#### 19 Abstract

20 The aim of the present study was to determine the differences in corpus luteum (CL) functionality 21 between the first *postpartum* estrous cycle and the following cycle in lactating dairy cows. Luteal 22 blood flow (LBF), luteal size and blood progesterone (P4) concentration were monitored during the 23 first and second *postpartum* estrous cycle. During the first and second *postpartum* estrous cycle, the 24 mean LBF value increased (P<0.05) from early to late diestrus, while it decreased rapidly in 25 proestrus, resulting statistically lower (P<0.05) than those registered in all previous phases. Statistically significant differences were not observed between overall LBF during first and second 26 27 postpartum estrous cycle (P>0.05). During the first postpartum estrous cycle, P4 blood 28 concentrations showed a significant reduction (P<0.05) from diestrus to proestrus. A different trend 29 of P4 concentrations was observed during the second *postpartum* estrous cycle, where mean P4 30 value registered in proestrus resulted statistically lower than those registered in the previous cycle 31 phases (P< 0.05). The mean P4 concentration registered over the first *postpartum* estrous cycle 32 resulted statistically lower (P<0.05) than that registered during the second one. A significant 33 correlation between P4 concentrations and LBF was registered only during the second postpartum 34 estrous cycle. Results indicate that during the first postpartum estrous cycle P4 concentration was 35 independent of luteal blood flow and luteal size.

36 Key words: dairy cow; *postpartum*; power Doppler; corpus luteum

#### 38 Introduction

39 Reproductive performance is one of the important factors determining the profitability of dairy 40 herds, but increased milk yield in dairy cattle determine a decline in their fertility (Wiltbank et al., 41 2002). The study of *postpartum* and the monitoring of the recovery of ovarian activity are important 42 elements for dairy farmer. An increase in the proportion of cows conceiving soon after the elective 43 waiting period will decrease the proportion of cows with extended lactations, that are less profitable 44 (Ribeiro et al., 2012). The increase in genetic merit for milk production over the past decades has 45 been associated with an overall decrease in reproductive performance of dairy cows (Lucy, 2001). 46 Indeed, the increased dry matter intake, liver blood flow and greater metabolic clearance rate in the 47 postpartum period are associated with reduced peripheral concentrations of steroid hormones such 48 as estradiol and progesterone in high-producing cows (P4; Sangsritavong et al., 2002). The reduced 49 blood hormones concentrations affect the hypothalamus-pituitary-ovarian axis (Wiltbank et al., 50 2006) and uterine physiology of the cow (Geisert et al., 1992) and could explain the poor 51 reproductive performance reported in modern dairy herds. Usually, the first postpartum period is 52 characterized by a physiological anestrous status that lasts about 15-20 days (Wiltbank et al., 2002). 53 As reported by different Authors, the first *postpartum* estrous cycle presents lower duration and 54 fertility than the subsequent cycles, because of an early corpus luteum (CL) regression, determined 55 by an untimely prostaglandin secretion by the uterine glands (Kozicki et al., 1998; Inskeep and 56 Dailey, 2004). The inefficiency of CL endocrine activity during the first *postpartum* estrous cycle is 57 evidenced by low milk (Kozicki et al., 1998) and blood (Kayacik et al., 2005) progesterone 58 concentrations.

59 Corpus Luteum is one of the most highly vascularized organs; it receives the greatest blood flow per 60 tissue volume in the body (Wiltbank et al., 1989). In the first week after ovulation, blood vessels 61 from the theca interna invade into the follicular cavity and form a network, which supplies luteal 62 cells. This neovascularization is necessary for provision of low-density lipoprotein, used by luteal 63 cells for progesterone (P4) biosynthesis, and for the delivery of luteal steroids to circulation (Carr et

