ABSTRACT

Using the astrometry from the ESA's *Gaia* mission, previous works have shown that the Milky Way stellar halo is dominated by metal-rich stars on highly eccentric orbits. To shed light on the nature of this prominent halo component, we have analysed 28 Galaxy analogues in the Auriga suite of cosmological hydrodynamics zoom-in simulations. Some three quarters of the Auriga galaxies contain prominent components with high radial velocity anisotropy, $\beta >$ 0.6. However, only in one third of the hosts do the high-β stars contribute significantly to the accreted stellar halo overall, similar to what is observed in the Milky Way. For this particular subset we reveal the origin of the dominant stellar halo component with high metallicity, [Fe/H] ~ -1, and high orbital anisotropy, $\beta > 0.8$, by tracing their stars back to the epoch of accretion. It appears that, typically, these stars come from a single dwarf galaxy with a stellar mass of the order of $10^9 - 10^{10} \, \mathrm{M_\odot}$ that merged around $6 - 10 \, \mathrm{Gyr}$ ago, causing a sharp increase in the halo mass. Our study therefore establishes a firm link between the excess of radially anisotropic stellar debris in the halo and an ancient head-on collision between the young Milky Way and a massive dwarf galaxy.

Key words: methods: numerical, obsevational – Galaxy: evolution – Galaxy: halo – Galaxy: kinematics and dynamics.

1 INTRODUCTION

The history of mass accretion on to the Milky Way can be constructed from the study of unrelaxed tidal debris in its stellar halo (e.g. De Lucia & Helmi 2008; Johnston et al. 2008; Cooper et al. 2010). This works particularly well for the most recent events, such as the infall of the Sagittarius (Sgr) dwarf (see e.g. Ibata, Gilmore & Irwin 1994; Majewski et al. 2003). Yet, despite the fact that the Sgr stream has been mapped in glorious detail over the last decade or so (see Ibata et al. 2001; Majewski et al. 2003; Newberg et al. 2003; Belokurov et al. 2006; Yanny et al. 2009; Koposov et al. 2012), we have been remarkably slow to comprehend the damage this

dwarf galaxy has been inflicting on to the Milky Way (see Purcell et al. 2011; Gómez et al. 2013; Laporte et al. 2018). Sgr is a striking example of how much destruction a massive satellite can bring to the fragile Milky Way's disc even on an orbit of moderate eccentricity (e.g. Price-Whelan et al. 2015; Bergemann et al. 2018; de Boer, Belokurov & Koposov 2018; Deason, Belokurov & Koposov 2018a; Hayes et al. 2018b).

Events in the distant past are normally less obvious, blurred by the debris' gradual relaxation in the host's gravitational potential and concealed behind the layers of the subsequent Galactic growth (e.g. Peñarrubia et al. 2006; Gómez & Helmi 2010; Buist & Helmi 2015; Erkal, Sanders & Belokurov 2016). Nonetheless, some episodes in the Milky Way's history are so cataclysmic that they are difficult to hide, even if they took place a long time ago.

$\star$ E-mail: azadeh.fattahi-savadjani@durham.ac.uk

It has been known for some time that the properties of the Milky Way stellar halo change drastically as a function of Galactocentric radius. This is revealed in the rapid variation of the stellar halo's kinematics and metallicity with radius (see e.g. Chiba & Beers 2001; Carollo et al. 2007, 2010) as well as the halo's density profile (see Watkins et al. 2009; Deason, Belokurov & Evans 2011; Sesar, Jurić & Ivezić 2011). Two possible explanations have been put forward, one invoking the presence of the so-called *in situ* halo (Zolotov et al. 2009; McCarthy et al. 2012; Tissera et al. 2013; Cooper et al. 2015) and one appealing to an early accretion of a massive galaxy (Deason et al. 2013). While unambiguous evidence for an *in situ* population is yet to be found (see e.g. Haywood et al. 2018), the hypothesis of a single accretion event dominating the nearby Galactic halo has been reinforced by multiple independent observations. These include the pattern of the stellar halo's alpha-abundances (see Venn et al. 2004; Tolstoy, Hill & Tosi 2009; Nissen & Schuster 2010; de Boer et al. 2014; Hayes et al. 2018a), the ratio of Blue Straggler to Blue Horizontal Branch stars (Deason, Belokurov & Weisz 2015), the evolution in the mixture of RR Lyrae of different Oosterhoff types (Belokurov et al. 2018a) and the relative scarcity of the Galactic stellar halo substructure (Helmi et al. 2011; Xue et al. 2011; Lancaster, Belokurov & Evans 2019).

Most recently, with the help of the astrometry from the ESA's *Gaia* mission (Gaia Collaboration et al. 2016), the Milky Way halo has been demonstrated to contain a large number of metal-rich stars on extremely eccentric orbits (Belokurov et al. 2018b; Haywood et al. 2018; Helmi et al. 2018; Mackereth et al. 2018; Myeong et al. 2018b). Using the established mass–metallicity relationship (Kirby et al. 2013) as well as numerical simulations of Galaxy formation, Belokurov et al. (2018b) have argued that the observed chemistry and the drastic radial anisotropy of the halo stars (the '*Gaia* Sausage') are telltale signs of an ancient collision between the Milky Way and a massive dwarf. This conjecture builds on the insights into the stellar halo assembly presented in the work by Amorisco (2017), which for the first time posits a link between high radial anisotropy and the infall of a massive satellite. The idea of an ancient intergalactic crash has since received additional support with the discovery of a large number of globular clusters associated with this accretion event (see Kruijssen et al. 2018; Myeong et al. 2018a). Additionally, the enormous extent of the 'Sausage' debris is now starting to become apparent with the studies of the stellar halo's anisotropy variation with radius (Bird et al. 2018; Lancaster et al. 2018). The break in the stellar halo density has been revealed to correspond to the apocentric pile-up of the 'Sausage' stars (see Deason et al. 2018b), while the large diffuse halo overdensities such as Hercules-Aquila and Virgo Clouds are now believed to be linked to the same accretion event (see Simion, Belokurov & Koposov 2018). While most of these studies rely on small subsamples of halo tracers with complete phase-space information, Wegg, Gerhard & Bieth (2018) and Iorio & Belokurov (2018) have recently used large, all-sky catalogues of RR Lyrae with proper motions to decipher the kinematic properties of the halo. As these authors demonstrate, the bulk of the Galactic stellar halo between 5 and 30 kpc – as traced by these old pulsating stars – is on strongly radial orbits, yielding estimates of $\beta \sim 0.9$.

The dominance of one massive accretion event is in good agreement with the general predictions of cosmological simulations. Several works have shown that the majority of stellar mass accreted on to Milky Way mass haloes is contributed by a small number of massive satellites (e.g. Bullock & Johnston 2005; Cooper et al. 2010; Deason, Mao & Wechsler 2016). The hypothesis of a small number of massive contributors is a direct consequence of the hierarchical

dark matter (DM) model, and the extremely steep stellar-to-halo mass relation in the dwarf galaxy regime (e.g. Eke et al. 2004; Moster, Naab & White 2013; Garrison-Kimmel et al. 2014; Brook et al. 2014; Sawala et al. 2016; Read et al. 2017; Jethwa, Erkal & Belokurov 2018; Fattahi et al. 2018; Simpson et al. 2018). Thus, despite the large numbers of low-mass dwarfs accreted by Milky Way-mass galaxies, the contribution of these low-mass dwarfs to the *total* accreted stellar mass is small (see Deason, Mao & Wechsler 2016).

