Conclusion: Multiphasic DECT iodine quantitation over time is significantly different between cirrhotics and non-cirrhotics, correlates with MELD score, and it could serve as a non-invasive measure of cirrhosis and disease severity with high diagnostic accuracy.
Limitations: Retrospective study.
Ethics committee approval: IRB and HIPAA-compliant study.

Quantification of local 3D texture maps for detection of fibrosis in the liver

W. Hamilton[1], S. Carey[1], B. E. Hoppel[2], Z. Afraz[1], P. Rogalla[1]; [1]*Toronto/CA,* [2]*Vernon Hills, WI/US (william.hamilton@uhn.ca)*

Purpose: To develop a method for detection and staging of liver fibrosis from low-dose single-energy CT by quantifying spatial distributions of local 3D texture maps.
Methods and materials: 33 patients who underwent a four-phase liver CT were categorised as having healthy (F0 and F1) or fibrotic livers (F3 and F4). Spherical ROIs, radius 20mm, were extracted from each liver. The ROIs were selected from regions close to the liver surface, avoiding major vessels and lesions. To simplify patterns in tissue structure, a Gaussian filter was applied to each ROI before binning gray levels using k-means clustering with k=20. Local 3D texture maps were produced from each binned ROI using the PyRadiomics library. The maps were computed voxel-wise for spherical subsets of 5-voxel radius. As a proof of concept, features were extracted from local 3D variance maps only. To quantify the spatial distributions of the features as they varied across each map, entropy, variance, gray level run length, and size zone matrices were computed from each local variance map.
Results: The mean entropy, variance, run length non-uniformity, and zone size variance for healthy (SD)/fibrotic (SD) livers are 0.200(0.247)/0.392(0.440), 0.071(0.087)/0.121(0.160), 1700.68(1410.26)/548.071(186.141), 0.267(0.366)/0.027(0.029), respectively. Kruskal-Wallis tests demonstrate significant differences between distributions of healthy and fibrotic livers for run length non-uniformity (U=7.456, p=0.006), however distributions of variance (U=0.938, p=0.333), entropy (U=0.926, p=0.336), and zone size variance (U=2.370, p=0.123) did not demonstrate significant differences.
Conclusion: Our novel approach shows promise for quantification of fibrosis in the liver and circumvents the need for objective comparison of parameter-sensitive texture features, which suffer from poor interpatient standardisation. Run length non-uniformity may represent the leading feature for separating healthy from fibrotic livers.
Limitations: Number of livers analysed.
Ethics committee approval: Research ethic board approval.

Liver vein to cava attenuation: a simple parameter to increase predictive value of caudate-right lobe ratio and liver segmental volume ratio to detect significant liver fibrosis on abdominal CT scans

J. Hrycyk, V. C. Obmann, C. Marx, W. Kajdi, D. Catucci, A. Berzigotti, L. Ebner, A. Christe, A. T. Huber; *Berne/CH (joris.hrycyk@insel.ch)*

Purpose: To investigate incremental value of liver vein to cava attenuation (LVCA) in combination with caudate-right lobe ratio (CRL-R) and liver segmental volume ratio (LSVR) to predict significant liver fibrosis on portal venous phase abdominal CT scans.
Methods and materials: 212 patients were retrospectively included: 107 consecutive patients with liver biopsy and portal venous phase abdominal CT within 6 months and 105 patients without liver fibrosis, based on liver MR elastography (<2.8 kPa). The patients were grouped into patients with clinically significant fibrosis (73 patients with fibrosis grade 2-4 in histology) and patients without clinically significant fibrosis (139 patients, 34 with fibrosis grade 0-1 and

