), the enhanced CWV variability over the northeastern Pacific  
432 is confined to the subtropics (presumably owing to the colder atmosphere and smaller moisture  
433 capacity in winter) and the mean northwesterly winds are from ocean regions where CWV  
434 variability appears insensitive to SST variability, both of which are unfavorable to enhance CWV  
435 variability over SWNA.

436         Which parts of the ocean are responsible for the intensification of precipitation variability  
437 over SWNA? To answer this question, we conduct additional experiments (Table 1) that are  
438 similar to the AM2.5 simulation but with time varying monthly SSTs from FLOR imposed in  
439 different oceans during different times (note that these experiments have first been reported in a  
440 companion study focusing on synoptic extreme precipitation in June over SWNA (Zhang 2020)).  
441 Four experiments are conducted, each 600 years long (corresponding to FLOR 2601-3200). The  
442 first one has monthly SSTs prescribed over the entire globe (for all months, hereafter, Globe\_1-  
443 12) to test whether this technique (AM2.5 imposed with monthly SSTs) can reproduce the FLOR  
444 precipitation variance over SWNA given that interactive ocean-atmosphere coupling may matter

445 (e.g., Bretherton and Battisti 2000; He et al. 2017, 2018b). The other three have monthly SSTs  
446 prescribed between 35°N and 35°S (with a 5° linear buffer zone) in the entire tropics for all  
447 months (Tropic\_1-12), the tropical Pacific for October to May (Pacific\_10-5) and the tropical  
448 Atlantic for May to October (Atlantic\_5-10), respectively. The reason for prescribing SSTs in  
449 Pacific\_10-5 and Atlantic\_5-10 only during the stated months is that SST correlations with the  
450 SWNA precipitation are only significant during the stated months over the respective ocean  
451 basins (Fig. 19 in appendix). Tropic\_1-12 can test the role of SSTs in the tropics versus  
452 extratropics, while Pacific\_10-5 and Atlantic\_5-10 can test the role of SSTs in the tropical  
453 Pacific from October to May and in the tropical Atlantic from May to October, respectively. We  
454 note that, in Pacific\_10-5 and Atlantic\_5-10, the May and October SSTs are extrapolated into  
455 their neighbor months such that September and June in Pacific\_10-5 and April and November in  
456 Atlantic\_5-10 also have anomalous SST forcing (by default in all AM2.5 simulations, monthly  
457 SST values are placed in the middle of each month before interpolation onto the model time  
458 step). These four experiments allow us to identify the oceans responsible for the amplification of  
459 precipitation variance over SWNA.

460           Compared to AM2.5 without the interactive ocean, Globe\_1-12 generally well reproduces  
461 the month-to-month variance (i.e., average of the year-to-year variance over twelve calendar  
462 months) of both precipitation and CWV over SWNA in FLOR, albeit a bit weaker and confined  
463 to lower latitudes (Fig. 12a-d). These similarities also hold true for the year-to-year variance  
464 (Fig. 20-21 in appendix), which justifies the experimental technique to pin down the oceans  
465 responsible for the enhanced precipitation variance over SWNA in FLOR. Tropic\_1-12 without  
466 extratropical SST variability also well reproduces the precipitation and CWV variance over  
467 SWNA in FLOR (Fig. 12e-f for month-to-month variance and Fig. 22-23 for year-to-year  
468 variance), suggesting that the tropical SST variability is responsible for the enhanced  
469 precipitation variance over SWNA in FLOR.

470           For the total month-to-month variability, Pacific\_10-5 (Fig. 12g-h) is able to enhance the  
471 variance in both CWV and precipitation over most of SWNA, while Atlantic\_5-10 (Fig. 12i-j)  
472 only enhances the CWV variance locally in the tropical Atlantic but neither the CWV nor the  
473 precipitation variance over SWNA (except southern Mexico and northern central America). For  
474 the year-to-year variability, Pacific\_10-5 enhances the precipitation (Fig. 13) and CWV (Fig. 14)  
475 variance over SWNA mainly during May and June (recall the extrapolation of SST forcing from

476 May to June), similar to the enhancement in FLOR, Globe\_1-12 and Tropic\_1-12. In contrast,  
477 Atlantic\_5-10 does not simulate systematic enhancement of precipitation (Fig. 15) and CWV  
478 (Fig. 16) variance over SWNA during May to October when the SST forcing is imposed in the  
479 tropical Atlantic. Together, these results suggest that it is the tropical Pacific that accounts for the  
480 enhanced precipitation variance over SWNA in FLOR relative to AM2.5.

481 The lack of impacts from the tropical Atlantic on the SWNA precipitation variance seems  
482 inconsistent with previous studies (Kushnir et al. 2010; Johnson et al. 2020). In particular,  
483 Johnson et al. (2020) have attributed most of the climatological precipitation biases over  
484 southern North America in the standard FLOR model to the strong SST biases in the tropical  
485 North Atlantic. This paradox can be explained by the different magnitudes of SST biases and  
486 variability in the tropical North Atlantic relative to the tropical Pacific. The SST biases in the  
487 standard FLOR model are much larger in the tropical North Atlantic (about 1-3K) than the  
488 tropical Pacific (less than 1K, see Fig. 2 in Johnson et al.), while the total month-to-month  
489 variability in the flux-adjusted FLOR is much stronger in the tropical Pacific than the tropical  
490 Atlantic (Fig. 2b). Therefore, our results from Atlantic\_5-10 should be interpreted as that SST  
491 variability in the tropical Atlantic is relatively weak and unable to significantly affect the  
492 variance of atmosphere moisture content and thus precipitation over SWNA. The enhancement  
493 of the SWNA precipitation variance in FLOR relative to AM2.5 is mainly caused by the tropical  
494 Pacific through the new mechanism proposed in this work.

495 We point out an important distinction between our new mechanism and the classic ENSO  
496 teleconnection mechanism. In the ENSO teleconnection mechanism, tropical Pacific SST  
497 anomalies drive anomalous atmosphere circulation over SWNA that is capable of inducing  
498 anomalous precipitation. Our mechanism does not directly involve changes in atmosphere  
499 circulation over SWNA, but only involve enhanced atmosphere moisture content variability, that  
500 is, larger atmosphere moisture content anomalies. A new implication from our mechanism is that  
501 an interactive ocean is crucial to simulate and predict the amplitude of precipitation variability  
502 (i.e., precipitation intensity) over SWNA.

