A retrospective observational study evaluated the risk factors for pre-slaughter losses (i.e. animal deaths occurring during transport and lairage) and their economic impact in Italian heavy pigs (~160 kg bodyweight). Of the 3 344 730 pigs transported, 1780 (0.053%) died before slaughter, with most losses occurring during transport (56.6%). The estimated economic impact was of 424 000 €. The percentage of batches with at least one animal lost pre-slaughter increased during summer ($P < 0.001$). The proportion of pre-slaughter losses was higher when journey lasted more than 90 min ($P < 0.001$) and was positively correlated with transport duration ($P < 0.01$). Losses were higher ($P < 0.01$) in batches transported at low stocking densities (i.e. when heavier pigs were transported). Batches with lower slaughtering order (i.e. longer lairage time) had higher proportions of losses ($P < 0.001$). Logistic regression analysis showed that the odds of a given batch to have at least one animal lost pre-slaughter were 1.32 times higher for batches slaughtered in summer, 1.54 times higher if journey durations exceeded 90 min, 1.25 times higher for batches with low slaughtering order, and not significantly influenced by stocking density during transport.

Additional keywords: economic impact, pig welfare, transport.

The identification of critical points during transport and slaughtering procedures may significantly improve animal welfare during transport. In heavy pigs, long travel duration, low stocking density and overnight lairage resulted in increased animal losses. The routine collection and analysis of animal-loss data at slaughterhouses could reduce the economic impact of animal losses and be of help in improving future legislation on the protection of pigs during transport.

Introduction

Transporting pigs to slaughter raises concerns principally from two points of view, namely, the welfare of the transported livestock, and the economic impact for the industry (Averós *et*

al. 2008). Animal losses (i.e. animal deaths occurring during transport and lairage) are a multifactorial problem involving genetics, management, handling, facilities and truck design, and processing plant and environmental factors. Ritter *et al.* (2009) defined animal losses as ‘pigs that die or become non-ambulatory at any stage of the marketing process, defined as movement from the grower–finisher environment to stunning at the abattoir’. Continued research efforts are needed to understand how each factor can affect animal welfare (Ritter *et al.* 2009) and, therefore, animal losses. Differences among continents and countries may include transportation times and distances, feed and water intervals (due to regulatory differences), road condition, trailer design, animal genetics and extreme weather conditions (Schwartzkopf-Genswein *et al.* 2012). All these variables add complexity to the individuation of deficiencies within the pre-slaughter logistic chain, since each of them, as well as their interaction, can considerably affect animal welfare and animal losses during transport (Carr *et al.* 2008; Miranda-de la Lama *et al.* 2014). However, despite differences, general principles are consistent among studies. Seasonality of pig losses during transport has been extensively studied in summer and in winter (Schwartzkopf-Genswein *et al.* 2012), and it is well known that transportation losses tend to be higher at warm environmental temperatures and that the welfare of pigs transported on the lower deck and in front compartments can be particularly compromised (Christensen and Barton-Gade 1999; Brown *et al.* 2011). Pig welfare may benefit from transportation at reduced loading densities (Ritter *et al.* 2007; Gerritzen *et al.* 2013), although the effect of stocking density on animal losses is less consistent in the literature (Barton Gade *et al.* 2007). Last, pre-slaughter losses can also occur at the slaughter plant, as a consequence of stressful (or uncontrolled) lairage conditions, such as unfamiliar environment, fasting and regrouping (Warriss 2003; Brandt and Aaslyng 2015).

In Italy, the typical slaughtering weight of pigs is considerably higher than in other countries, since the production of protected designation of origin (PDO) hams, such as Parma ham, requires the attainment of at least 160 kg of body weight (BW; Consortium for Parma Ham 1992). It has been suggested that losses during transport could be greater in heavier pigs (>100 kg BW), since they might show a greater metabolic response and increase in rectal temperature when handled and transported (Ellis and Ritter 2005). Greater losses in heavy pigs may also be related to a lack of respect for appropriate space allowance in the truck, especially given the absence of specific legislative requirements for pigs above 100 kg BW (EC 2005).

To the best of our knowledge, only very recently a study analysed the factors associated with mortality of heavy pigs during transport and lairage (Vitali *et al.* 2014). However, conversely to the present study, the mentioned research did not estimate the economic impact of pre-slaughter losses, and did not take into account stocking density during transport.

The present survey followed the case study of a single Italian abattoir, collecting retrospective data on the batches shipped to the abattoir over almost 5 years, so as to

- (1) describe and analyse the amount and causes of pre-slaughter animal losses (i.e. losses occurring during transport and lairage);
- (2) analyse the risk factors associated with pre-slaughter animal losses (season, transport duration, stocking density, slaughtering order); and
- (3) assess the economic impact of animal losses.