105 patients without liver fibrosis based on MR elastography). CRL-R and LSVR were calculated alone and multiplied with LVCA (1: liver veins hyperdense, 2: isodense, 3: hypodense compared to vena cava, 4: liver veins not contrasted). Resulting scores were called liver imaging morphology and attenuation based fibrosis score (LIMA) and liver segmental volume and attenuation ratio (LSVAR). ROC-analysis was performed.
Results: LVCA-enhanced LIMA fibrosis score and LSVAR (AUC 0.76 and 0.80, p<0.001) performed better than CRL-R and LSVR (AUC 0.72 and 0.76, p<0.001). Simple LIMA fibrosis score showed similar performance as liver volumetry based LSVR, requiring time-consuming image post-processing.
Conclusion: LIMA fibrosis score, as a combination of LVCA and CRL-R, showed better performance than CRL-R alone and similar performance than time-consuming LSVR. LSVAR, as a combination of LVCA and LSVR was the overall best predictor for significant liver fibrosis.
Limitations: A limitation of the present study is its retrospective nature.
Ethics committee approval: An agreement of the local ethics commitee of Bern, Switzerland, was obtained.
Funding: No funding was received for this work.

Quantitative measurement of hepatic fibrosis on gadoxetic acid–enhanced magnetic resonance imaging in patients with chronic liver disease: multicentre study
Y. R. Kim[1], Y. H. Lee[1], D. M. Kang[1], M. J. Kim[1], T.-H. Kim[1], K. W. Kim[2], Y. Y. Jeong[3], K.-H. Yoon[1]; *[1]Iksan/KR, [2]Seoul/KR, [3]Jeonnam/KR (sweetynn@naver.com)*

Purpose: The aims of this study were to compare coefficient of variation (CV) in MR hepatobiliary image and serum biomarkers such as aspartate aminotransferase to platelet ratio index (APRI) and fibrosis-4 index (FIB-4) values according to the histopathologic fibrosis score, to identify the diagnostic performance of CV map in diagnosing hepatic fibrosis.
Methods and materials: This study was a prospective multicenter study which included 71 patients who underwent liver MRI using gadolinium EOB-DTPA and liver biopsy or surgery. Patients were divided into 4 groups according to the liver fibrosis score; Group 1 (F0, 1), Group 2 (F2), Group 3 (F3), Group 4 (F4). To quantitatively measure the hepatic fibrosis, a hepatobiliary image was analysed to identify inhomogeneous signal intensities calculated from CV map in the liver parenchyma. We also evaluated the comparison study of among CV, APRI, and FIB-4. The diagnostic performance of the CV map for fibrosis and cirrhosis was evaluated using ROC curve.
Results: Mean CV values in each group were Group 1 (n=18): 3.50±0.36, Group 2 (n=8): 4.09±0.50, Group 3 (n=21): 4.45±0.70, and Group 4 (n=30): 5.49±1.12, respectively (p<0.001). Mean FIB-4 values were Group 1: 1.19±1.20, Group 2: 3.36±2.74, Group 3: 3.38±3.12, and Group 4: 4.86±3.39, respectively (p=0.001). Area under curves of CV values on ROC analysis were 0.930 for significant fibrosis, 0.874 for cirrhosis (p<0.001, respectively).
Conclusion: CV value based on hepatobiliary MR image provides accurate discrimination of hepatic fibrosis with reliable measurements and demonstrates high diagnostic performance.
Limitations: Small study populations. Various MR vendors/protocols.
Ethics committee approval: Approved by the institutional review board.

RPS 601c-6 11:45
Functional liver imaging score derived from gadoxetic acid-enhanced MRI predicts outcomes in patients with chronic liver disease
L. Beer, N. Bastati-Huber, M. Mandorfer, S. Pötter-Lang, Y. Bican, G. Semmler, B. Simbrunner, T. Reiberger, A. Ba-Ssalamah*; Vienna/AT (lucian.beer@meduniwien.ac.at)*