503

#### 504 **4. Summary and Discussion**

505 We have quantified the atmospheric and oceanic contributions to North American  
506 precipitation variability on seasonal and longer time scales in the FLOR model. FLOR features a

507 50km resolution in its atmosphere/land components and flux adjustment to correct biases in  
508 mean SST; as a result, it greatly reduces the pervasive biases in North American precipitation  
509 that have plagued climate models of the same generation. FLOR also realistically simulates  
510 tropical and midlatitude climate variability as well as the ENSO teleconnection, all of which are  
511 critical for a reliable quantification of the atmospheric and oceanic contributions to North  
512 American precipitation variability.

513         Comparing two millennium-long simulations with and without an active ocean (FLOR  
514 and AM2.5), we find that the dominant modes of variability in North American monthly  
515 precipitation between the two simulations share a nearly identical spatial structure, explained  
516 fraction of total variance and white-noise spectra with no persistence. Furthermore, the  
517 associated large-scale atmosphere circulation and surface temperature anomalies over North  
518 America are also very similar in terms of both spatial pattern and magnitude. These similarities  
519 suggest that the dominant modes of North American precipitation variability do not owe their  
520 existence to the ocean, but rather arise from internal atmosphere processes and coupling with  
521 land.

522         In the fully coupled FLOR, however, the dominant modes of North American  
523 precipitation variability are still significantly correlated with the tropical oceans, especially the  
524 tropical Pacific and Indian Oceans. These correlations are consistent with observations and  
525 previous studies that have demonstrated a role for the tropical oceans. How the tropical oceans  
526 affect extratropical climate variability has been long debated, with some arguing that tropical  
527 variability exerts its own unique impacts by driving atmospheric circulation anomalies that are  
528 distinct from internal modes of atmospheric variability (e.g., Straus and Shukla 2000) but others  
529 arguing that tropical variability merely excites modes of variability that already exist in the  
530 atmosphere (e.g., Simmons et al. 1983; Palmer and Mansfield 1984; Geisler et al. 1985; Palmer  
531 1993; Lau and Nath 1994; Saravanan 1998; Hoerling and Kumar 2002; Barsugli and  
532 Sardeshmukh 2002; Dai et al. 2017; Henderson et al. 2020). Here our results on North American  
533 precipitation variability support the latter argument. In particular, the ENSO teleconnection  
534 pattern over the Pacific/North America sector in FLOR appears in AM2.5 without the interactive  
535 ocean as the leading mode of midlatitude variability. This corroborates the idea that tropical  
536 climate variability affects the extratropics by exciting modes of variability that already exist in  
537 the atmosphere. Taken together, our modeling results suggest that internal atmosphere dynamics

538 and coupling with land determine the spatial and spectral characteristics of the leading modes of  
539 North American precipitation variability and dictate their explained fraction of total variance,  
540 while the tropical oceans contribute by exciting the same atmosphere dynamical processes.

541         Although the tropical oceans do not change the spatial and spectral characteristics of the  
542 leading modes of precipitation variability over the entire North America, they significantly  
543 enhance the variance of monthly precipitation over SWNA in FLOR relative to AM2.5. This  
544 enhancement in FLOR is seasonal and occurs mainly during late spring through summer when  
545 the ENSO variability is weakest (Fig. 2) and the correlation between the tropical Pacific SST and  
546 SWNA precipitation is weak or not significant (Fig. 19 in appendix). Examining the two factors  
547 critical for land precipitation, we find significant enhancement in the variance of atmosphere  
548 moisture content but not of divergent circulation over SWNA. The enhanced variability of  
549 atmosphere moisture content over SWNA is traced down to the tropical Pacific, where SST  
550 variability amplifies atmosphere moisture content variability, which is then transported into the  
551 SWNA region during late spring to summer by the seasonal mean southwesterly winds. This  
552 interpretation is different from the classic ENSO teleconnection mechanism not only in that it  
553 operates mainly during non-ENSO seasons, but more importantly, because it involves a different  
554 pathway of influence from the northeastern tropical Pacific to SWNA that is associated with the  
555 mean circulation and moisture anomalies as opposed to the dominance of anomalous circulation  
556 in the classic ENSO teleconnection mechanism. Therefore, our interpretation is a new  
557 mechanism, in addition to the classic ENSO teleconnection, via which the tropical Pacific Ocean  
558 variability affects precipitation over SWNA. Note that this mechanism has been invoked in a  
559 companion study (Zhang 2020) to explain how the tropical Pacific intensifies extreme rainfall  
560 over parts of SWNA in June. Here we extend the mechanism from synoptic time scales to  
561 seasonal and longer time scales.

562         We point out that the amplification of the SWNA precipitation variability by the tropical  
563 oceans has been noted by Seager et al. (2014, see their Fig. 5 and the relevant discussions), but  
564 their presumed interpretation is the classic ENSO teleconnection. In addition, projected future  
565 amplification in hydroclimate variability (Seager et al. 2011; Pendergrass et al. 2017) has been  
566 attributed to global warming-induced increases in *mean* atmosphere moisture content via the  
567 thermodynamic Clausius-Clapeyron relationship. Our work differs from those projection studies  
568 in that we focus on internal climate variability for a constant radiative forcing with a steady

569 atmosphere moisture content climatology. The variability in atmosphere moisture content (over  
570 the ocean) comes mostly from a dynamical redistribution (i.e., convergence or divergence) of  
571 atmosphere moisture induced by SST variability.

572 SST variability in the tropical Atlantic does not significantly contribute to the  
573 amplification of precipitation variance over SWNA (except for southern Mexico and northern  
574 central America), in contrast to previous studies demonstrating a role for the tropical North  
575 Atlantic. This paradox is likely attributed to the weak amplitude of the tropical Atlantic SST  
576 variability, which is unable to enhance the variance of atmosphere moisture content over SWNA.  
577 We emphasize that the tropical Atlantic SST variability can still affect the precipitation  
578 variability over SWNA through other dynamical processes (Kushnir et al. 2010; Johnson et al.  
579 2020).