All data were retrieved from the Public Veterinary Service database filled by the veterinarians performing meat inspections at the surveyed plant. The routine records of causes for pig and carcass condemnations at slaughterhouses can, in fact, constitute a database for studies regarding animal welfare, swine diseases and conditions responsible for economic losses due to total or partial carcass and offal condemnations. Nevertheless, the literature available regarding the causes of carcass condemnations in pigs is scarce ([Garcia-Diez and Coelho 2014](#)). The aim of the present study was to partially fill this knowledge gap on pre-slaughter animal losses by elaborating data collected under current commercial conditions.

Materials and methods

Data collection

The survey was conducted in a slaughterhouse located in the Emilia–Romagna Region, northern Italy. The company owning the plant is a leader in slaughtering and processing pig meat. The activities of the company include the entire productive chain (slaughtering, deboning, primal cuts) and its products are sold both on national and international markets, mainly to food industries and large retail chains. The plant where the study was conducted presently slaughters more than 780 000 pigs per year; these pigs are almost entirely heavy pigs (i.e. slaughtered at 160 kg or higher BW and at a minimum age of 9 months) intended for PDO Parma ham production ([Consortium for Parma Ham 1992](#)), at a line speed of ~450 pigs per hour.

The survey was conducted as a retrospective observational study, and it was performed by analysing the database of the local Public Veterinary Services (Azienda Unità Sanitaria Locale di Modena), whose veterinarians conducted meat inspections in the surveyed plant. Data collection refers to the period between 10 April 2009 and 31 December 2013 (~57 months of activity).

The following data were retrieved from the database for each slaughtering batch (pigs from the same pig unit transported to the slaughterhouse on the same day), so as to evaluate their relationships with pre-slaughter losses occurred during transport and lairage:

- geographic provenance (province and region) of the batches, as obtained from the authorisation code of each farm;
- journey duration: an estimate was obtained using a common web-based application (www.viamichelin.it, last accessed December 15, 2015) to calculate the time required to travel from the municipality of the farm to the municipality of the slaughterhouse; although the calculated journey duration does not take into account the exact distance from farm or possible delays due to accidents occurred during the journey, still, this travel duration has been used because it allowed to standardise travel duration based on the geographic location of the farm;
- day of the week and month when the slaughter took place;
- number of pigs per batch (obtained by adding the number of carcasses actually inspected to the number of animals lost pre-slaughter);
- slaughtering order, which was the number attributed to every batch on arrival; lower values correspond to pigs that reached the slaughterhouse on the day before slaughtering, spending the night in lairage and being the first slaughtered on the day after their arrival.

During unloading at the slaughterhouse, veterinarians inspected the health status of the pigs and the characteristics of the vehicles to assess transport conditions (e.g. stocking density), so as to evaluate compliance with the European regulation concerning the transport of slaughter pigs (EC 2005).

Due to the study design, some factors related to transport (truck driver, number of truck stops, truck design, average temperature during transport) or lairage (lairage duration, and stocking density for each batch) could not be taken into account. The trucks used by the abattoir in the large majority of transports were three-deck type, having an overall internal area of $\sim 49.6 \text{ m}^2$. Transport could be carried out with the tractor+trailer alone (semi-trailer truck, commonly loading ~ 70 pigs) or with the addition of a second trailer (overall load: ~ 140 pigs). The number of pigs that could be loaded on the truck was calculated at loading on the basis of the average BW of the batch, so as to comply with the stocking density during transport prescribed by law (235 kg/m^2 maximum, EC 2005).

At the slaughterhouse, animals were kept in lairage pens on slatted floors. To ensure that different batches are not mixed, the slaughterhouse has 20 large pens that can be divided into eight sections each. Every section can contain 15 pigs, and is equipped with a drinker and a water sprinkler.

Statistical analyses

Data were preliminary analysed using descriptive statistics, so as to study the main productive indicators of the plant (e.g. number of pigs introduced, season of the year, geographic provenance, average batch size, pre-slaughter losses) both as absolute values and in relation to independent variables (e.g. year, season, day of the week).

Transport could be undertaken with the tractor+trailer alone (semi-trailer truck) or with the addition of a second trailer. To account for this difference, the subsequent statistical analysis was conducted after dichotomising stocking density during transport according to the number of animals. The median was calculated for each category (71 and 140 pigs respectively). This method allowed the identification of batches of 'high density during transport', i.e. all batches of more than 71 pigs transported by the same trailer or all batches of more than 140 pigs (in this case a second trailer was used).