Curiously, some of the first efforts to study the emergence of orbital patterns in simulated stellar haloes already saw trends similar to those recently discovered in the Milky Way (see e.g. Brook et al. 2003; Meza et al. 2005; Navarro et al. 2011). While those works were limited to a small number of hand-picked cases, here we strive to carry out a systematic analysis using a statistically significant sample of realistic simulations of Milky Way analogues. Monachesi et al. (2018) recently studied the global properties of stellar haloes in the Auriga simulations (Grand et al. 2017). Indeed, in agreement with earlier work, these authors find that the global properties of the stellar haloes, such as the average metallicity, total stellar halo mass, and density profile, are directly related to the small number of stellar halo progenitors.

In this work we use the Auriga simulations (Grand et al. 2017) to understand the relatively local stellar halo kinematics, within 20 kpc of the Galactic centre,[1] to compare with the recent *Gaia* results. Ours is not the first attempt to interpret the observed local stellar halo properties with the help of simulated Milky Way (MW) like haloes. Most recently, Mackereth et al. (2018) compared *Gaia* and APOGEE data with the orbital and chemical properties of the accreted halo stars in the EAGLE simulation suite (see Crain et al. 2015; Schaye et al. 2015). They come to the conclusion that to explain the measured α versus [Fe/H] trend as a function of eccentricity, an early accretion of a massive dwarf galaxy is required. A similar conclusion is reached by Fernández-Alvar et al. (2018) who use the stellar haloes in hydrodynamical simulations of Aquarius MW-like haloes (Aquila, see e.g. Scannapieco et al. 2009; Springel et al. 2008; Tissera et al. 2013). The Auriga simulations used here provide a higher resolution compared to EAGLE, and it gives us access to a significantly larger sample size with richer physics compared to Aquila.

Our paper is structured as follows. In Section 2 we describe the *Gaia* Data Release 2 observations of a 'Sausage-like' component in the phase space of the stellar halo. We describe the Auriga simulations in Section 3 and make a comparison with the *Gaia* results. In particular, we show how these highly eccentric, metal-rich stellar halo components (referred to as the radially biased components, hereafter) are also produced in the simulations. Finally, in Section 4 we summarize and discuss our main results.

2 OBSERVATIONS

As a point of reference we use the view of the Milky Way's stellar halo provided in Data Release 2 (GDR2; see Gaia Collaboration et al. 2018) of the *Gaia* mission (see Gaia Collaboration et al. 2016). Specifically, we use a sample of GDR2 stars with radial velocities measured by *Gaia* (see Cropper et al. 2018; Katz et al. 2018; Sartoretti et al. 2018). Out of $\sim 7 \times 10^6$ stars with available spectroscopic information, we select $\sim 12\,000$ with good parallaxes,

---

[1]Note that Monachesi et al. (2018) studied the stellar halo components at larger distances of $10 - 100$ kpc.
Figure 1. The '*Gaia* Sausage' as viewed with the GDR2 sample. Left*:* Logarithm of the stellar density in spherical v_r, v_θ coordinates, corresponding to the radial and azimuthal velocity components. Two prominent overdensities are visible, one corresponding to the (thick) disc with $\bar{v}_\theta \sim 170\,\mathrm{km\,s^{-1}}$ and one corresponding to the halo with no apparent rotation. Right*:* Residuals of the multi-variate three-component Gaussian mixture model. Here excess (depletion) of the data with respect to the model are shown as a dark (light) region. Two thirds of the halo stars are in a radially biased ($\beta \sim 0.86$) 'Sausage' component indicated with a solid black line. The rest of the halo is in a much more isotropic component with $\beta \sim 0.4$ shown as dashed red line. Finally, at least half of this local GDR2 sample belongs to the disc, marked with a white solid line.

$\varpi/\sigma_\varpi > 3$ and $2 < |z|/\,\mathrm{kpc} < 4$, $|b| > 25°$ and [Fe/H] ≤ -1. The latter three of the above cuts, including that on the *Gaia*'s template metallicity (see Katz et al. 2018, for details), are applied to minimize the Galactic disc contamination. We convert the celestial positions and parallaxes into Galactocentric Cartesian coordinates, assuming a solar radius of 8 kpc and a Sun's height above the Galactic plane of 0. The proper motions and the line-of-sight velocities are translated into velocity components in spherical polars, using the Solar peculiar motion from Coşkunoğlu et al. (2011) and marginalizing over the Local Standard of Rest (LSR) values assuming they are Gaussian distributed[2] with a mean at 238 km s⁻¹ and a standard deviation of 9 km s⁻¹ (see Schönrich 2012). The uncertainties are propagated using Monte Carlo sampling and the medians of the distributions for each object, as well as the scaled median absolute deviations, are used for the analysis below.

Fig. 1 shows the distribution of the median radial, v_r, and azimuthal, v_θ, velocity components in the sample described above. Two populations are immediately apparent: the Galactic disc, with significant mean rotation, and the non-rotating Galactic halo. We estimate the properties of each component by modelling the 3-D velocity distribution with a mixture of three multivariate Gaussians using the Extreme Deconvolution code (ED, see Bovy, Hogg & Roweis 2011) which takes the measurement uncertainties into account. In this model, the Gaussians represent the disc and the two components of the halo, a radially biased and a more isotropic one. The results of the ED fitting exercise are shown in the right panel of Fig. 1, where the residuals of data minus model are shown as a greyscale, with dark (white) regions corresponding to an excess (lack) of data points compared to the model prediction. Overlaid are the isodensity contours of the three Gaussians given by the best-fitting model, with white solid representing the disc, black solid the radially biased halo, and red dashed the second, more isotropic halo component.

As inferred from the ED modelling, 50 per cent of our sample belongs to the (thick) disc with a mean rotation of $\bar{v}_\theta \sim 170\,\mathrm{km\,s^{-1}}$, 37 per cent belong to the radially biased halo population with

$\beta \sim 0.86$ and 13 per cent to the halo component with $\beta \sim 0.4$. More specifically, the radially anisotropic 'Sausage' component, whose radial, azimuthal and polar velocity dispersions are 177, 61 and 70 km s⁻¹, respectively, contains just over two thirds of the total halo population locally in good agreement with Belokurov et al. (2018b). Interestingly, according to this Gaussian mixture model, the radially biased component is centred on zero in all three velocity components, i.e. it exhibits no net rotation, in mild tension with some of the earlier results (e.g. Belokurov et al. 2018b; Necib, Lisanti & Belokurov 2018), where a prograde rotation of $\sim 20\,\mathrm{km\,s^{-1}}$ was reported. The quality of the fit can be judged from the right panel of Fig. 1. Leaving aside the residuals at high v_θ associated with the disc, there is a dark/light pattern of under/oversubtraction of the model from the data. The excess of observed stars with high $|v_r|$ velocities is consistent with previous modelling attempts. However, a less prominent but noticeable ridge of positive residuals exists at negative v_θ. This implies that there may be a significant spray of retrograde debris possibly associated with the 'Sausage' (see Helmi et al. 2018; Myeong et al. 2018b) not accounted for by our model. Judging by the shape of the data in the left panel of the figure as well as the residuals in the right, we conjecture that these residuals are likely due to the strongly non-Gaussian shape of the velocity distribution in the 'Sausage' component. The complicated structure of the residuals advocates the use of more sophisticated models of the 'Sausage' kinematics as those recently proposed in Necib, Lisanti & Belokurov (2018) and Lancaster et al. (2018). We, however, choose to use the relatively simple ED modelling here that can be applied to the simulations as well. This will enable us to make a comparison between the simulations and observations, and also between different simulated galaxies.