580 The contributions of atmospheric and oceanic processes to North American precipitation  
581 variability on seasonal and longer time scales in FLOR are summarized as follows. The spatial  
582 and spectral characteristics of the dominant modes of variability in North American monthly  
583 (and seasonal) precipitation along with their explained fraction of total variance are controlled by  
584 internal atmosphere processes and coupling with land. Ocean variability, mainly from the  
585 tropical oceans, contributes to North American precipitation variability in two ways. First, on  
586 continental scales, it dynamically excites the same internal atmosphere processes as above (to  
587 some extent, as beating a drum excites its normal modes), and thus does not change the spatial  
588 characteristics of the leading modes. This impact is secondary compared to internal atmosphere  
589 processes and unable to significantly modify the leading modes' white-noise spectrum and  
590 explained fraction of total variance. Nonetheless, this ocean impact provides potential long-term  
591 predictability for North American precipitation beyond the timescales limited by internal  
592 atmosphere processes. Second, on regional scales, SST variability in the tropical Pacific  
593 amplifies atmosphere moisture content variability, which during late spring to summer is  
594 transported by mean southwesterly winds into the SWNA region and enhances the variance of  
595 precipitation over SWNA. This enhancement implies that the tropical Pacific is required for a  
596 reliable simulation and prediction of the intensity of precipitation over SWNA.

821

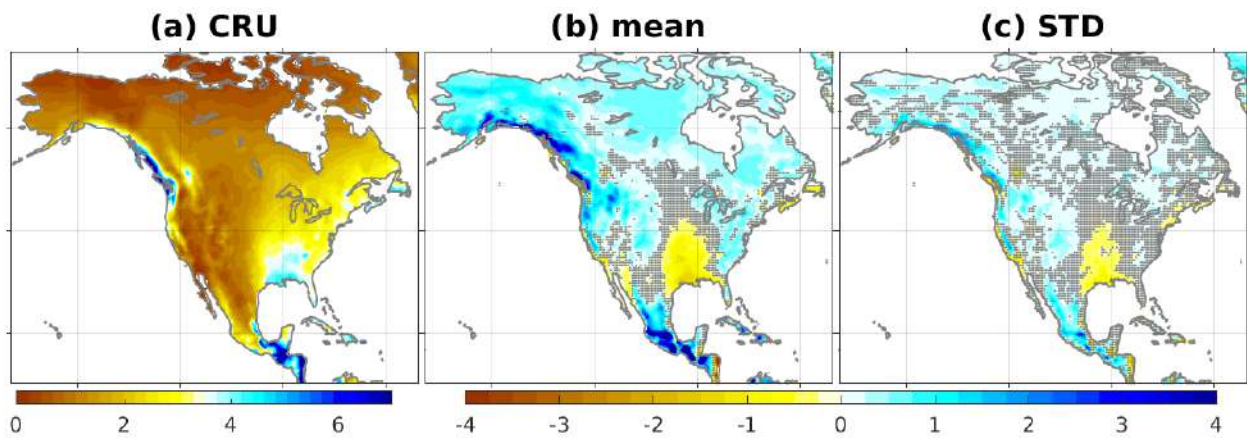

822 Table 1. Simulations.

Experiments	Forcing	Length (yr)
FLOR	preindustrial-level atmospheric composition and radiation (the same for all experiments), flux adjustment	3500
AM2.5	driven by climatological annual cycle of SST and sea ice from last 1000 years of FLOR	1000
Globe_1-12	as AM2.5, but driven by monthly varying SSTs from 600 years of FLOR over entire globe and for all months	600
Tropic_1-12	as AM2.5, but driven by monthly varying SSTs from 600 years of FLOR over the tropics (35°N and 35°S) and for all months	600
Pacific_10-5	as AM2.5, but driven by monthly varying SSTs from 600 years of FLOR over the tropical Pacific (35°N and 35°S) and only from October to May	600
Atlantic_5-10	as AM2.5, but driven by monthly varying SSTs from 600 years of FLOR over the tropical Atlantic (35°N and 35°S) and only from May to October	600

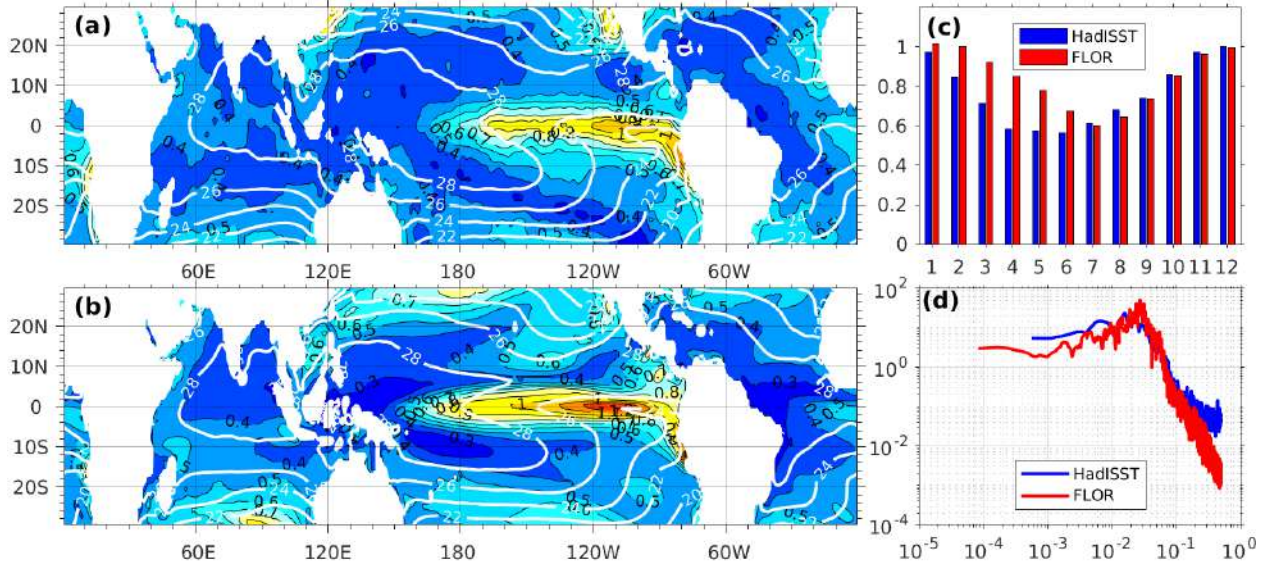

823 Note that preindustrial radiative forcing is nearly in balance at top of the atmosphere and thus  
 824 more suitable for millennium-long steady state simulations than present-day conditions.