64 al., 1982). Furthermore, luteal endothelial cells secrete vasoactive substance, such as nitric oxide, 65 endothelin-1, angiotensin-II or prostaglandins, directly involved in P4 secretion. Therefore, both 66 endothelial cells and blood vessels of CL play a crucial role in its functionality (Miyamoto et al., 67 2009). Since luteal vascularization is very important for the CL function, the study of luteal blood 68 flow (LBF) give a valuable information about it (Miyamoto et al., 2009). Until the advent of 69 Doppler technology, vascularization of the bovine ovaries was investigated experimentally using 70 invasive procedures (Bollwein et al., 2013). In the past 15 years, Doppler technology has replaced 71 invasive techniques for monitoring of bovine reproductive system (Ford et al., 1979). Since blood 72 vessels of the CL have a very low blood flow velocity, Color Power Doppler ultrasonography, a 73 noninvasive diagnostic method detecting the number of red cells moving through vessel per time 74 unit and showing them as colored pixels, is the most advantageous method for evaluating Luteal 75 Blood Flow (LBF) (Bude et al., 1994). Despite several Authors examined LBF during different 76 stage of bovine estrous cycle (Vasconcelos et al., 2001; Shirasuna et al., 2004; Miyamoto et al., 77 2005; Herzog et al., 2010; Lüttgenau et al., 2011) or for early pregnancy diagnosis (Utt et al., 2009; 78 Siqueira et al., 2013; Kanazawa et al., 2016), no data have been reported on LBF in postpartum 79 dairy cows. Therefore, the aim of the present study was to compare luteal competency by serum 80 progesterone concentrations and LBF, measured by Power Doppler technique, during the first and 81 second *postpartum* estrous cycle in Holstein Friesian cows.

82

#### 83 Materials and methods

84

85 Animals

This study was conducted on lactating dairy Holstein cows housed at the farm of Department of
Veterinary Medical Sciences, University of Bologna. All experimental procedures were approved
by the University of Bologna Ethical Review Committee and the Ministry of Health.

89 An anamnestic investigation and a complete physical examination were performed before starting. 90 Only cows between 2 and 5 years old, 15 days after delivery were examined. The average number 91 of calving per cow was 2 (range 1-3) (Table 1). To remove any influence of disease on the ovarian 92 conditions, cows with BCS<2.5 (Body Condition Score: scale 1 to 5, with 0.25-point increments; 93 Ferguson et al., 1994), history of caesarean section or dystocia, retained foetal membranes, vaginal 94 laceration or severe systemic diseases were excluded from this study, as well as cows treated with 95 systemic antibiotic therapy or intrauterine therapy before enrollment. In total, 14 cows were 96 examined. Four animals developed endometritis during the experiment so were excluded, since it 97 was demonstrated that reproductive and systemic diseases could influence LBF and P4 blood 98 concentrations (Strüve et al., 2013). Furthermore, 4 cows developed other pathologies and were 99 excluded from the study (follicular cyst; luteal cyst; persistent corpus luteum; ketosis), leaving only 100 6 cows eligible for inclusion in the experiment.

101

Animals were housed in curtain-sided free-stall barns and fed a total mixed ration based on alfalfa/grass hay (50% ration dry matter), corn, barley and protein supplements. The cows were non-seasonal, year-round calves, milked twice daily with herd average 305-days milk yield around 9000-10.000 Kg per cow.

106

107 Luteal blood flow and Luteal area assessment

In order to identify the precise moment of ovarian activity resumption, the investigation of internal genital structures was carried out by trans-rectal palpation and ultrasound examination (5MHz linear probe, Tringa Lineare Vet, <sup>©</sup>2012 Esaote S.p.A., Milan), twice a week, starting from Day 15 after calving. All sonographic investigations were conducted by the same operator; during manipulations, cows were at the feeding rack and no animal was sedated.

For all enrolled cows, during the first and second *postpartum* estrous cycle, ultrasound examinations were ideally (considering a standard 21 days cycle) carried out to follow CL function

115 on Day 6-7 (Cycle phase 1 - early diestrus), 9-10 (Cycle phase 2 - diestrus), 14-15 (Cycle phase 3 -116 late diestrus) and 17-end of the cycle (Cycle phase 4 - regressing CL, proestrus) (Day 0=ovulation). Power-flow Doppler (5 MHz linear probe, MicroMaxx<sup>®</sup> SonoSite Inc. Bothell, WA) was used for 117 118 luteal blood flow mapping. Care was taken to locate the entire CL transverse section within the 119 Doppler sample box, in order to avoid flash alterations and to evaluate maximal blood flow within 120 the CL. At least three images without flash artifacts and with a maximum number of colored areas 121 were recorded. The analysis of the stored Doppler images was carried out using an image 122 processing software (ImageJ-2; National Institutes of Health, USA). The entire luteal structure and 123 its blood flow area were separated from the rest of ovarian tissue, and colored area within this 124 region was calculated. The area of detectable CL blood flow is expressed as a percentage of the CL 125 area and it was calculated by the application of the following ratio:

tot pixel: 100 = color pixel: X

where X represents the percentage of vascularized CL (Ginther et al., 2004). The mean of the threesingle images was calculated and used for statistical analysis.