3 AURIGA SIMULATIONS

We use cosmological magneto-hydrodynamical (MHD) simulations of MW-like haloes from the Auriga project (Grand et al. 2017) to interpret the origin of the '*Gaia* Sausage' described in the previous section. The Auriga project includes a suite of 30 MW size haloes simulated at high resolution, using the 'zoom-in' technique (Frenk et al. 1996; Jenkins 2013) and the Tree-PM moving-mesh code AREPO (Springel 2010). The simulations have been performed at different levels of resolution. We use the standard resolution runs (level-4) in this study rather than the higher resolution ones (level-3), as only eight haloes have been run at level-3. The mass resolution of the standard level-4 runs is $5 \times 10^4\,\mathrm{M_\odot}$ and $3 \times 10^5\,\mathrm{M_\odot}$ per gas and DM particles, respectively. The selection of MW candidates, as well as the subgrid physics model, has been described in detail in Grand et al. (2017). Here we give a brief summary.

MW-like haloes were selected from the $100^3\,\mathrm{Mpc^3}$ DM-only periodic box of the EAGLE project (Crain et al. 2015; Schaye et al. 2015), based on their virial[3] mass, $\sim 10^{12}\,\mathrm{M_\odot}$, and an isolation criterion. The subgrid physics model in the re-simulations includes a spatially uniform photoionizing UV background, primordial and metal line cooling, star formation, stellar evolution and supernovae feedback, supermassive black hole growth and feedback, and magnetic fields. A fixed set of chemical elements, including Fe and H, have been consistently tracked within the simulations. Haloes and bound structures and substructures were identified using the FoF and SUBFIND algorithms (Davis et al. 1985; Springel, Yoshida &

---

[2]We are neglecting the asymmetric drift here, as we are interested in the $V_\theta \sim 0$ component where this effect is small.

[3]Virial quantities are defined by reference to a mean overdensity of 200 times the critical density.

White [2001]), respectively. We refer to the central galaxy of the main halo in each Auriga simulation as a MW analogue. The cosmological parameters adopted for the simulations are those of Planck Collaboration XVI (Planck Collaboration et al. [2014]): matter density of $\Omega_m = 0.307$, baryonic density of $\Omega_b = 0.048$, and a Hubble constant of $H_0 = 67.77$ km s^{-1} Mpc^{-1}.

We use all 30 MW analogues of the level-4 (standard) runs, except for Au-11 and Au-20. These two galaxies are undergoing a merger at the present time and this distorts the phase-space distribution of star particles around the galactic discs.

The coordinate and velocity reference frame of the MW analogues are based on SUBFIND. The galactic discs are defined, and visually confirmed, using the net angular momentum of star particles in the inner 10 kpc. For our stellar samples, we keep star particles between $r = 5$ and 20 kpc from the galaxy centre, with galactic latitude $|b| > 15°$, assuming a random azimuthal angle for the position of the Sun at 8 kpc to roughly mimic the observational selections of Belokurov et al. ([2018b]).[4] We only include stars bound to the MW analogues (not to the satellites) and shift the [Fe/H] of star particles by a constant value of ~0.5 to roughly match the median and the [5th,95th] percentile of an equivalent sample in SDSS (Ahn et al. [2012]). We adopt -2.0, -0.83, and -0.23 as the 5th, 50th, and 95th percentiles for SDSS stars, respectively.

We identify 'accreted' star particles as those that were bound to galaxies other than the main progenitors of the MW analogues at the snapshot following their formation time. According to this definition, stars that were formed out of the stripped gas from the satellites will be flagged as '*in situ*' if they are bound to the MW analogues' progenitors right after their birth. We note that this identification method is dependent on the time resolution of the output snapshots. The temporal resolution is always better than 200 Myr in Auriga level-4 simulations, and therefore, for our purposes, is not a major concern.

3.1 The radially biased stellar halo components in Auriga

Following Belokurov et al. ([2018b]), we plot the distribution of stars in a 2D velocity space: azimuthal (V_θ) versus radial (V_r) in spherical coordinates, at different galactic height bins and metallicities for all our MW analogues. Examples of the velocity space in a grid of height and [Fe/H] are presented in Appendix A. Here we focus our analysis on star particles at $9 < |z|/$ kpc < 15 and $-1 <$ [Fe/H] < -0.7. This galactic height range is larger than what was used in the MW analysis in Section 2. The reason behind our choice is that the differences between Auriga haloes are clearer at these heights and metallicities. At lower heights (but similar [Fe/H]), the distribution is dominated by stars in the galactic disc and at lower [Fe/H] values, the radially biased components become weaker. Our choice of sample selection criteria is reasonable since our goal is not to find an exact match to the MW's '*Gaia* Sausage' in the simulations, but rather more generally to investigate the origin of components with similar properties to those of the structure found in the MW.

The top row of Fig. [2] shows the velocity space of four example haloes (Au-5, Au-8, Au-28, and Au-30), for star particles at $9 < |z|/$ kpc < 15 and $-1 <$ [Fe/H] < -0.7. The rotating component with $V_\theta \sim 200$ km s^{-1} in the top panels of Fig. [2] corresponds to

the disc.[5] The halo components of these examples, which have much lower rotation (i.e. $V_\theta \sim 0$), appear very different. Au-5 has a prominent radially biased component, similar to the real MW in Fig. [1]; while Au-8 lacks such a component and is much more isotropic. These two galaxies illustrate the two ends of the spectrum of inner stellar halo kinematic features in the Auriga MW analogues.

The second row of Fig. [2] shows the velocity space of the accreted component only, with the same selection cuts as the top panels. We note that a large number of stars are removed from the top row when we select only accreted stars. For the particular spatial and metallicity selections used in this figure, the fraction of accreted stars is on average 30 per cent amongst 28 Auriga haloes. The fraction increases to 40 per cent if we relax the metallicity cut, mainly because the stellar halo is more metal poor. These numbers are overall consistent with the results of Monachesi et al. ([2018]). An exact comparison is not possible since they used different spatial and kinematic selections.

According to Fig. [2], the rotating (disc) component is, in most cases, not present in the accreted stars. A radially biased component stands out in both Au-5 and Au-28, while the latter case is less prominent. Au-30 and Au-8, on the other hand, are isotropic. Moreover, Au-8 has an accreted component in its disc. The existence of accreted (or 'ex situ') disc components is not surprising. Gómez et al. ([2017]) extensively discussed their origin in Auriga galaxies, and Rodriguez-Gomez et al. ([2016]) also report their existence in the Illustris simulations. Fig. [2] illustrates that the radially biased component is more easily identified in the accreted stars. Moreover, the existence of an *in situ* halo component in the MW is still under debate (see e.g. Helmi et al. [2011]; Bonaca et al. [2017]; Deason et al. [2017]; Haywood et al. [2018]). We therefore include only accreted particles for the rest of our analysis, unless otherwise stated.