Purpose: The aim of the study was to investigate the accuracy of the gadoxetic acid-enhanced MRI based functional liver imaging score (FLIS) in predicting hepatic decompensation and transplant-free survival (TFS) in patients with chronic liver disease (CLD).
Methods and materials: 265 with CLD met the inclusion criteria of this retrospective study. Those patients were retrospectively assigned a FLIS based on the sum of three hepatobiliary-phase features, each scored on an ordinal 0-2 scale: enhancement, excretion, and portal-vein-sign. FLIS scores of 0-3 and 4-6 indicate impaired and preserved liver function, respectively. Patients were further stratified into three groups: non-advanced CLD (non-ACLD); compensated advanced CLD (cACLD); and decompensated advanced CLD (dACLD). The predictive value of FLIS for first and/or further hepatic decompensation and for TFS was investigated using Kaplan-Meier analysis, log-rank tests, and Cox-regression.
Results: Intraobserver (correlation-coefficient κ=0.983; 95% confidence-interval [CI]:0.971-0.991) and interobserver (κ=0.931; 95%CI: 0.898-0.954) agreement for FLIS was excellent. In patients with cACLD, the FLIS was independently predictive of a first hepatic decompensation (adjusted-hazard-ratio, [aHR]: 3.72,95%CI: 1.1-12.64; P=.04), but not for further hepatic decompensations in patients with dACLD (aHR:1.43, 95%CI:0.92-1.94, P=.17). The FLIS was an independent risk factor for mortality in both patients with cACLD (aHR:7.44, 95%CI:2.74-20.17, P<.001) and those with dACLD (aHR: 3.84, 95%CI:1.16-9.48; P=.004).
Conclusion: A simple gadoxetic acid-enhanced MRI-derived FLIS can identify patients with advance chronic liver disease at increased risk for hepatic decompensation and mortality.
Limitations: Single-centre study.
Ethics committee approval: Approved by the Ethics Committee of the Medical University of Vienna.

RPS 601c-7 11:51
Multi-parameter magnetic resonance imaging for staging liver fibrosis and detecting macrophage polarisation
Y. M. Lu, D. Wang*; Shanghai/CN (lym1007@sjtu.edu.cn)*

Purpose: To evaluate MRI T1 and T1ρ mapping with calculation of extracellular volume (ECV) for diagnosis and grading of liver fibrosis, and to explore correlation between those parameters and macrophage polarisation in a rat model.
Methods and materials: Different degrees of fibrosis were induced in 60 male Sprague-Dawley rats by bile duct ligation (BDL) and carbon-tetrachloride (CCl4) injection. Liver fibrosis was graded by Sirius red and α-smooth muscle actin staining. The native T1 values, Tρ values, and ECV were assessed by using quantitative MRI mapping techniques at 11.7T. The METAVIR system was used for the staging of fibrosis. Expressions of M2-related factors were analysed with RT-PCR and immunohistochemistry.
Results: The T1 values in liver cirrhosis (F4) and significant fibrosis (≥ F2) after BDL were greater than in control animals (1246msec±52 vs 1124±34msec vs 1066±63, respectively, P<.001); T1ρ values in liver cirrhosis and significant fibrosis after BDL were also greater than in control animals (66.53±5,64 vs 37.76±6.48 vs 29.68±3.22, respectively, P<.001); ECV was greater in liver cirrhosis and significant fibrosis after BDL compared with control animals (33.6%±2.5 vs 26.03%±3.8 vs 16.65%±2.9, respectively; P< .001). Analogous T1, T1ρ, and ECV results were observed after CCl4 injection. Middle and high correlations were found between native T1, ECV and the expression of CD204, IL-10 and TGFβ1.

Conclusion: T1, T1ρ values, and ECV may be accurate methods for noninvasively assessing liver fibrosis. Elevation of T1 and ECV was associated with macrophage M2 polarisation.
Limitations: We didn't discuss the impact of other pathological factors to those paremeters.
Ethics committee approval: Approved by the Institutional Animal Care and Use Committee of Xinhua Hospital affiliated to Shanghai Jiao Tong University School of Medicine.
Funding: No funding was received for this work.