For luteal area assessment, three cross-sectional images with maximal areas were recorded and analyzed using a computer-assisted images analysis software (ImageJ-2; National Institutes of Health, USA).

132

133 Hormone analysis

Immediately after ultrasonographic examinations of each animal, blood samples were collected from the coccygeal veins into evacuated tubes (4.9 mL test-tube Monovette <sup>®</sup> Serum gel, Sarstedt, Germany). Serum was separated by samples centrifugation at 1500 x g for 10 minutes and then stored in a 1.5 mL test-tube (Sarstedt, Germany) at -80 C° until the hormone assays were performed. Serum progesterone levels were assessed by an enzyme immunoassay (IMMULITE<sup>®</sup> Immunoassay System, Siemens Health Care and Diagnostic Inc., Gweynedd, UK). This is a

sequential competitive immunoassay system characterized by two incubation cycles (1 x 30 min).
The lower detection limit was 0.2 ng/mL.

142

143 Statistical analysis

144 After knowing the length of every single estrous cycle, data collected were proportionally 145 (considering the supposed phases during an ideal 21 days cycle) positioned in the right phase of that 146 cycle. Data were analyzed for normality using a Shapiro-Wilk test. Milk production, cycle length, 147 P4 and LBF levels in the single phases were compared between cycles using a paired Student T-test 148 or a Wilcoxon test. Statistical differences in P4 and LBF levels over time were assessed by repeated measure GLM or a Friedman test, using a Tukey HSD test for post hoc comparison or a Wilcoxon-149 150 Mann-Whitney test. A Pearson test was used for analysis of P4, LBF and luteal area correlations. 151 All tests were performed using IBM SPSS Statistics 25 (IBM Corporation, Milan, Italy). For all 152 analyses, P<0.05 was considered significant.

153 **Results** 

Enrolled cows had the first ovulation between 18 and 50 days after calving (mean value: 29.7  $\pm$ 11.7 days after calving). No statistically significance differences (P>0.05) were found between first and second *postpartum* estrous cycle in milk production (37.7  $\pm$  4.3 vs 38.8  $\pm$  4.3, respectively) and cycle length (18.3  $\pm$  5.2, range 10-26 days vs 23.8  $\pm$  5.8, range 15-30 days, respectively).

- LBF trend in the first and second estrous cycle is showed in Figure 1. Mean LBF values registered in single cycle phases were similar during the first and the second *postpartum* estrous cycles (P>0.05; Table 2).
- During the first *postpartum* estrous cycle, the mean LBF value increased (P<0.05) from phase 1 to phase 3 (12.1  $\pm$  5.1 vs 23.3  $\pm$  13.9 %), while it decreased rapidly in cycle phase 4, resulting statistically lower (P<0.05) than those registered in all previous phases (Table 2 and Figure 1). The same trend of LBF was observed also during the second *postpartum* estrous cycle. Indeed LBF increased (P<0.05) from cycle phase 1 to cycle phase 3 (12.2  $\pm$  6.5 % vs 22.7  $\pm$  6.3 %), while the

mean value registered in cycle phase 4 was the lowest (P<0.05; Table 2; Figure 1). Statistically</li>
significant differences were not observed between overall LBF during first and second *postpartum*estrous cycle (P>0.05).

169 During the first *postpartum* estrous cycle, P4 blood concentrations showed a significant reduction 170 (P<0.05) from cycle phase 2 to 4 ( $3.7 \pm 1.3 \text{ ng/mL}$  vs  $0.85 \pm 0.71 \text{ ng/mL}$ ) (Table 2 and Figure 2). A 171 different trend of P4 concentrations was observed during the second postpartum estrous cycle, 172 where mean P4 value registered in cycle phase 4 ( $0.4 \pm 0.15$  ng/mL) resulted statistically lower than 173 those registered in the previous cycle phases (P < 0.05) (Table 2; Figure 2). Blood progesterone 174 concentrations measured during the second estrous cycle were not statistically different (P>0.05) 175 than those registered during the same phases of the first *postpartum* estrous cycle. However, the 176 mean blood P4 concentration registered over the first *postpartum* estrous cycle resulted statistically 177 lower (P<0.05) than that registered during the second *postpartum* estrous cycle (Table 2 and Figure 178 2).