In order to quantify the kinematic components in Auriga we decompose the velocity space of stars, at different heights and metallicities, into multi-variate Gaussian components using the Extreme Deconvolution method, similar to Section 2. The details of the procedure are described in Appendix B. In summary, we first combine star particles for each MW analogue in various [Fe/H] bins, and then decompose the velocity distribution at each galactic height into either two or three Gaussians, depending on the existence of a rotating (accreted) disc component. The velocity ellipsoids have six free parameters describing their centre and shape, at this stage. The three-component fits include one for the disc and two for the halo-like stars; the two-component fits typically include two halo-like ones. We visually inspect all 28 Auriga simulations to check that the fits are reasonable. For the second stage of the fitting, we fix the centre and shape of the ellipsoids from the previous step, and fit them to different [Fe/H] bins at each height, letting the amplitude (i.e. contribution) of the components vary.

The bottom row of Fig. [2] shows the residuals of the fits to the accreted stars. The ellipses illustrate the components of the fits: a radially biased halo component (black ellipse) and a more isotropic one (red dashed ellipse) for Au-5 and Au-28; two relatively isotropic halo components for Au-30 where one (black ellipse) is slightly more radial than the other (red ellipse); an isotropic halo component (black ellipse) and a disc component for Au-8.[6] The black ellipse of

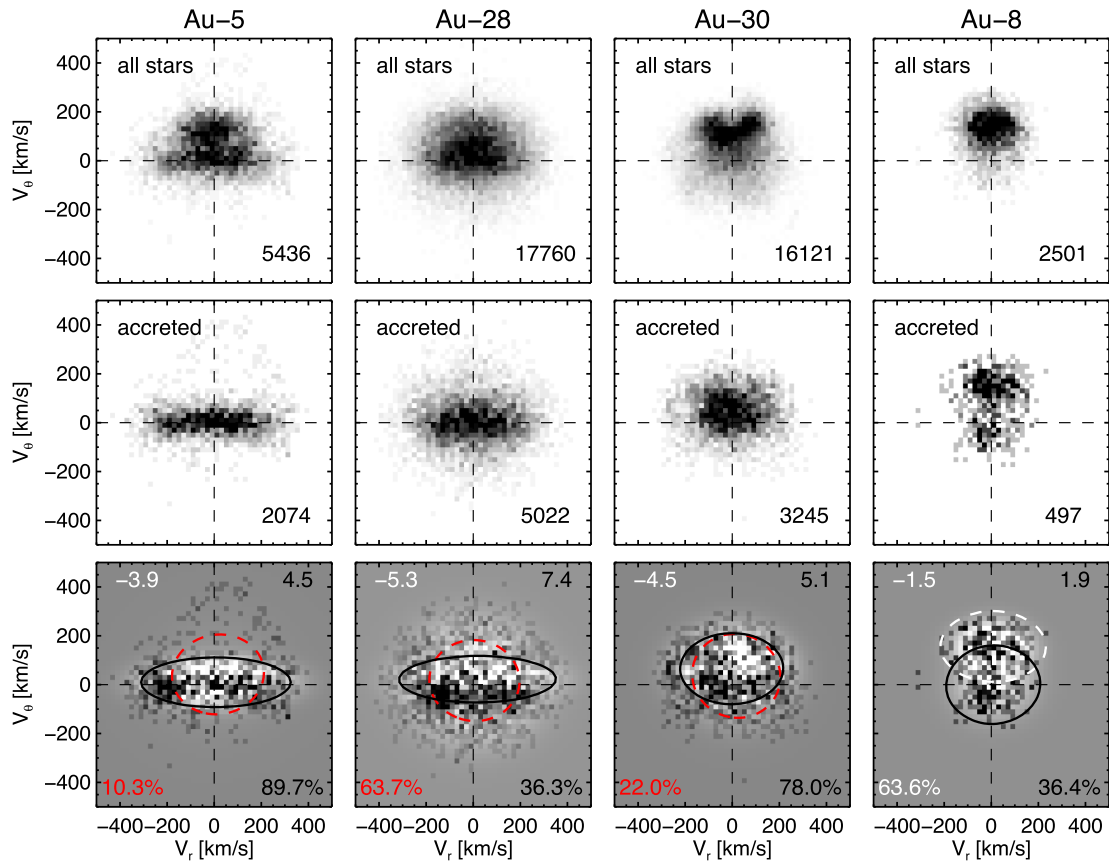

Figure 2. Distribution of star particles in velocity space for four Auriga haloes (Au-5, Au-8, Au-28, Au-30) shown in different columns. The particles are located between 9 and 15 kpc above and below the disc and have $-1 <$ [Fe/H] < -0.7. These examples illustrate the variety of kinematic features found in the inner stellar halo in Auriga galaxies. Au-5 and Au-28 have a highly radial population of stars, while Au-8 and Au-30 lack such a component. Top: velocity space of all star particles in the given height and metallicity bin. The number of star particles in each panel is quoted in the legend. Middle: similar to the top row but only for accreted stars. Bottom: the residuals of the fits to the velocity space of the accreted stars. The fits include two components. The black (white) pixels represent excess (depletion) of data relative to the model. The numbers in the top corners of each panel give the highest and lowest values of the residuals, while the percentages on the lower corners give the contribution of different components with corresponding colours.

Au-5, which is equivalent to the radially biased component observed in *Gaia*, indicates $\beta \sim 0.9$ with a large contribution to the stellar distribution ($\sim$90 per cent). The highly eccentric component of Au-28, however, contributes a much lower fraction. The contributions of each component are given by the percentages written in the bottom corners. We find that the radially biased components, if they exist, become less prominent with decreasing metallicity (see Figs A1 and B2), similar to pattern in the observations of Belokurov et al. (2018b).

Fig. 3 presents the properties of the *higher β component* of the stellar haloes as inferred by ED, at $9 < |z|/$ kpc < 15 and $-1 <$ [Fe/H] < -0.7, in the 28 Auriga galaxies. A significant fraction of these galaxies, $\sim$75 per cent, has a halo component with high anisotropy ($\beta > 0.7$). A key point to consider is the component's contribution to the (accreted) stellar halo within the spatial and metallicity selection cuts (see examples in Fig. 2). Recall that the radially biased component of the MW dominates the mass of the inner stellar halo, as discussed in Section 2. Therefore, we identify haloes with high β *as well as* a large fractional contribution to the halo (the top-right corner of Fig. 3) as being similar to the MW. More precisely, we apply the cuts $\beta > 0.8$ and contribution > 50 per cent, marked by the dashed lines. Out of 28 Auriga galaxies, 10 ($\sim$1/3) survive these cuts.

We emphasize that the general conclusions from Fig. 3 do not change when we perform our analysis on all stars, instead of only accreted stars. We indeed tried performing the ED analysis on all stars, and found good fits using three components (one disc component and two halo-like ones). We find that some of the *in situ* stars are potentially associated with the radially biased components according to their kinematics, and that their formation time is correlated with the merger time of the progenitors of these radially biased components (more on the progenitors of the radially biased components in the next section). We plan to address the origin of such *in situ* stars in a follow-up paper.