825

826 **Figures**

827 **Fig. 1** Precipitation (mm/day) biases in FLOR compared to observations. (a) 1981-2010 CRU  
 828 climatology; FLOR biases (FLOR – CRU) in (b) climatology and (c) standard deviation.  
 829 Stippling is a measure of insignificance, indicating at least one of CRU and GPCC is inside the  
 830 range of a synthetic 33-member FLOR ensemble, which is constructed by sampling the 1000-  
 831 year FLOR simulation with a 30-year (to mimic 1981-2010) non-overlapping period.  
 832

836  
837  
838  
839  
840

**Fig. 2** Tropical SST variability ( $^{\circ}\text{C}$ ) in FLOR versus HadISST 1870-2018. SST standard deviation (shading) and climatology (white contours) in HadISST (a) and FLOR (b); monthly standard deviation (c) and spectrum (d) of the Niño3.4 index (SST time series averaged over  $170^{\circ}\text{W}$ - $120^{\circ}\text{W}$ ,  $5^{\circ}\text{N}$ - $5^{\circ}\text{S}$ ). The spectrum is normalized by the variance of the Niño3.4 index. X-axis has a unit of calendar month in (c) and frequency of per month in (d), respectively.

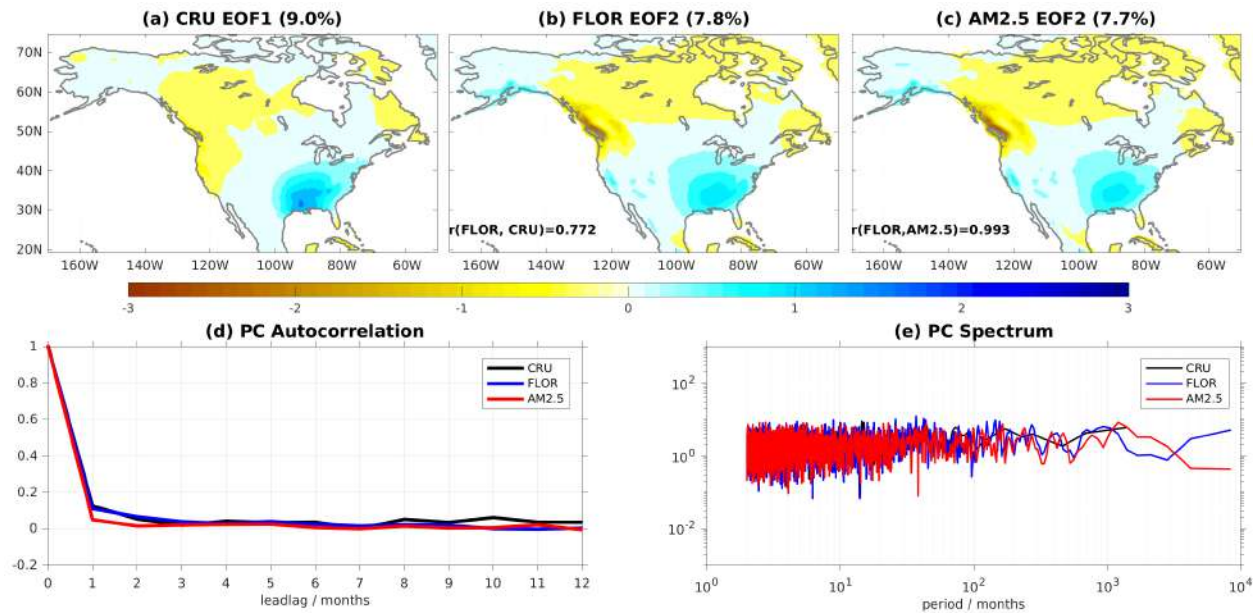

841  
842  
843  
844  
845  
846  
847

**Fig. 3** ENSO teleconnection in observations 1901-2012 (a, b) and FLOR (c, d). Teleconnection is assessed during DJF as correlation coefficients between the Niño3.4 index and SST (shading), 200mb geopotential height (black contours) in (a, c), land precipitation in (b, d). Here 112 years are used for observations, while 1000 years are used for FLOR. Random sampling of 112-year segments from FLOR leads to small changes in correlation pattern and magnitude (not shown).