Luteal mean area registered during the first and the second *postpartum* estrous cycles, expressed in pixels, are reported in Table 3; no statistically significant differences were registered between the two considered estrous cycles (P>0.05). Pearson test showed only a significant (P<0.05) correlation between total blood progesterone concentrations and total LBF registered during the second *postpartum* estrous cycle (R = 0.692; Table 3). In both estrous cycles studied in the present work, no correlations were found between LBF and luteal area neither between P4 blood concentrations and luteal area (P>0.05; Table 3).

186

#### 187 Discussion

While transitioning from late gestation to early *postpartum*, high-producing dairy cows experience profound metabolic changes involving regulation of energy status, liver function, mammary gland demand for glucose as required for lactation (Drackley, 1999). These changes are often linked to abnormal ovarian processes associated with poor reproductive performance (Wiltbank et al., 2006).

192 It can also be confirmed in the present study by the number of excluded animals from enrolled cows (8/14). The presence of atypical estrous cycles early *postpartum* is associated with reduced fertility 193 194 (Lamming and Darwash, 1998). Therefore, the evaluation of ovarian function may enhance the 195 understanding of the declining trend in fertility in the high-producing dairy cow (Norman et al., 196 2009). As previously reported (Kawashima et al., 2006), cows enrolled in the present study ovulated 197 within three weeks *postpartum* and milk yield is not different between first and second *postpartum* 198 estrous cycle (Sakaguchi et al., 2004; Lüttgenau et al., 2011). The duration of the first and second 199 *postpartum* estrous cycle registered in this study are similar to those reported for higher number of 200 animals (Townson et al., 2002). It is likely that the number of finally enrolled cows was not enough 201 to obtain a statistically significant difference between the length of the two examined cycles. 202 Usually the second ovulation occurs after a short luteal phase: before the first *postpartum* ovulation, 203 low concentrations of preovulatory estradiol may result in early generation of a luteolytic 204 mechanism (Mann and Lamming, 2000). This may indicate that luteal activity was compromised 205 during the first ovarian cycle compared with that of the second cycle. Our results confirm this 206 hypothesis, since mean P4 concentration during the first *postpartum* cycle is lower than in the 207 second, as already reported in previous studies (Kawashima et al., 2006; Rutter and Randel, 1984). 208 The normal development of CL and its capability to produce progesterone, growth and angiogenic 209 factors and vasoactive substances depends on its vascularization. After ovulation, CL develops from 210 the wall of ruptured follicle and it is characterized by highly active vascularization and repeated 211 mitosis of steroidogenic cells (Acosta and Miyamoto, 2004). The intensity of this process reaches a 212 peak 2-3 days after ovulation (Reynolds et al., 2000). In the past 15 years, Doppler ultrasonography 213 has become one of the most important techniques for determining the LBF area to assess luteal 214 function (Matsui and Miyamoto, 2009). In the present study, in both estrous cycles considered, the 215 mean LBF value increased from cycle phase 1 (early diestrus) to cycle phase 3 (late diestrus). Lei et 216 al. (1991) demonstrated, by a histological examination, that in bovine CL the vascular space 217 increased by 25% between days 6 and 12 after ovulation, whereas the non-luteal cells decreased

218 throughout that period by 15%. Thus the increased LBF seems to be determined by vasodilation of 219 existing arterioles and not by further vascularization. Shirasuna et al. (2004) suggested that  $PGF_{2\alpha}$ 220 release by the uterus stimulates nitric oxide production in the arterioles of the peripheral vasculature 221 of the mature CL, determining vasodilatation. This could explain why in both estrous cycles the 222 LBF keeps growing until late diestrus (cycle phase 3) while it decreases in proestrus (cycle phase 223 4). However, despite the decrease in LBF occurs in parallel with the decrease in P4, in the present 224 study a positive correlation between LBF and P4 concentration was registered only in the second 225 *postpartum* estrous cycle. P4 levels in the first cycle decline significantly after phase 2 while in the 226 second cycle after phase 3, highlighting a shorter luteal activity in the first cycle and demonstrating 227 that P4 concentrations, particularly in the mid-luteal phase, is independent of luteal blood flow 228 (Lüttgenau et al., 2011). Furthermore, during the first and second estrous cycle no correlations were 229 found between P4 levels and luteal size. Therefore, lower P4 concentrations registered during the 230 first postpartum estrous cycle are not related to the amount of luteal tissue neither to its 231 vascularization.