Risk factors correlated with the increase in the probability that a given batch has at least one animal lost pre-slaughter were identified using a two-stage analysis.

In the first stage, the proportion of batches with at least one animal lost pre-slaughter (during transport and lairage) was evaluated according to different possible risk factors using the chi-square test. The evaluated factors were season (winter period, from October to March; summer period, from April to September), journey duration, slaughtering order and stocking density. Continuous variables were divided into two categories on the basis of the median value; the two categories for travel duration were either less or more than 90 min, and for slaughtering order were either $1 \div 11$ or ≥ 12 .

In the second stage of the statistical analysis, so as to estimate the influence of risk factors on the probability for the batches to have at least one animal lost pre-slaughter, factors with $P < 0.15$ were evaluated using a binary logistic model. The model was based on the simultaneous entry of all variables (season, journey duration, slaughtering order and density during transport), and its efficacy was assessed on the basis of the likelihood-ratio and the Hosmer–Lemeshow statistic. The odds ratio (OR) and 95% confidence intervals (95% CI) were calculated from the final binary logistic model.

Kolmogorov–Smirnov test for goodness of adaptation was used to verify distribution normality. On the basis of the results of Kolmogorov–Smirnov test (all variables were not normally distributed), Mann–Whitney U or Kruskal–Wallis H test were used to compare quantitative data.

All statistical analyses were performed using the software IBM SPSS version 21 (IBM Corp., Armonk, NY).

Results

Animals and their origin

In the period of the survey, 26 635 pig batches were slaughtered over 1059 working days (on average 25 batches/day), for a total of 3 344 730 pigs (3158 per day on average).

Batches came from 1896 farms, even if 50% of the batches came from only 88 farms.

Overall, the average number of pigs slaughtered monthly was close to 60 000, with comparable trends between the years considered in the survey. Reduced volumes were recorded in April 2009 (–28%, due to the fact that data were available only from the second week of the month) and in June 2010 (–34%, due to a workers' union controversy that involved the abattoir).

The number of pigs introduced per week day is constant across the week, with the exception of Thursdays, when, due to internal organisation reasons, the abattoir works for fewer hours per day and, therefore, the number of pigs slaughtered is lowered to 30–40% if compared with the full days.

The animals received by the slaughterhouse during the 5 years of the survey came for most part (88.9% of pigs and 89.4% of batches) from Emilia–Romagna or from nearby northern Italian regions (Piedmont and Lombardy), within a radius of ~250 km from the slaughterhouse.

Animal losses and the estimate of the economic impact

During the survey, a total of 1780 pigs (0.053% of the pigs transported to the plant) died before slaughter. At the average BW of 160 kg, the overall weigh of the pre-slaughter losses equals to 284 800 kg. Of the carcasses, 1834 (corresponding to ~51% of total animal losses) were judged not suitable for human consumption (i.e. condemned). Total animal losses (pre- and post-slaughter) accounted for 3614 animals and carcasses, of which ~51% were carcass condemnations.

Commodity exchange quotations in the province of the abattoir (<http://borsamercimodena.it>, last accessed December 15, 2015) for slaughtering pigs weighing between 160 and 176 kg showed in the period of the survey prices that varied between a minimum of 1.26 and a maximum of 1.76 €/kg BW, with an average price of 1.49 € in the last year of the survey (2013). The economic impact of pre-slaughter losses in the entire period can be estimated at about 424 000 €, corresponding to 0.053% of the profit arising from slaughtering during the period of the survey. Moreover, this figure does not take into account

the loss of profit arising from the fact that a significant portion of meat is intended for high-value cured-ham production.

Pre-slaughter losses

In 1523 of the 26 635 batches that were slaughtered during the survey (5.7%), at least one pig had been lost pre-slaughter (i.e. either found dead or killed); within this category, only in 10.1% of the batches, the number of pigs lost was ≥ 2 (Fig. 1). In one single case, occurring in 2012, 32 pigs were found dead on the truck on arrival as a consequence of severe negligence by the transporter. The reason for pre-slaughter losses was known for 1364 of the 1780 pigs lost (76.6%). Losses occurred mostly during transport (56.6% of the animals lost pre-slaughter were found dead at unloading) and during lairage (39.1% of the losses occurred in lairage pens), whereas only a small percentage of pigs was euthanized (1.7%). For ~3% of losses, it has not been possible to discriminate whether the animal death occurred during transport or lairage, and animal losses were generically attributed to 'truck and lairage'.