3.2 Origin of the radially biased component

In Fig. 4 we present the DM accretion history of the Auriga MW analogues. They are split into two groups, one with a significant radially biased component (red), and the rest (blue). Solid lines indicate the median mass accreted as a function of time for each group, and the shaded regions correspond to the full range of variation. Even though the sample is small, it is obvious that the galaxies with a significantly radially biased component grow faster
Figure 3. Anisotropy parameter (β) of the more radial component of the Auriga stellar haloes, versus their relative contribution to the stellar halo. These results are based on the decomposition of the velocity space (see bottom panels of Fig. 2 and the text for further details). We only consider accreted stars at galactic height of $9 < |z|/\,\mathrm{kpc} < 15$ with $-1 < $ [Fe/H] < -0.7. Galaxies inside the dashed lines have a dominant, highly radial component similar to the *Gaia* Sausage. The four haloes highlighted in the top-right corner (Au-5, Au-9, Au-10, Au-18) are the extreme cases, also marked in the next plots, where a highly radial component dominates their inner stellar halo. The small numbers inside each symbol represent the halo number of the Auriga galaxies for reference.
Figure 4. DM accretion history of Auriga galaxies, normalized to the present-day halo virial mass. The red line (shaded region) illustrates the median (full range) of the accretion histories for galaxies with a significant radially biased stellar halo component (highlighted in the top-right corner of Fig. 3). The blue line and shaded region correspond to the accretion history of the other galaxies.

between $t = 4$ and $8\,\mathrm{Gyr}$[7] compared to the rest of the galaxies. A larger sample of galaxies is, however, needed to confirm whether the biased assembly history is statistically significant. The result of Fig. 4 is broadly consistent with the proposal by Belokurov et al. (2018b) that the origin of the '*Gaia* Sausage' is a massive, early merger.

We investigate the origin of the prominent radially biased components (i.e. $\beta > 0.8$ and contribution > 50 per cent) in the Auriga galaxies by tracking their star particles back in time. We select the (accreted) stars 'associated' with the radially biased components using: (i) metallicity, $-1.3 < $ [Fe/H] < -0.7; (ii) galactic height, $9 < |z|/\,\mathrm{kpc} < 15$; (iii) azimuthal velocity, $|V_\theta - V_{\mathrm{mean}}| < 50\,\mathrm{km\,s^{-1}}$; and (iv) radial velocity $|V_r| > 100\,\mathrm{km\,s^{-1}}$. V_{mean} refers to the azimuthal velocity of the radially biased component derived from the ED modelling of the previous section. The radial velocity cut is used to clean the sample from stars potentially associated with a more isotropic component. We checked that the following analysis is not sensitive to the exact values of the aforementioned cuts. The total mass of the sample of stars 'associated' with the radially biased component is referred to as M_{radial} in the following analysis.

We identify all of the progenitor galaxies which brought in the stars that ended up in the sample of stars 'associated' with the radially biased component, in any target galaxy. We then rank the progenitors by their mass contribution (M_c) to the sample. The progenitor that contributed the most is identified as the main progenitor (or main contributor) of the radially biased component.[8] Fig. 5 presents the peak stellar mass of the main progenitor, its relative contribution to the stars associated with the radially biased component (i.e. M_c/M_{radial}), and its merger time with the main progenitors of the MW analogue.[9]

The top panel of Fig. 5 demonstrates that the stars belonging to the radially biased component predominantly come from a single progenitor: a massive ($M_{\mathrm{star}} \sim 10^9 - 10^{10}\,\mathrm{M}_\odot$) galaxy which contributed more than ~ 50 per cent to the component. The few cases where the main progenitor contributed less than ~ 40 per cent have one or two additional massive progenitors. The merger time of the main contributors, according to the bottom panel of Fig. 5, spans the wide range $t \sim 4$–8 Gyr, with some concentration frequency around $t \sim 4$–5 Gyr. The filled symbols, which correspond to the four cases in the top-right corner of Fig. 3, correspond roughly to a single LMC-like progenitor and a wide range of merger times. The preference for an early merger with a massive dwarf galaxy around $t \sim 4$–5 Gyr explains the behaviour of the mass accretion history (illustrated in Fig. 4) of the galaxies with the radially biased component. The main progenitor of a radially biased component must have contributed notably to the growth of the MW analogues.

We now examine the contribution of the main progenitor of the radially biased component to the inner regions of the MW analogues at $z = 0$. The top panel of Fig. 6 shows how much of the stellar mass in the inner $20\,\mathrm{kpc}$ of the MW analogues were brought in by those progenitors, compared to the total accreted mass within $20\,\mathrm{kpc}$. The main progenitors of the radially biased component contribute a significant fraction to the inner stellar halo, and the contribution is consistently $\sim 1/3$–$1/2$ (inside $20\,\mathrm{kpc}$), except in one case (Au-26).

---

[7]$t = 0\,\mathrm{Gyr}$ corresponds to the big bang.
[8]According to our definition, the main progenitor is not necessarily the most massive progenitor, but is typically amongst the most massive ones.
[9]Merger time is defined as the time when SUBFIND fails to find the merging galaxy as a separate bound substructure.
Figure 5. Top: the stellar mass of the progenitor galaxy which contributed the most to the radially-biased component in the Auriga galaxies, versus their mass contribution to that component. See text for full details of the selection of the stars belonging to the radially biased component. Bottom: Merger time of the main contributors with the [progenitors of the] MW analogues, versus their peak stellar mass. Filled symbols correspond to the four haloes highlighted in the top-right corner of Fig. 3 with extremely anisotropic components dominating the inner halo. The distributions shown on each axis correspond to projecting all of the plotted points on one axis, smoothed with a Epanechnikov kernel.

The bottom panel of Fig. 6 shows that the situation is different for the DM: the contribution of the progenitor of the radially biased stars to the DM in the inner region ($r < 20$ kpc) varies by more than an order of magnitude amongst different haloes, and is much less significant compared to the stellar contribution ($\sim 1 - 10$ per cent). There are two reasons behind the observed difference between the DM and stellar contributions of the main progenitors. First, stars are more centrally concentrated than the DM; hence they occupy different regions of the energy-angular momentum space after becoming tidally stripped. The progenitors start to lose their DM before their stars, and therefore deposit their DM in a larger volume. Secondly,
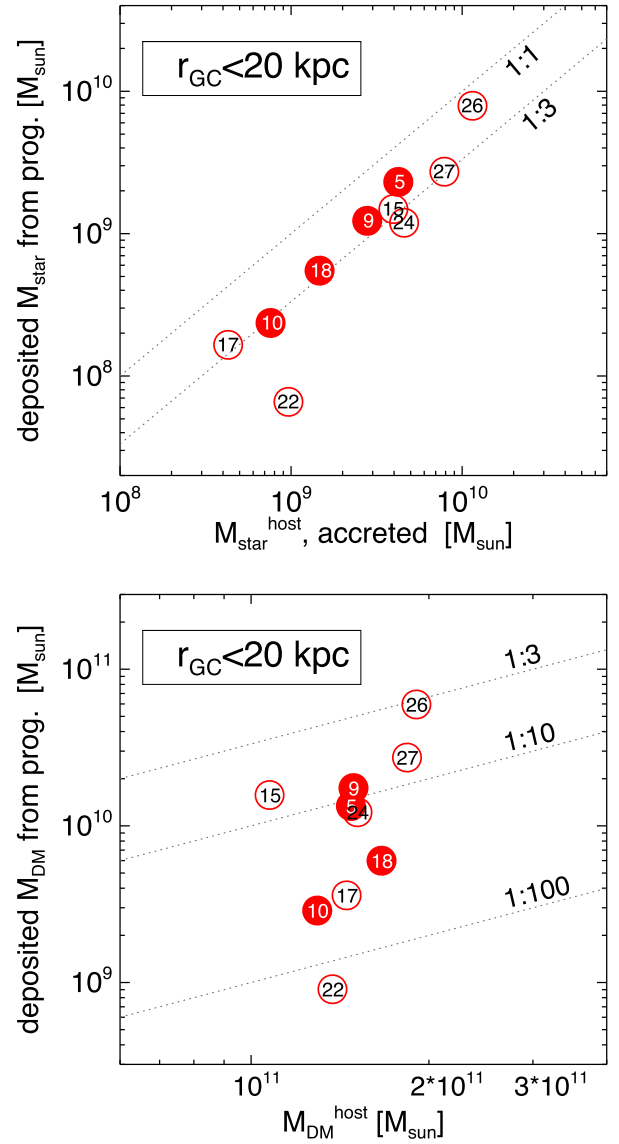