232 In postpartum dairy cows the increased feed intake and milk yield increases the hepatic blood flow 233 and metabolic clearance rate of estradiol and P4, reducing their circulating concentrations 234 (Wiltbank et al., 2006). Particularly, the reduced P4 might increase LH pulse frequency (Stock and 235 Fortune, 1993), overexposing the pre-ovulatory follicle to lower intensity LH pulses (Wiltbank et 236 al., 2006). This overexposure to LH pulses may mature the oocytes earlier, compromising oocyte 237 quality and delaying ovulatory events in the early postpartum period (Wiltbank et al., 2006). 238 Recently, Bruinjè et al (2017), have demonstrated that later commencement of luteal activity in 239 postpartum dairy cows is associated with lower conception rates, increased days open, higher 240 embryonic mortality, and required more veterinary interventions (suggesting more health or 241 reproductive disorders) than those having normal activity. Apparently, there is possibly a link 242 between health or metabolic disorders (Santos and Rutigliano, 2009; Vercouteren et al., 2015), compromised ovarian activity (Opsomer et al., 2000), and subsequent fertility in dairy cows. 243

244	In this way, the lower fertility registered by farmer in cows inseminated at the first postpartum
245	estrous cycle is determined by lower blood P4 concentrations not related to CL dimension or
246	vascularization but more likely to a reduced luteal tissue functionality. As already supposed by
247	other Authors, the present study confirm that the P4 blood levels could be used as benchmarks in
248	herds monitoring fertility.

Cow	Age (years)	N° Calving	BCS
1	5	3	2.75
2	4.5	3	3
3	3.5	2	2.25
4	3	2	2.75
5	2.5	1	2.5
6	3.5	2	2.5
$Mean \pm SD$	3.7 ±0.9	$2.2\pm0.8$	2.6 ±0.3

	First oestrus cycle		Second oestrus cycle	
Cycle phase	P4 (ng/mL)	% LBF	P4 (ng/mL)	% LBF
	(Mean±SD)	(Mean±SD)	(Mean±SD)	(Mean±SD)
1	2.5±0.8	12.1±5.1	3.5±1.3 <sup>a</sup>	12.2±6.5
2	$3.7{\pm}1.3^{a}$	18.7±9.9	$4.8 \pm 1.4^{a}$	20.0±14.5
3	2.3±1.4	23.3±12.6	3.9±0.6 <sup>a</sup>	22.7±6.3
4	$0.8\pm0.5^{b}$	8.8±5.4	$0.6 \pm 0.1^{b}$	8.6±2.4
Mean±SD	2.4±1.5 <sup>c</sup>	15.9±11.0	3.3±1.9 <sup>d</sup>	16.2±10.4

404 Table 2. Mean values of blood progesterone concentration and LBF on phase 1 (early diestrus), 2
405 (diestrus), 3 (late diestrus), 4 (proestrus) of the first and second *postpartum* estrous cycle.

406 In the same column a vs b are significantly different (P<0.05); in the same line c vs d are

407 significantly different (P<0.05).

409 Table 3. Mean values of Luteal area (pixels), LBF and blood progesterone concentration of the first

	Values	First oestrus cycle	Second oestrus cycle		
	P4 (ng/mL)	2.4±1.5	3.3±1.9*		
	% LBF	15.9±11.0	16.2±10.4*		
	Luteal area (pixels)	10416.0±5912.0	14732.5±7113.6		
411	*significant positive correlation (P<0.05): R=0.692				

410 and second *postpartum* estrous cycle. The values are expressed as Mean±SD.

413

### **Figure Legend:**

- 415 Figure 1. Mean values of LBF during the first and second *postpartum* estrous cycle.
- 416 Figure 2. Mean values of blood progesterone concentration registered during the first and second
- *postpartum* estrous cycle.