Figure 2 shows the distribution across the months of pre-slaughter losses that occurred during the whole survey and by year. The percentage of pre-slaughter animal losses showed a seasonal variation, with an increase during the warmer months (between June and September). So as to verify the hypothesis that pre-slaughter losses could depend on season (and therefore on environmental and truck internal temperatures), the proportion of batches with at least one animal lost pre-slaughter was evaluated in relation to the period of the year (summer = from April to September; winter = from October to March; see Table 1). Results indicated that there was a statistically significant increase (+1.6%) in the percentage of batches with at least one animal lost during summer when compared with winter ($\chi^2 = 28.27$, $P < 0.001$). Similar results could be obtained if the variable taken into account was the number of animals lost pre-slaughter per batch or the number of animals lost pre-slaughter per number of animals received by the abattoir per batch (Table 2). Differences were statistically significant also in this case (Mann–Whitney $U = 87\,232\,898$, $P < 0.001$; and Mann–Whitney $U = 87\,235\,611$, $P < 0.001$), with an increase in animal losses during the warmer months.

Figure 3 further confirms the seasonal variations, but also shows different trends in the years considered. More accurately, the seasonal difference in the percentage of batches with at least one animal lost pre-slaughter was significant ($P < 0.05$) in years 2010, 2011 and 2013, but was not significant in 2009 and in 2012.

No difference ($P > 0.05$) was detected (data not shown) concerning the distribution of pre-slaughter animal losses on a week-day basis.

The relationship between pre-slaughter animal losses and transport duration was also studied. Journey duration was estimated as described in the Materials and methods section. The percentage of animals lost pre-slaughter of the total number of animals received by the abattoir (data per batch) was significantly ($P < 0.01$) correlated with transport duration (non-parametric Spearman correlation coefficient = 0.070). Similar results were found when the winter and summer periods were considered separately.

So as to allow a further comprehension of the relationship between the two parameters, the mean of animals lost pre-slaughter per batch and the rate of animals lost pre-slaughter per batch (i.e. the number of animals lost pre-slaughter per number animals received by the abattoir per batch) were calculated depending on journey duration; two categories were set according to the median journey duration, namely, less than or more than 90 min (Table 2). The mean of animals lost pre-slaughter per batch and the rate of animals lost pre-slaughter per batch were significantly higher (Mann–Whitney $U = 86448609$, $P < 0.001$; and Mann–Whitney $U = 86411823$, $P < 0.001$, respectively) when journey lasted more than 90 min.

Table 1 shows the batches with at least one animal lost pre-slaughter by journey duration. Batches that were transported for longer than 90 min had a significantly increased probability ($\chi^2 = 74.16$, $P < 0.001$) of having at least one animal lost pre-slaughter.

The relationship between animal losses and the slaughtering order of batches was analysed. Since the slaughtering order depends on the order of arrival at the slaughterplant, the aim of the analysis was to understand whether longer lairage is associated with increased pre-slaughter losses. The batches with lower slaughtering order (<12, i.e. those subjected to longer lairage times, since they arrived at the abattoir during the night before slaughtering) had significantly higher proportions of animal losses ($\chi^2 = 23.67$, $P < 0.001$, see Table 1). Similar results were obtained if the variable taken into account was the mean of animals lost pre-slaughter per batch or the rate of animals lost pre-slaughter per batch (Table 2). Differences were statistically significant also in this case (Mann–Whitney $U = 87225794$, $P < 0.001$; and Mann–Whitney $U = 87226022$, $P < 0.001$, respectively), with an increase in animal losses if slaughtering order was ≥ 12 .

Results concerning pre-slaughter losses in relation to stocking density during transport are shown in Tables 1 and 2. Unexpectedly, the percentage of batches with at least one animal lost pre-slaughter was significantly higher in animals that were transported at lower stocking densities ($\chi^2 = 7.59$; $P < 0.01$). The analysis of quantitative data (mean of animals lost pre-slaughter per batch or the rate of animals lost pre-slaughter per batch) confirmed significantly increased losses (Mann–Whitney $U = 87976426$, $P < 0.01$; and Mann–Whitney $U =$

87782870, $P < 0.001$, respectively) in batches transported at lower stocking densities (Table 2).

The results of the logistic regression analysis are reported in Table 3. The odds of a given batch to show at least one animal loss pre-slaughter were 1.32 times higher for batches slaughtered in summer season, 1.54 times higher if journey durations exceeded 90 min and 1.25 times higher for batches with a lower slaughtering order. The odds of a given batch to show at least one animal lost pre-slaughter was not significantly influenced by the stocking density.

