## Abstract

The hot electron injection model presently available in the TCAD tools has been investigated against experiments on new test devices to the purpose of gaining an insight on its predictability in the context of the new-generation technologies. The study has been carried out on electron emission in extremely high electric fields, as expected in power LDMOS devices at the onset of avalanche breakdown, reaching for the first time injection probabilities as high as 0.01. The numerical analysis clearly showed that the new Si/SiO<sub>2</sub> interfaces experience different features with respect to the old ones. The TCAD method based on the deterministic solution of the Boltzmann equation can accurately capture such effects.

---

## 1. Introduction

One of the key challenges in building devices for analog and high-voltage applications in advanced technology platforms is given by their reliability concerns. The scaling of CMOS devices inevitably leads to hot-carrier-stress instability and charge injection [1]. This leads to the need of predictive models suitable for the design stage. Recently, a TCAD approach has been proposed based on the deterministic solution of the Boltzmann equation through the Spherical Harmonic Expansion (SHE-BTE) [2]. The model was implemented in the Synopsys TCAD tool [3] and was shown to fairly reproduce the charge-injection experiments reported by Ning [4]. It accounts for the microscopic scattering mechanisms caused by acoustic and intervalley phonons, ionized impurities, and impact ionization and uses the band-structure quantities obtained from the nonlocal empirical pseudopotential method for relaxed silicon up to the fourth band, which starts at about 3.23 eV. It is expected that more bands appear at higher energies, but the SHE-BTE solution is assumed to be accurate for the description of the relevant injection probabilities as they are mostly characterized by the distribution function close to the

Si/SiO<sub>2</sub> energy barrier (3.1 eV) further corrected by the barrier-lowering effects when high fields are applied [4, 5]. The tail of the distribution function usually shows an exponential decrease, thus the description of the bands and scattering rates at energies higher than about 4 eV should not significantly affect the hot-carrier injection predictions. In addition, the injection model based on the BTE-SHE solution was recently applied to nanoscale devices to verify its predictions on inhomogeneous cases, and it demonstrates to reproduce the Monte Carlo gate current densities and the experimental gate-to-drain current ratios without any calibration [6]. Thus, it is expected to give a rigorous prediction of hot-carrier injection probability even in analog and power devices.

In this work, the Synopsys-TCAD hot-electron injection model has been adopted to reproduce the experiments of new test devices. The numerical analysis clearly showed that the new Si/SiO<sub>2</sub> interfaces experience different features with respect to the old ones.

## 2. Test structures and experiments

A conventional n-channel MOSFET fabricated with a BCD process has been used with an additional

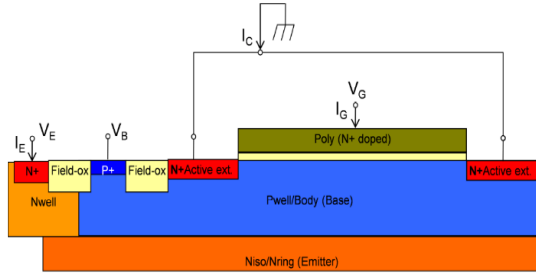

Fig. 1. Schematic view and bias conditions of the n-channel MOSFET with sub-surface emitter region used to inject carriers in the MOSFET substrate.

sub-surface emitter region to control the electron injection from the forward-biased emitter-base junction into the MOSFET substrate (Fig. 1). The device has a 7nm-thick gate oxide. The body (p-well) of the MOSFET has a near-surface boron concentration of about  $3 \times 10^{17} \text{ cm}^{-3}$ . The experiments are performed at constant temperature  $T = 25^\circ \text{C}$ , controlled by a thermo-chuck. The device has been biased at zero drain-to-source voltage, above threshold ( $V_G = 1.4 \div 7 \text{ V}$ ) to modulate the oxide electric field  $E_{ox}$ , and with different negative body voltage ( $V_B = 0 \div -5 \text{ V}$ ) to modulate the depletion region below the gate. Electrons have been injected by forcing  $I_E = -100 \mu\text{A}$ , the body voltage is swept from 0 to -5 V and the collector, body and gate currents are monitored. The injection probability ( $P_{inj}$ ) is equal to the ratio between the gate and collector current.

For a preliminary analysis,  $P_{inj}$  measured for different  $V_G$  has been reported in Fig. 2 as function of the distance  $d$  from the Si/SiO<sub>2</sub> interface where the potential energy in the substrate is equal to the barrier height. The drift-diffusion TCAD simulations, carried out by solving the electron and hole transport equations accounting for the corresponding impact-ionization generation terms, have been calibrated against the  $I_C$ - $V_B$  experiments, as they clearly show the effect of avalanche with a significant increase of  $I_C$  with decreasing  $V_B$  leading to  $I_C$  even larger than  $I_E$  for  $V_B < -4.5 \text{ V}$ . The calibrated TCAD simulations have been used to extract  $d$  at different  $V_B$ . Due to the larger doping concentration, a significant reduction of  $d$  is experienced by the new devices. The barrier height as a function of  $E_{ox}$  has been initially modelled according to [4] because it showed good predictions on devices with different doping profiles. By modelling the emission

Fig. 2. Injection probability as a function of the distance  $d$  from the Si/SiO<sub>2</sub> interface. Black symbols: Ning experiments [4]. Open blue symbols: experiments carried out on the new devices for different  $E_{ox}$ , reported as functions of  $d$  accounting for barrier lowering. Closed blue symbols: new experiments as functions of  $d$  without barrier lowering. Dashed lines were calculated as  $P_{inj} = A \exp(-d/\lambda)$  following [4].

probability with the expression  $P_{inj} = A \exp(-d/\lambda)$ , with  $A$  and  $\lambda$  fitting parameters (dashed curves in Fig. 2), the new data (open blue symbols) clearly show a different barrier dependence with respect to Ning experiments (open black symbols). By assuming a zero Schottky-barrier lowering, trends in accordance with Ning data have been obtained (Fig. 2, closed blue symbols).