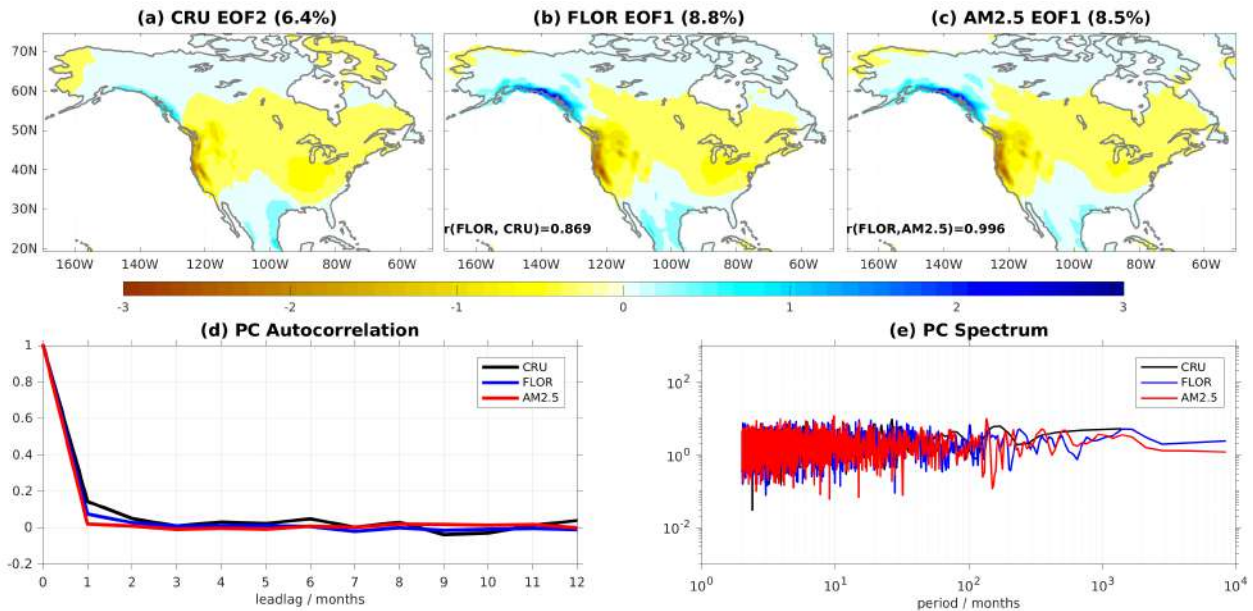

848  
 849 **Fig. 4** Midlatitude variability of monthly SLP (hPa) in observations (top row), FLOR (middle  
 850 row) and AM2.5 (bottom row). The leading three EOF modes are shown with their explained  
 851 variance inside the parentheses above each panel. Contours (positive solid and negative dashed)  
 852 in the EOF1 panels (left column, top two rows) are the regression coefficients (hPa/K) of  
 853 monthly SLP anomaly against the Niño3.4 index, a measure of the ENSO teleconnection.  
 854  
 855

856

857 **Fig. 5** Top row: (a) the first EOF mode in CRU observations and the second EOF mode in (b)  
 858 FLOR and (c) AM2.5. The explained variance percentage is denoted above each panel. Pattern  
 859 correlation is 0.772 between CRU and FLOR and 0.993 between FLOR and AM2.5. Bottom  
 860 row: (d) the associated PC autocorrelation and (e) spectrum.  
 861

862 **Fig. 6** The same as Fig. 5 but for the second EOF mode in observations and the first EOF mode  
 863 in FLOR and AM2.5. Pattern correlation is 0.869 between CRU and FLOR and 0.996 between  
 864 FLOR and AM2.5.  
 865

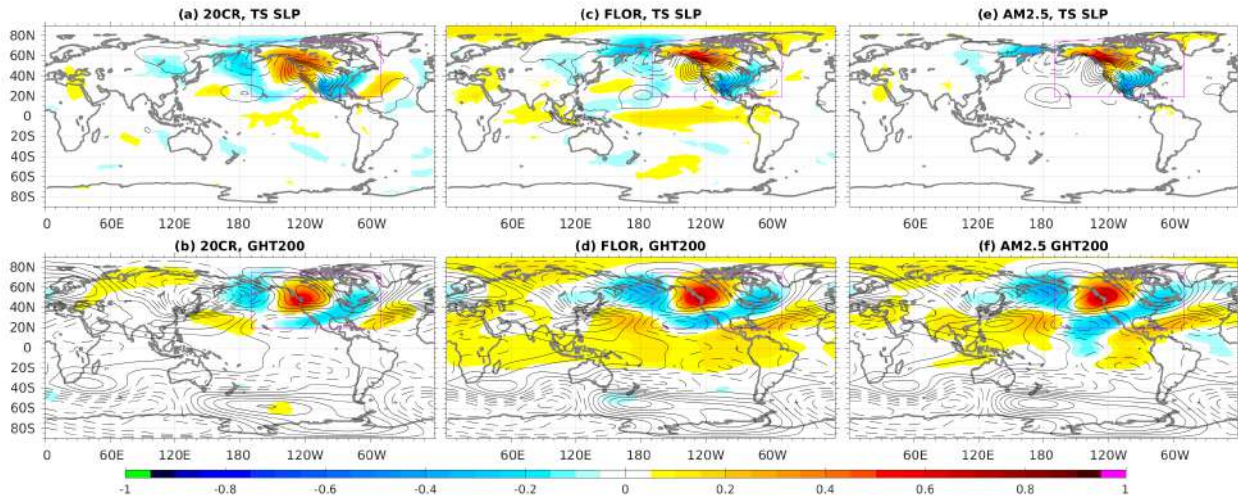

866  
 867

868 **Fig. 7** Large-scale pattern of correlation coefficients between the PCs of the EOF modes in Fig. 5  
 869 (reflecting precipitation variability over the southeastern United States) and surface temperature  
 870 (shading in top row), SLP (contours in top row) and 200mb geopotential height (shading in  
 871 bottom row) in observations (left column, 20CR dataset), FLOR (middle column) and AM2.5  
 872 (right column). Contours in the bottom row are the departure of climatological GHT200 from its  
 873 zonal mean, denoting climatological stationary eddies. Contour interval is 0.1 for SLP  
 874

875 correlation and 20m for GHT200, and solid (dashed) contours denote positive (negative) values  
 876 (zeros omitted). The magenta box in each panel denotes the region where the EOF  
 877 decomposition is conducted.