Figure 6. Top: Contribution of the main progenitor of the radially-biased component to the stellar mass in the inner 20 kpc of the Auriga galaxies at $z = 0$, versus the total accreted stellar mass in the same volume. The diagonal lines correspond to the 1:1 and 1:3 mass ratios as indicated by the labels. Bottom: DM contribution of the main progenitor to the inner 20 kpc, versus the total DM mass in $r < 20$ kpc.

the stellar mass–halo mass relation at the faint end is so steep in ΛCDM that almost all dwarf galaxies live in similar haloes of mass $\sim 10^{10}$ M$_\odot$ (Eke et al. 2004; Behroozi et al. 2013; Deason et al. 2016; Sawala et al. 2016; Fattahi et al. 2018; Simpson et al. 2018). As a consequence, while the build up of the accreted stellar halo can be dominated by the merger of a few relatively bright dwarf galaxies, their DM contribution is more representative of fainter dwarfs (see Wang et al. 2011, for a detailed analysis on the build-up of MW-like haloes).

4 SUMMARY AND DISCUSSION

We use the Auriga MHD simulations of MW-like galaxies to study the origin and frequency of a highly radial ($\beta \sim 0.9$) and metal-rich component of the inner halo, recently reported by Belokurov

et al. (2018b) using *Gaia* DR1. This component is believed to be the same population discussed by Helmi et al. (2018). First, we present an updated version of the results of Belokurov et al. (2018b) using *Gaia* DR2. We confirm the existence of a large group of stars on highly radial orbits with $\beta \sim 0.86$ (the '*Gaia* Sausage'), in *Gaia* DR2.

Secondly, we search for the phase-space signatures of such a radially biased population of star particles amongst Auriga galaxies and find that they are relatively common: around 1/3 of the simulated galaxies have a significant population of stars residing above and below the disc, with [Fe/H] ~ -1, which resemble the observations. In addition, we find that the significance of the sausage-like components, when they exist, always decreases at lower [Fe/H]. This metallicity dependence trend has also been observed in the MW by Belokurov et al. (2018b). Essentially, the phase space of all galaxies looks similar at metallicities below [Fe/H] ~ -2.0 and is dominated by a halo component with $\beta \sim 0.3$.

We demonstrate that the accretion history of Auriga galaxies with a radially biased component is biased, on average, towards steeper growth at $t \sim 4-6$ Gyr, suggesting more mergers at those early times. It is intriguing that Mackereth et al. (2018) find, using the EAGLE simulations, a similar early accretion bias for galaxies that show alpha-bimodality in their stars. This is supported also by the study of Grand et al. (2018), which found that the early accretion of a gas-rich major merger at around redshift 2 is required to form a prominent alpha-bimodality. The connection between alpha-bimodality and the radially-biased components is worth pursuing in follow-up studies.

By tracing back the star particles associated with the radially biased component of each Auriga galaxy, we find that their main progenitor is typically a massive dwarf galaxy with peak stellar mass of $10^9 - 10^{10}$ M$_\odot$, which merged with the progenitor of the MW analogues $\sim$6–10 Gyr ago. Such a massive dwarf progenitor also explains why the radially biased component is prominent at relatively higher metallicities ([Fe/H] ~ -1): it is a consequence of the tight stellar mass–metallicity relation (Kirby et al. 2013).

Given that the main progenitors of the radially biased components in Auriga haloes are as massive as the LMC (or even more massive), their merger with the MW progenitor can have a large impact on the structure of the disc. In some cases the merger almost completely destroys the disc, and a new younger disc has to regrow. We note that these mergers are different from those reported by Gómez et al. (2017) in the Auriga galaxies which brought in ex situ disc stars. These have different orbits which deposit the tidally stripped stars in circular orbits co planar with the disc, as opposed to the radially biased components studied here. We will present a thorough analysis of the mergers which made the '*Gaia* Sausage'-like components, and their influence on the evolution of the MW, in a subsequent paper.

Finally, we find that the star particles brought in by the main progenitors of the radially biased components make up $\sim$30 per cent $-$ 50 per cent of the total amount of the accreted stars in the inner 20 kpc of the MW analogues at $z = 0$. The DM contribution of the progenitors to the same volume, however, is much lower and varies significantly between different haloes ($\sim$1 per cent $-$ 10 per cent). This is a consequence of the inefficient galaxy formation at low-mass scales, as well as the difference in the tidal stripping of dark matter particles and stars from the progenitor dwarf. Thus the accreted stellar halo does not *directly* trace the build-up of the DM halo.

APPENDIX A: PHASE-SPACE EXAMPLES OF AURIGA GALAXIES

Here we present the 2D velocity space of accreted stars (azimuthal versus radial components), on a full grid of height and metallicity, for two examples of Auriga galaxies: one where the '*Gaia* Sausage'-component is prominent (Fig. A1) and one with no notable highly radial component (Fig. A2). The galactic height increases from the top row to bottom in the range $|z| = 1 - 15$ kpc; [Fe/H] increases from -4 to -0.7, from left to right.