Discussion

Pre-slaughter losses

During the survey, the yearly percentage of animal losses pre-slaughter varied between 0.042% and 0.070%. Such a value is considerably lower than the data collected in North-American studies, and lower than what has been observed in many European countries (as reviewed by Ritter *et al.* 2009). However, the percentage is in agreement with a recent Italian study (Vitali *et al.* 2014). If we exclude the incomplete data from Year 2009, overall pre-slaughter losses were consistent throughout the years of the survey and, on average, accounted for 0.050% of the animals received by the abattoir, varying between a minimum of 0.042% (302 pigs) in 2013 and a maximum of 0.056% (377 pigs) in 2010.

Losses occurred mostly during transport (animals found dead at unloading) and during lairage (animals found dead between unloading and slaughtering), whereas only a small number of pigs was euthanized by a veterinarian. It is worth noting that, although pre-slaughter handling (i.e. loading, transport and unloading) is recognised as one of the strongest stressor in a pig's life (Pérez *et al.* 2002; García-Celadrán *et al.* 2012), also lairage (especially when aggressions due to mixing occur) may raise considerable welfare concerns (Geverink *et al.* 1996; Brandt and Aaslyng 2015). A certain degree of contradiction exists among studies about the definition of optimal lairage duration (Salmi *et al.* 2012). Nevertheless, it is well known that inadequate treatment during lairage (e.g. group mixing, water and food deprivation, lack of environmental control, poor handling) may result in additional stress, and increase economic losses due to deaths, skin damage and poor meat quality (Pérez *et al.* 2002; Warriss 2003). Although in our study lairage conditions were not monitored, an increase in pre-slaughter losses was observed when pigs stayed overnight in lairage pens, which could indicate the existence of uncontrolled conditions that may have increased animal losses.

A strong relationship was found between season of the year and pre-slaughter losses, with an increase in losses during the summer months. The seasonal difference in the percentage of batches with at least one animal lost pre-slaughter was significant in years 2010, 2011 and

2013, but not significant in 2009 and in 2012. However, it should be considered that data for the year 2009 were incomplete, since they were collected only from the month of April onward and this excluded data collection from the cold months of January and February, limiting the effect of the cold season on the total losses. The increase in animal losses during the warmer months is in agreement with the literature, since many authors observed how hot temperatures, especially when combined with high relative humidity, impair the dissipation of body heat in pigs, increasing physical exhaustion and animal losses (Warriss and Brown 1994; Abbott *et al.* 1995; Barton Gade *et al.* 2007; Haley *et al.* 2008b; Schwartzkopf-Genswein *et al.* 2012; Nannoni *et al.* 2014; Vitali *et al.* 2014). In agreement with the cited literature, pre-slaughter losses reached a maximum in the month of August in our study. A further confirmation of the trend can be found if the yearly averages are considered in relation to the historical weather data for the geographic area of the slaughterhouse. In fact, average pre-slaughter losses reached 0.061% in the month of June, 0.070% in July and 0.082% in August. In July 2010, pre-slaughter losses peaked at 0.097%. Historical weather reports show that the summer of years 2009, 2011 and 2013 were characterised by particularly high temperatures (during summer, the following temperatures were recorded in the area of the slaughterhouse: in 2009, average 21.1°C, range 34.6–9.25°C; in 2010, average 19.8°C, range 32.7–7.4°C; in 2011, average 20.8°C, range 34.1–7.8°C; in 2012, average 20.6°C, range 34.4–7.1°C; in 2013, average 19.9°C, range 33.4–7.9°C; SCIA 2015), and these observations are in good agreement with the fact that, in 2011 and 2013, a significant increase in pre-slaughter losses during summer has been observed. In regard to year 2010, data show that July 2010 was one of the hottest months recorded in northern Italy (the mean temperature in the geographic area of the slaughterhouse exceeded the historical average temperature by 2.74°C, with the average of 25.3°C, range 37.2–12.9°C; SCIA 2015). Furthermore, in year 2010 (i.e. when the highest pre-slaughter losses were recorded), abundant precipitations were recorded in northern Italy, and the subsequently high relative humidity may have increased the discomfort experienced by animals transported in the hot season. Although information available on the effects of humidity at different temperatures on pig behaviour is scarce, according to Huynh *et al.* (2005), high humidity accentuates the effects of temperature on pig behaviour. Schrama *et al.* (1996) also observed that the combination of high temperature and high humidity reduces the ability of pigs to dissipate body heat effectively through radiative, convective or evaporative means.