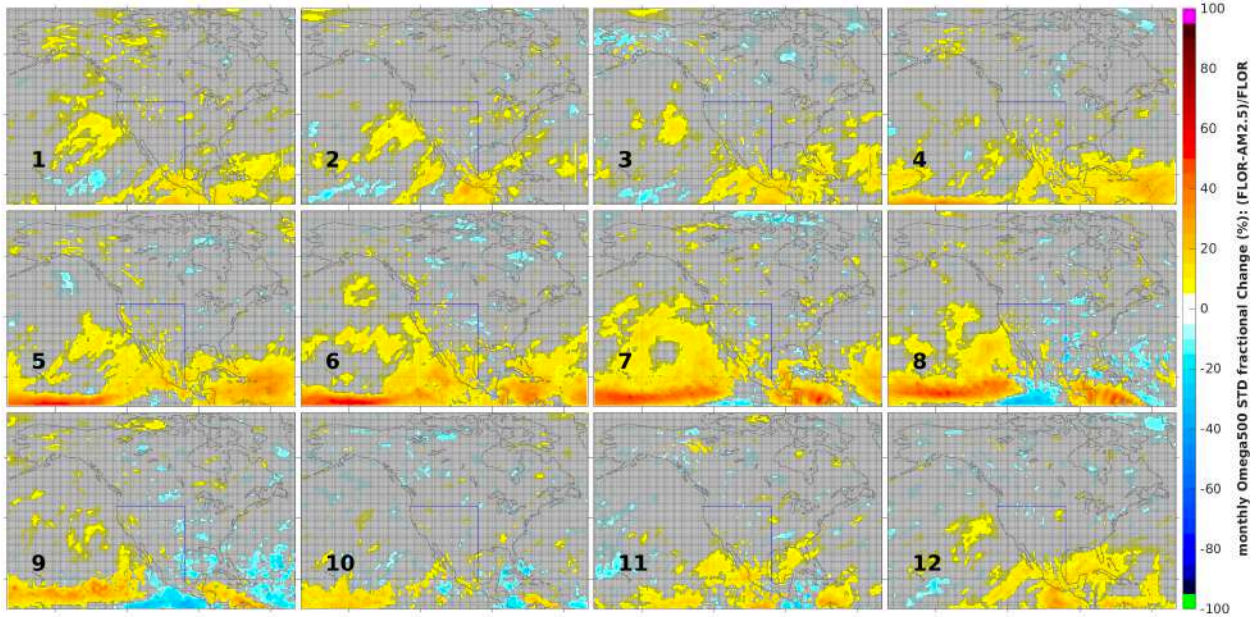

878  
 879

880  
 881 **Fig. 8** The same as Fig. 7 but for the EOF modes shown in Fig. 6 (reflecting precipitation  
 882 variability over the Pacific Northwest).  
 883

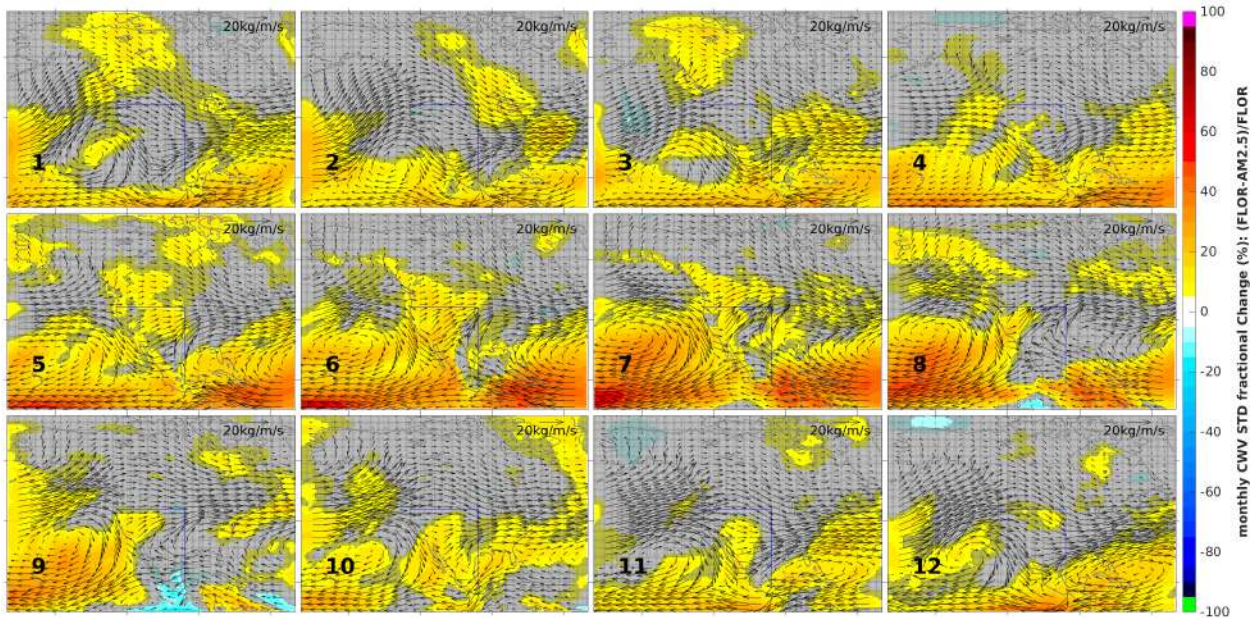

884  
 885 **Fig. 9** Fractional change (%) in year-to-year standard deviation of monthly precipitation between  
 886 FLOR and AM2.5 as a function of calendar month, defined as  $(\text{FLOR}-\text{AM2.5})/\text{FLOR} \times 100\%$ .  
 887 Gray stippling indicates changes are not significant at the 1% level based on a two-sided Fisher  
 888 test. The blue transposed 'L' outlines the SWNA region where the month-to-month variance of  
 889 monthly precipitation (Fig. 12a) is significantly enhanced by the ocean in FLOR relative to  
 890 AM2.5.  
 891

892  
893

**Fig. 10** The same as Fig. 9 but for 500mb omega.

894  
895  
896  
897  
898

**Fig. 11** The same as Fig. 9 but for CWV (atmosphere moisture content). Vectors denote the vertically integrated flux of standard deviation of specific humidity by mean circulation (kg/m/s). A scale vector of 20kg/m/s is shown in the upper right corner of each panel.