The component at higher metallicities with $v_r \sim 0$ km s^{-1} and $v_\theta \sim 200$ km s^{-1} is the disc of the galaxies. In Fig. A1, the highly radial component is obvious at higher metallicities, and becomes less and less obvious at lower metallicities. We also note that the radial component is more visible at higher $|z|$; this is due to the fact that the disc is more dominant at lower $|z|$ over the halo component. Therefore, the difference due to the existence (or lack) of the highly radial component is apparent at higher $|z|$ and higher [Fe/H] (bottom-right panels).
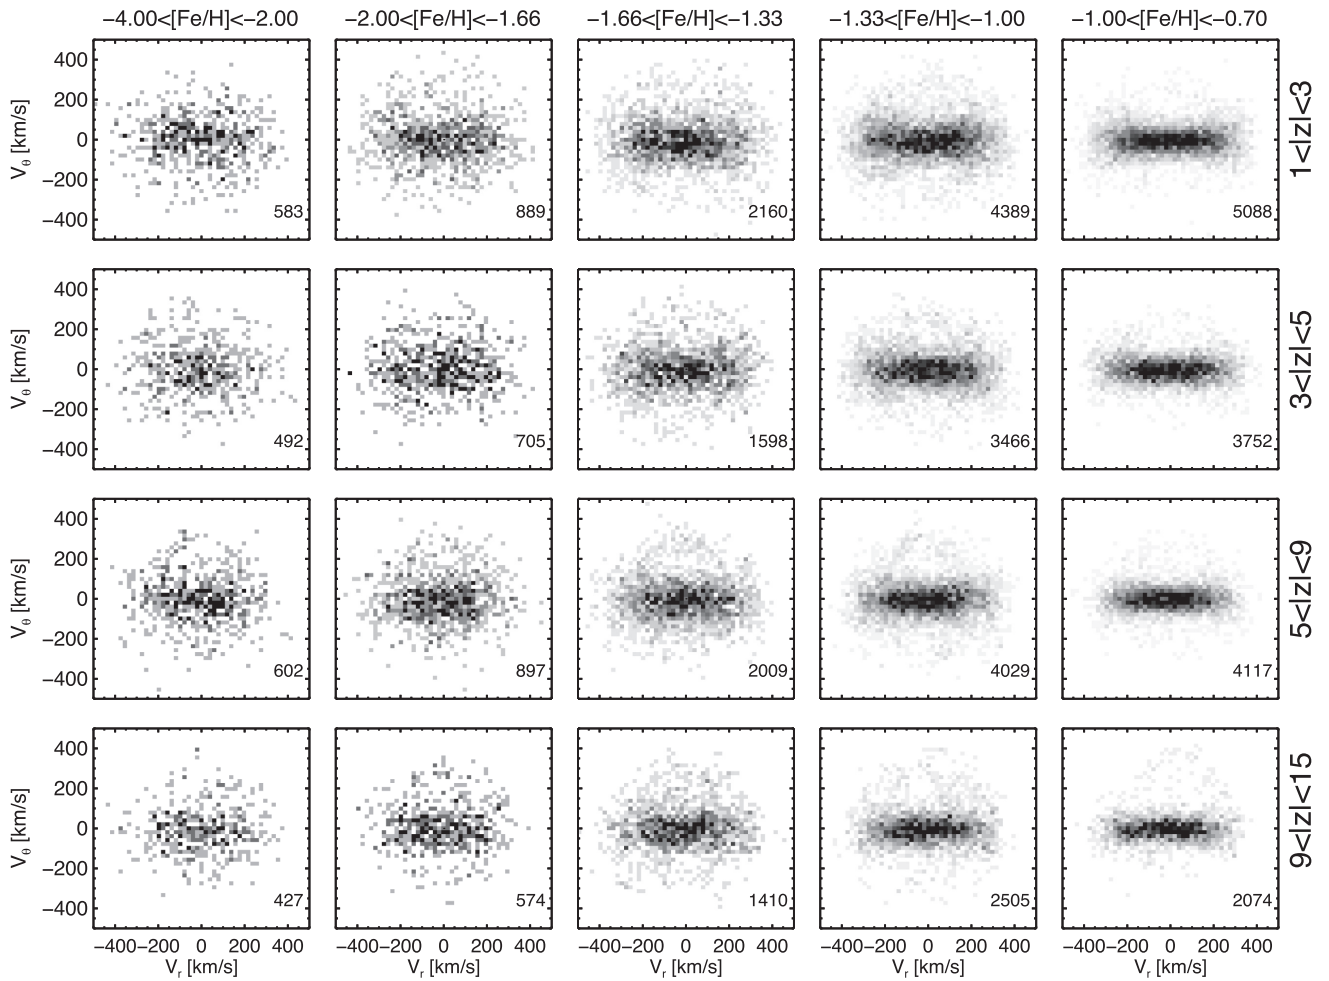

Figure A1. 2D velocity space (azimuthal versus radial) of accreted stars for an Auriga halo (Au-5) at different heights |z| and [Fe/H]. Rows from top to bottom correspond to as 1–3, 3–5, 5–9, 9 − 15 kpc above and below the galactic disc. Different columns represent different [Fe/H] of < −2, −2.0, −1.7, −1.7, −1.3, −1.3, −1.0, and −1.0, −0.7. This is a clear example of a galaxy with a highly radial population of stars at higher [Fe/H], similar to the *Gaia* observations of the MW (Belokurov et al. 2018b).
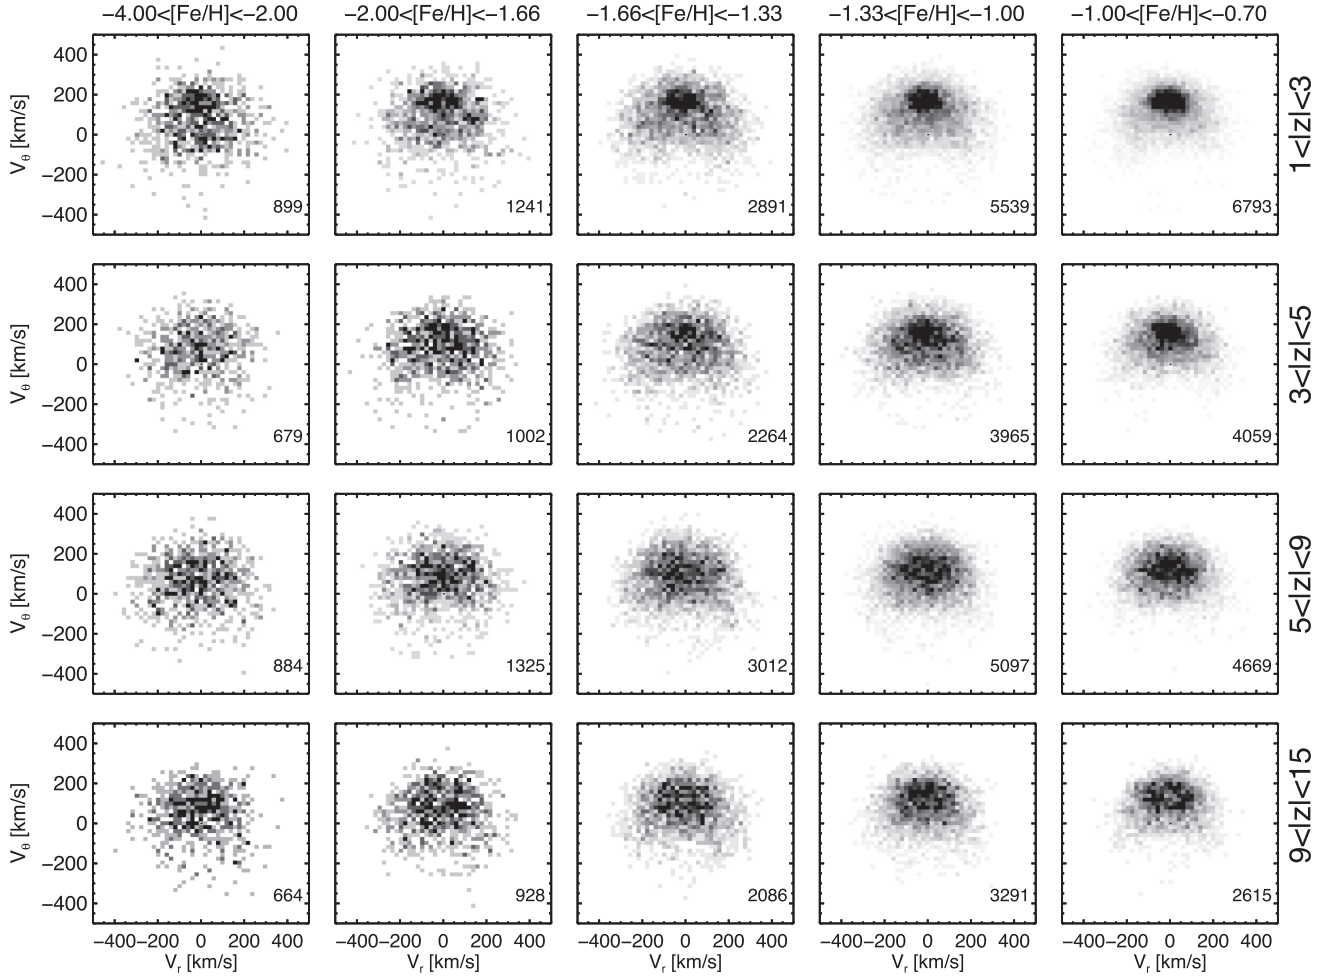

Figure A2. Similar to Fig. A1, but for a galaxy (Au-16) with no considerable radially biased ('sausage'-like) component.