However, it is worth noting that climatic factors may play differently across countries and that, for example, studies conducted in North America have highlighted increased transport losses during winter and autumn (Ritter *et al.* 2008; Sutherland *et al.* 2009).

In the present study, prolonged journey durations (i.e. exceeding 90 min) resulted in greater pre-slaughter losses. This finding is in agreement with what is described in the literature.

[Gosálvez *et al.* \(2006\)](#) observed that mortality and weight losses increased as distance increased, and found the more marked effects in journeys greater than 100 km. Similarly, [Sutherland *et al.* \(2009\)](#) found an increase in mortality when journey duration increased from 30 min to 4 h. However, it is worth noting that, according to [Werner *et al.* \(2007\)](#), if initial stress were reduced by good loading practices, subsequent stress during transport would be reduced as well. In their study, [Werner *et al.* \(2007\)](#) observed increased mortality rates both during very long (>8 h) and in very short (<1 h) transports, and suggested that during journeys between 1 and 8 h, animals may have time to recover from loading, whereas during longer journeys (more than 8 h), other factors (water and food deprivation, balancing movements, vibrations, temperature extremes) may compromise animal welfare, resulting in increased mortality rates.

The well known relationship between journey duration and pre-slaughter losses raises specific concerns in countries, such as Italy, where, in the past decades, pig slaughtering has gradually concentrated in a smaller number of large plants, likely resulting in longer average trip durations. This aspect should be kept in consideration for the development of future animal protection policies.

When regarding stocking density during transport, it is worth remembering that, in North America, some national and provincial guidelines take into account environmental temperature variation together with slaughter weight, although there is no firm agreement on how much loading densities should be reduced at warmer temperatures ([Schwartzkopf-Genswein *et al.* 2012](#)). At present, no similar guideline is available in Italy where, on the basis of European legislation ([EC 2005](#)), the loading density for pigs of ~100 kg should not exceed 235 kg/m². For pigs of 160-kg BW, this provision results in a stocking density of 0.681 pigs/m². However, it is acknowledged that an increase up to 20% of the minimum required surface area may be needed depending on the meteorological conditions and the journey time ([EC 2005](#)). In the present survey, loading density has been retrospectively defined as ‘high’ or ‘low’ on the basis of the number of pigs transported and the type of the truck. With this simple dichotomy, a reduction in pre-slaughter animal losses was observed at high loading densities. Such a result is in contrast with the literature, since most authors have found a positive correlation between stocking density and animal losses ([Barton Gade *et al.* 2007](#); [Ritter *et al.* 2007](#); [Fitzgerald *et al.* 2009](#); [Pilcher *et al.* 2011](#)). However, the aforementioned studies were conducted on pigs whose average BW did not exceed 130 kg, i.e. they were considerably lighter if compared with those involved in the present study. Conversely, [Haley *et al.* \(2008a\)](#) failed to find such a correlation when data were adjusted for temperature. It is

also worth noting that, according to Ritter *et al.* (2007), in pigs of ~130-kg BW, increased space allowance during transport resulted in reduced mortality only up to a certain threshold (i.e. 0.462 m²/pig), and no additional effect was observed when space allowance was further increased (0.489 and 0.520 m²/pig).

To the best of our knowledge, the relationship between loading density and transport losses in heavier pigs has never been investigated, and the only study dealing with transport losses in heavy pigs (Vitali *et al.* 2014) did not distinguish between the effect relative to stocking density during transport and during lairage. There is some evidence in the literature that providing pigs with too much space during transport to slaughter may have negative effects on welfare and meat quality, due to the fact that the animals can be thrown around and get struck and bruised as a result of unexpected movements of the lorry (Barton Gade and Christensen 1998). Moreover, if pigs can move around, they may be involved in confrontation and fights and this can cause muscular fatigue and glycogen depletion, making them prone to dark, firm, dry meat (Guàrdia *et al.* 2005). However, it is worth noting that, due to the fact that loading conditions were not surveyed in the present study, some confounding effects may have occurred. For example, in the present study, loading density was defined retrospectively on the basis of the number of pigs loaded on each truck. For this reason, low loading densities were recorded when fewer pigs were transported on a truck, regardless of their BW. Considering that pigs intended for Parma ham are generally slaughtered at a BW ranging from 155 kg to 176 kg, and that the stocking density required by law is expressed in kg/m², it is reasonable to expect that low-density transports may have involved heavier pigs, which are more susceptible to excessive metabolic responses when handled and transported (Ellis and Ritter 2005). However, it should be considered that the logistic regression analysis does not show a significantly increased risk of having at least one animal loss pre-slaughter due to the different stocking density.