918  
919  
920  
921  
922

**Fig. 16** The same as Fig. 15 but for CWV in Atlantic\_5-10.

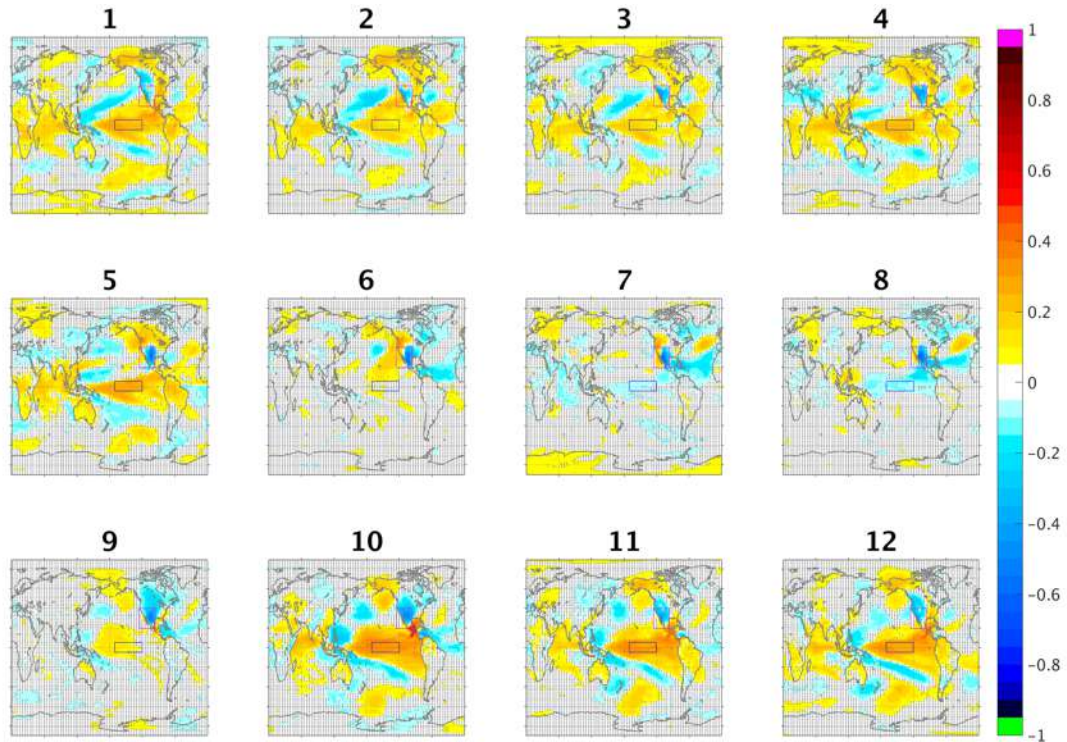

925 **Fig. 17** Biases of monthly precipitation climatology (mm/day) in FLOR compared to the 1980-  
926 2010 CRU and GPCC observations. Shown here is FLOR – CRU. Stippling is measure of  
927 insignificance, indicating either CRU or GPCC climatology is inside the range of a synthetic 33-  
928 member FLOR ensemble, which is constructed by sampling the 1000-year FLOR simulation  
929 member FLOR ensemble, which is constructed by sampling the 1000-year FLOR simulation  
930 with a 30-year non-overlapping period.  
931  
932

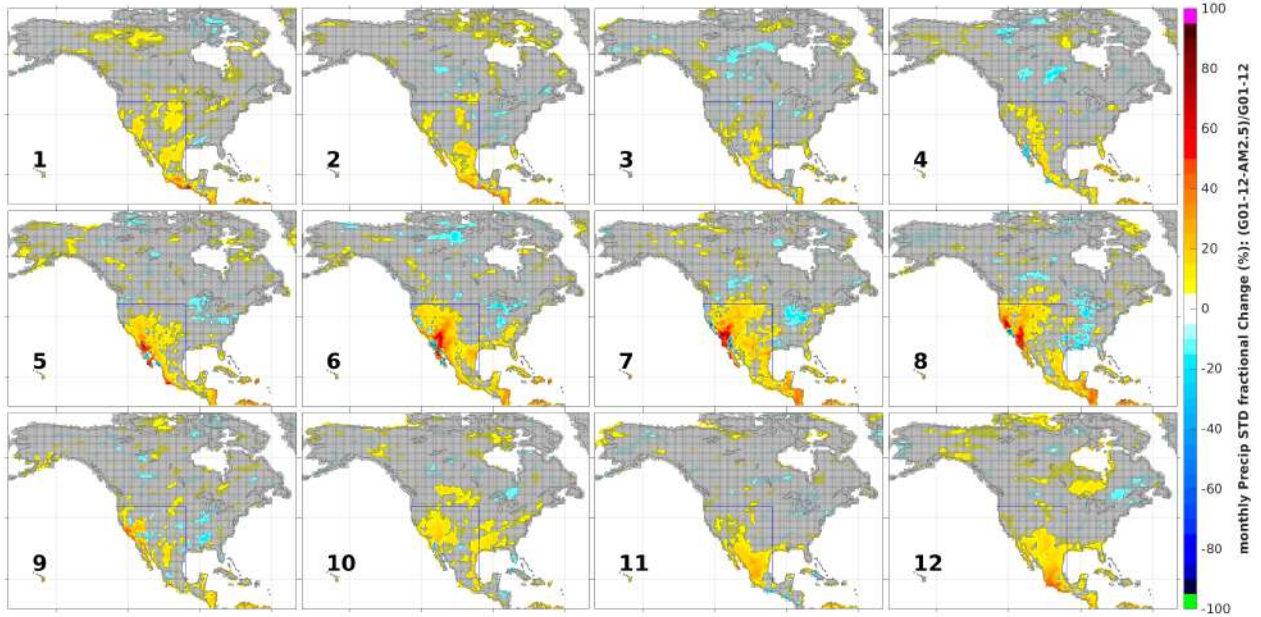

933 **Fig. 18** Biases in year-to-year standard deviation of monthly precipitation (mm/day) over North  
934 America in FLOR compared to the 1980-2010 CRU and GPCC observations. Stippling is a  
935 measure of insignificance, indicating either CRU or GPCC standard deviation is inside the range  
936

937 of a synthetic 33-member FLOR ensemble, which is constructed by sampling the 1000-year  
938 FLOR simulation with a 30-year non-overlapping period.  
939