### 3. TCAD simulations of the SHE-BTE

The accurate simulation of hot electron injection is a complex task as underlined in [5]. At high energies, the phonon and impact-ionization scattering are expected to determine the shape of the distribution tail, thus we checked the parameters in the TCAD model and changed the impact-ionization rate consistently with the data reported in [5] and references therein (Fig. 3). The SHE-BTE scattering rates nicely compare with the Monte Carlo data up to 5eV.

The structure of the device reported in Fig. 1 has been used to create the simulation deck for the new test structures and the devices reported by Ning ("15-12-8" in [4]). In Fig. 4, the electron energy distributions at the Si/SiO<sub>2</sub> interface obtained by the SHE-BTE solution are compared for both devices at the maximum  $V_G$  and  $V_B$ . The tail of the distribution function in the new structure is significantly higher than the old device due to the larger doping concentration. As expected, the

new devices cover a range of hot-carrier energies which

Fig. 5. Measured and simulated probability of injection into SiO<sub>2</sub> as a function of the square root of the oxide field at three different body biases. Measured data (symbols) show a weak dependence on  $E_{ox}$  at high injection conditions, which is in accordance with the results shown in Fig. 2. Solid lines: TCAD predictions without barrier lowering. Dashed lines: TCAD predictions with barrier lowering. TCAD results with barrier lowering switched off show the best fitting with experiments.

was not reached by the old structures.

#### 4. TCAD calculations of the gate current

The implemented gate current model available in [3] covers tunnelling and thermionic emission components and accurately fits the Ning experiments as shown in [2]. It takes into account the image potential barrier lowering and the scattering probability within the oxide. More specifically, the probability of electrons moving from silicon to oxide without scattering is given by  $P_{ins} = \exp(-r_0/\lambda_{ins})$ , with  $r_0$  the distance of the barrier peak in the oxide, and  $\lambda_{ins}$  the mean free path in the insulator. The gate current is calculated from the solution of the SHE-BTE and is proportional to  $P_{ins}$ . By observing the results of Fig. 2, the comparison between new and old experiments provides the indication that a much smaller barrier lowering is experienced in the new structures, thus the corresponding image-potential barrier-lowering model [2, 5] has been switched off in the TCAD simulations. A slight calibration of the barrier height has been applied ( $E_{B0}=3.0$  instead of 3.1eV). In addition, a significant oxide scattering has been assumed, leading to a strongly reduced mean free path. In Fig. 5, the TCAD results of  $P_{inj}$  as a function of  $E_{ox}$  by ignoring the barrier-lowering effect on the barrier height (but keeping the oxide scattering effect)

Fig. 6. Measured and simulated probability of injection into SiO<sub>2</sub> as a function of the square root of the oxide field at three different body biases. Symbols: “15-12-8” Ning experiments [5], showing an exponential increase with the square root of  $E_{ox}$ . Solid lines: TCAD results with barrier lowering switched off and the default value for  $\lambda_{ins}$ . Dashed lines: TCAD results with barrier lowering switched off and  $\lambda_{ins} = 0.3$  nm. The best fitting with experiments is obtained by using the default value for the insulator mean free path.

nicely reproduce the measured data for all biases, while numerical data assuming the barrier lowering show a clear overestimation at larger biases. The best fitting is obtained by using  $\lambda_{ins} = 0.3$  instead of 2 nm. In Fig. 6, the TCAD simulations on the old device by ignoring the barrier-lowering effect on the barrier height have been reported as functions of  $E_{ox}$ : the dependence on  $E_{ox}$  is still high enough to accurately fit Ning experiments, provided that the usual value of  $\lambda_{ins}$  is adopted [2, 3]. The obtained results showed that, on the one hand, the barrier lowering effect is not observed at very high  $E_{ox}$  and is not necessary to fit the experiments. On the other hand, the scattering rate at the oxide barrier seems to be much more relevant in the new devices with respect to the old ones as different values of the mean free path have been extracted against experiments, which might be related to the different process features such as oxide growth conditions and chemical composition.

## 5. Conclusions

In this work, the hot electron injection model presently available in the TCAD tools has been investigated against experiments on new test devices to the purpose of gaining an insight on its predictability in the context of the new-generation BCD technologies.

The study has been carried out on electron emission in extremely high electric fields, as expected in power LDMOS devices at the onset of avalanche breakdown, reaching for the first time injection probabilities as high as 0.01. The numerical analysis clearly showed that the new Si/SiO<sub>2</sub> interfaces experience different features with respect to the old ones. The TCAD method based on the deterministic solution of the Boltzmann equation can accurately capture such effects, confirming to be an interesting approach for future analyses.