Economic impact

In the present study, the economic impact of pre-slaughter losses was estimated on the basis of the number of carcasses that were condemned (i.e. on the kilograms of meat that was condemned and not used for human consumption), and amounted to 0.053% of the income arising from pig slaughtering. In other words, the value of pre-slaughter losses accounts for 0.13 € for each pig slaughtered. Considering a mean of 3158 animals slaughtered per day, the daily loss would be about 400 €. This value can represent a parameter for evaluating the cost-effectiveness of some interventions to reduce losses pre-slaughter (e.g. improvement of transport, reduction of lairage time).

When pre-slaughter welfare is suboptimal, there are also additional costs, besides deaths, which increase the economic losses (Ritter *et al.* 2009). First of all, bruised carcasses (especially in non-ambulatory pigs) may require extensive trimming, increasing both meat losses and the labour needed on the carcass. Second, slaughtering plants have additional costs for disposing carcasses and increased labour costs to move non-ambulatory pigs humanely. Last, it is well known that fatigued and exhausted pigs are in a metabolic state of acidosis. This metabolic condition may seriously affect pork quality, resulting either in pale, soft, exudative (PSE) or in dark, firm, dry (DFD) meats, depending on when the pig becomes fatigued during the marketing process (Fortin 2002; Carr *et al.* 2005; Ritter *et al.* 2009).

A further consistent loss of profit arises from the fact that Italian heavy pigs are intended for high economic-value productions (e.g. Parma ham). According to recent estimates, the average added value in the period 2009–2013 amounted to 0.42 € per kg of fresh Parma ham (De Roest *et al.* 2014).

Conclusions

The present study identified some risk factors associated with transport losses in heavy pigs and quantified the economic impact of pre-slaughter losses. Some risk factors were found to be similar to those described for lighter pigs (long journeys, high environmental temperatures), whereas other factors were less well documented in the literature (low density during transport, first batches slaughtered). Overall, the factors highlighted may be helpful in identifying critical points during transport and slaughtering procedures. It is noteworthy that most of the mentioned risk factors would not need specific surveys but could be monitored by analysing the transport and slaughtering data that are routinely collected by slaughterhouses and by the public veterinary services. It is, therefore, hoped that, similarly to what has been proposed for broilers (EC 2007), the evaluation of the outcomes of transport and lairage in terms of swine welfare will be included in the future legislation on the protection of pigs. Last, it could be interesting to conduct further research to assess the economic impact of animal losses along the entire production chain.

Manuscript received 22 December 2015, accepted 2 August 2016

Fig. 1. Frequency distribution of the absolute number of animals lost pre-slaughter per batch. The percentages are calculated within batches with at least one animal lost pre-slaughter.

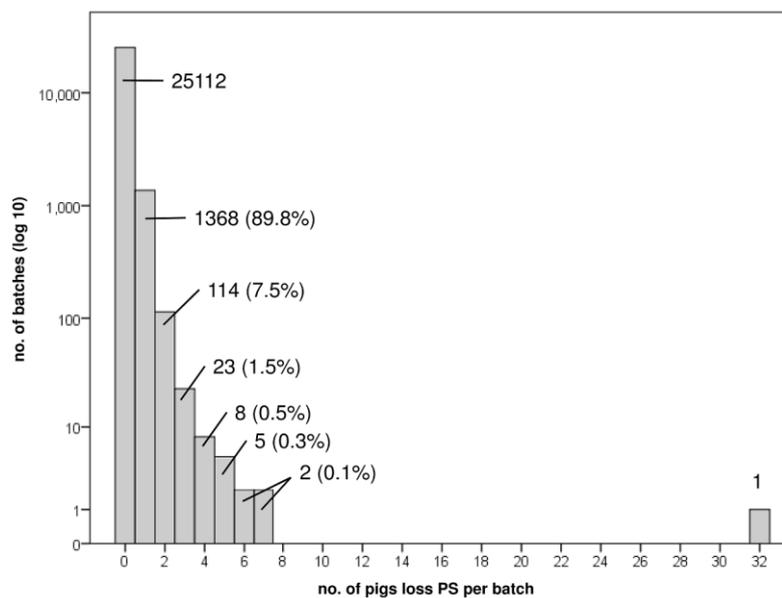

Fig. 2. Monthly average of the percentage of animals lost pre-slaughter (calculated on the whole number of animals received by the abattoir) during the entire survey.