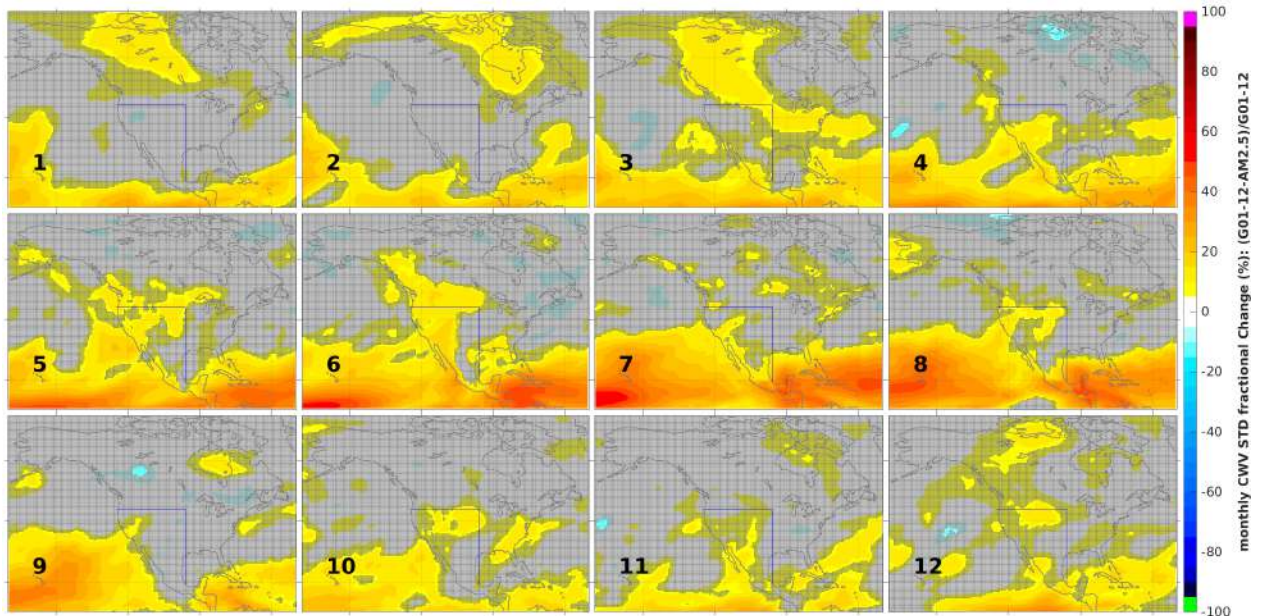

940  
941 **Fig. 19** Correlation of monthly surface temperature with monthly precipitation averaged over  
942 southwestern North America (19-40°N, 125-96°W, indicated by a red box in each panel) as a  
943 function of calendar months in FLOR. Gray stippling denotes that the correlation is not  
944 significant at 5% level (based on a two-sided student t test). Note that this figure has been  
945 published in Zhang (2020, Fig. 13).  
946

947  
 948 **Fig. 20** Fractional change (%) in year-to-year standard deviation of monthly precipitation in  
 949 Globe\_1-12 relative to AM2.5,  $(\text{Globe\_1-12} - \text{AM2.5})/\text{Globe\_1-12} \times 100\%$ , as a function of  
 950 calendar month. Gray stippling indicates changes are not significant at the 1% level based on a  
 951 two-sided Fisher test.

952  
 953

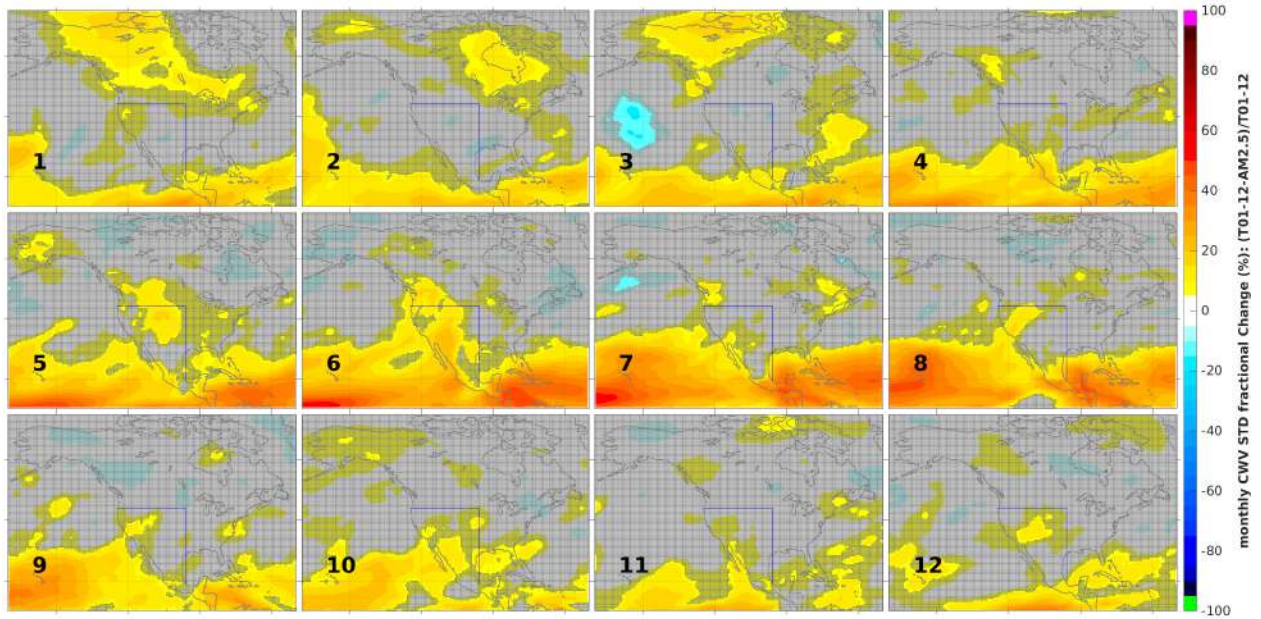

954  
 955 **Fig. 21** The same as Fig. 20 but for CWV in Globe\_1-12.

956

957  
958  
959  
960

**Fig. 22** The same as Fig. 20 but for Tropic\_1-12.

961  
962