APPENDIX B: DECOMPOSITION OF PHASE SPACE

We adopt the following two-step procedure to decompose the phase space of stars in each Auriga galaxy.

(i) We start with the 3D velocity space of stars with [Fe/H] < −0.7, at different heights. This is equivalent to stacking columns of Fig. A1. We decompose the velocity space at each height, using the 'extreme deconvolution' method of Bovy, Hogg & Roweis (2011), into three components (velocity ellipsoids) with free parameters. The initialization of parameters ensures that the three components

include a disc and two halo-like components. Fig. B1 illustrates this step.

(ii) In the next step, we divide each height into different metallicity bins (equivalent of Fig. A1). After fixing the centre and shape of the velocity ellipsoids from the previous step, we fit them to different metallicities and let the amplitude (contribution) vary. Fig. B2 shows the residuals of the fit to an example Auriga galaxy. The rows and columns are similar to Figs A1 and A2. Note that the velocity ellipses (the models) are fixed across any given row by our procedure.
Figure B1. An illustration of the first step of the fitting procedure: the deconvolution of the velocity space into two or three Gaussian components, after combining [Fe/H] bins at each galactic height. The left column shows the velocity space at different heights (different rows), while the right column shows the residuals of the corresponding model. The three components of the model at each height include three velocity ellipsoids; one for the disc (white ellipse) and two for the halo-like components (black and red ellipses). The two-component fit (last row) includes only two halo-like components. The example shown is Au-6.
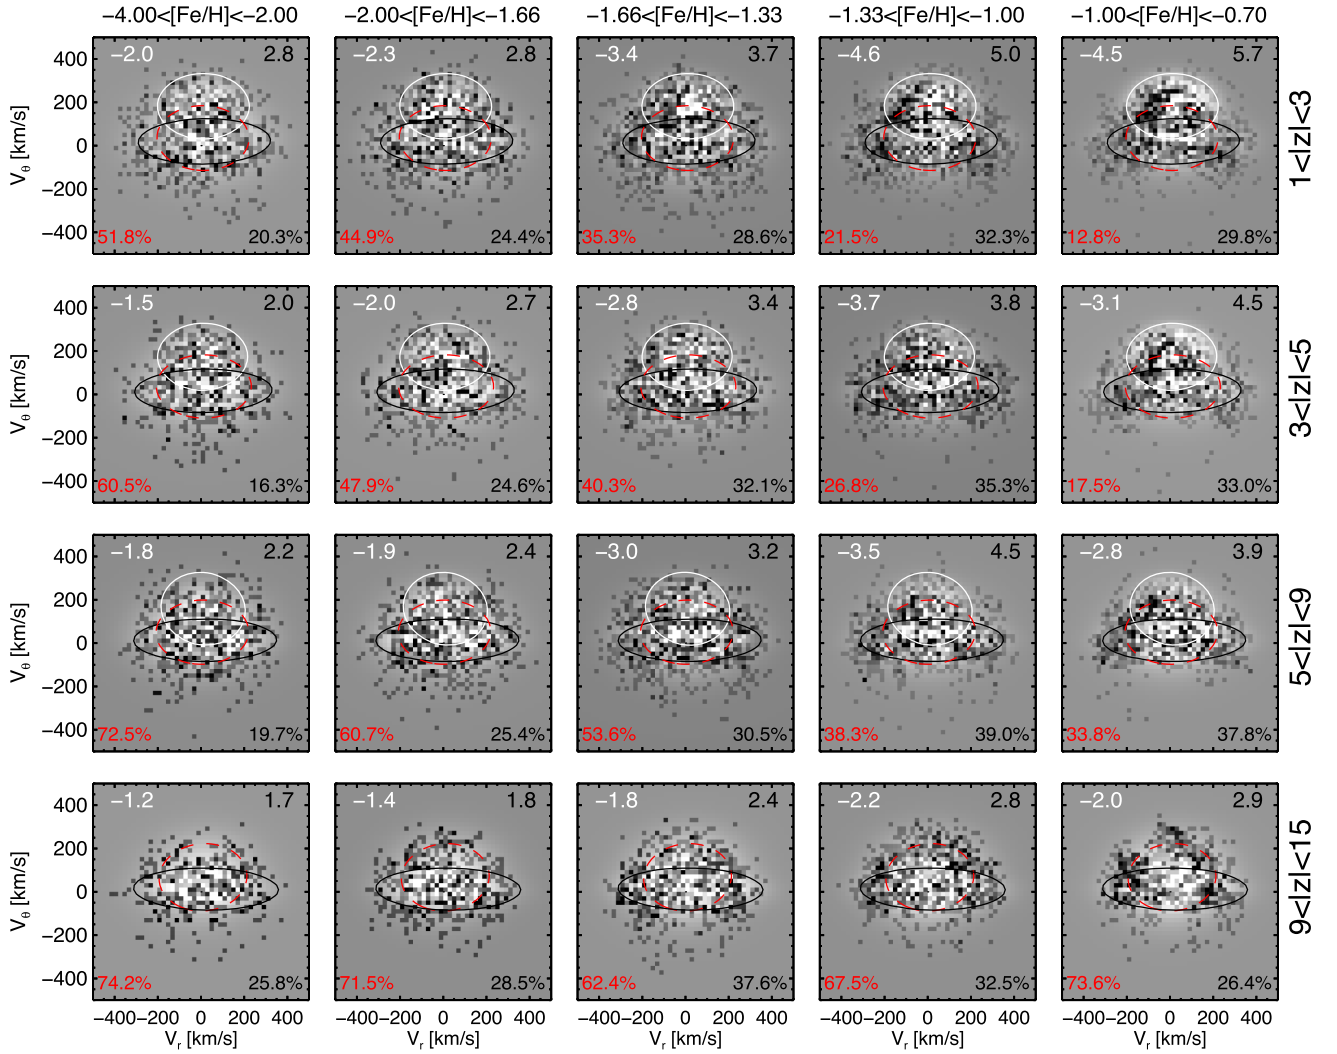

Figure B2. Second step of the fitting procedure. The centre and shape of the velocity ellipsoids from the previous step (Fig. B1) are fixed, and the amplitudes of the ellipsoids vary across different [Fe/H] bins. The residuals are shown here in a grid of height (rows) and metallicity (columns). The numbers in the top corners of each panel show the highest and lowest values of residuals, while the percentages in the lower corners show the contribution of different components with corresponding colours. This example is the same galaxy as Fig. B1.

This paper has been typeset from a TEX/LATEX file prepared by the author.