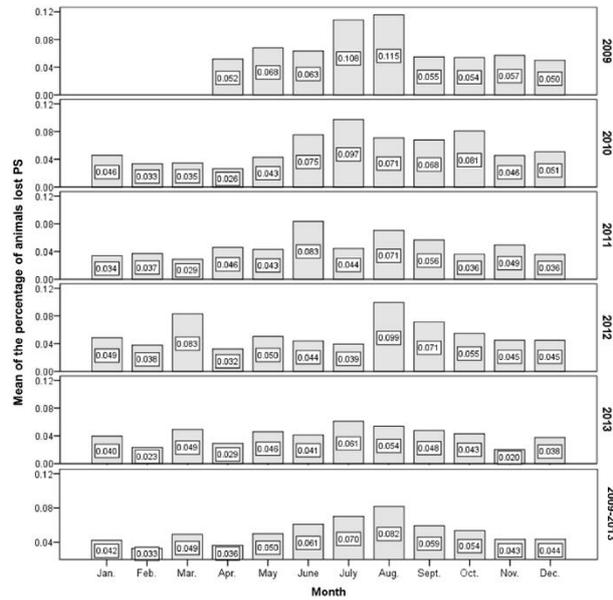

Fig. 3. Proportion of batches with at least one pig lost pre-slaughter by season or by year. Asterisks indicate the presence of significant ($P < 0.05$) seasonal differences within the year.

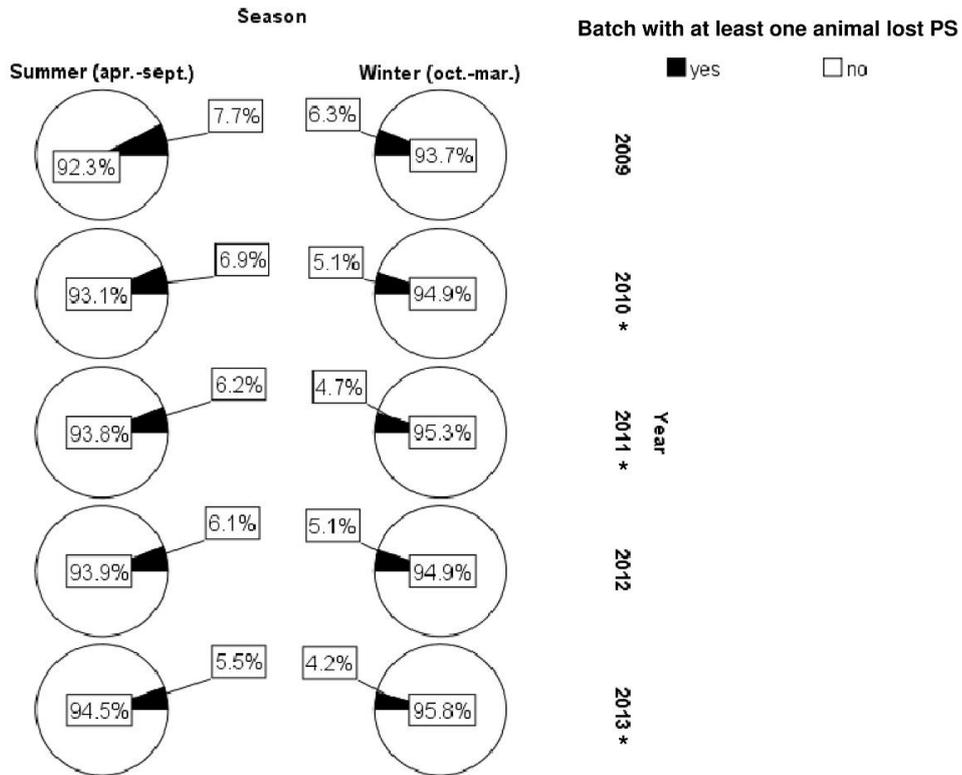

Table 1. Number of batches as a function of season, journey duration, slaughtering order and density during transport

Slaughtering order: a progressive number attributed to every batch on arrival. Lower values correspond to batches of pigs that reached the slaughterhouse on the day before slaughtering, spending the night in lairage and being the first slaughtered on the day after their arrival. Stocking density during transport was dichotomised according to median animal numerosity. Batches of ‘high density during transport’ were defined as all batches of more than 71 pigs transported by the same trailer or all batches of more than 140 pigs (in this case a second trailer was used)

Parameter	Parameter state	Batches with at least one animal lost PS (%)			<i>P</i> -value
		Yes	No	Total	
Season	Summer (Apr.–Sept.)	886 (6.5)	12 848 (93.5)	13 734	<0.001
	Winter (Oct.–Mar.)	637 (4.9)	12 264 (95.1)	12 901