RPS 601c-8 11:57

Multiparametric MRI for activity grading and staging of hepatic fibrosis: role of T2-mapping, multi-gradient-echo MRI, and MR elastography

S. M. Skawran, H. Honcharova-Biletska, S. Blümel, D. Segna, C. Jüngst, A. Weber, C. Gubler, C. S. Reiner*; Zurich/CH*

Purpose: To evaluate whether T2-mapping, multi-gradient-echo-sequence, and MR-elastography (MRE) can diagnose activity grade and stage of hepatic fibrosis.
Methods and materials: 61 patients with suspicion of hepatic fibrosis undergoing MRI at 3.0T - including T2-mapping, multi-gradient-echo-sequence for proton-density-fat-fraction (PDFF), and MRE - and liver biopsy between 2015 and 2019 were prospectively analysed. ROIs were placed in the liver in the corresponding maps. Patients with probable iron overload were excluded (R2*>100s-1). Histologic inflammatory activity grading and fibrosis staging systems were applied according to underlying etiology and unified yielding activity grades G0-3 and fibrosis stages F0-4. The cohort was split into steatohepatitis (n=24) and all other etiologies (n=37). Descriptive statistics and ROC-analysis were performed.
Results: In the steatohepatitis group, PDFF was significantly higher in G2-3 vs G0-1 (p=0.02) with an AUC=0.779. T2-values were not significantly different between grades (p=0.06). Stiffness was significantly higher when any fibrosis was present (p=0.008) with an AUC=0.887. T2-values (p=0.84) and PDFF (p=0.84) were not significantly different across F0-F4. In the general fibrosis group, PDFF and T2-values were similar across G0-3 (p=0.81; p=0.10) and F0-F4 (p=0.17; p=0.06). Stiffness was significantly higher when any fibrosis was present (p=0.02) with an AUC=0.827 and for clinically relevant fibrosis (F2-4 vs. F0-1: p<0.001) with an AUC=0.846.
Conclusion: PDFF may serve as a marker for activity of steatohepatitis. MRE can identify fibrosis in steatohepatitis and in other etiologies of fibrosis. An independent role for T2-mapping could not be established.
Limitations: T2-mapping is susceptible to fat deposition, which might explain the limited value in our cohort. Whether it might have a role in a multiparametric model will be subject to further research.
Ethics committee approval: Prospective study approved by local ethics committee. Patients gave written informed consent.
Funding: No funding was received for this work.

RPS 601c-9 12:03

Evaluation of liver fibrosis and cirrhosis on the basis of T1 mapping considering acute inflammation, age, and liver volume as confounding factors

C. Breit, D. Boll, D. J. Winkel, M. Henkel, T. Heye*; Basel/CH*

Purpose: To evaluate confounding factors for the assessment of liver fibrosis by T1 mapping.
Methods and materials: 200 patients who underwent routine abdominal MRI at 1.5T and 3T scanners were retrospective included. 93 patients were defined as healthy based on the information of the hospital information system, 40 patients showed acute elevation of liver and bile parameters, and 67 subjects had a clinically or biopsy proven liver fibrosis or cirrhosis. A ROI based analysis of the T1 maps of the liver was performed. Additionally fat fraction, R2*, liver volume, laboratory parameters, sex, and age were regarded as potential confounding factors. Fibrosis was staged by using the Child-Pugh score and the METAVIR score.
Results: There was a significant difference at 1.5T between T1 values in patients without known fibrotic changes and normal laboratory parameters (574.8+/-56ms) and those with elevated liver enzymes and bile levels (657.4+/-73ms) or known fibrotic liver disease (643.8+/-83 ms). At 3T the T1 values for patients with liver fibrosis or cirrhosis (995+/-150.3ms) were significantly higher than for the healthy group (870+/-128ms) and not significantly higher than for patients with laboratory abnormalities (952.4+/-137ms). There was a significant, moderate positive correlation between T1 values and the Child-Pugh stage at 1.5T (ρ=0.38, p=0.0112) and a non-significant, moderate positive correlation at 3T (ρ=0.3, p=0.26). There was no correlation between age and T1 values at 1.5T and 3T.
Conclusion: T1 mapping is a reasonable method for the detection of liver fibrosis and cirrhosis. Age is no confounding factor hence age independent thresholds can be defined. Acute liver diseases are a confounding factor that need to be regarded.
Limitations: Retrospective study with potential selection bias.
Ethics committee approval: Informed consent waived.
Funding: No funding was received for this work.

RPS 601c-10 12:09

T1 relaxation times of the liver and spleen to predict significant liver fibrosis: is there an additional value of normalisation to the blood pool?

V. C. Obmann, A. Christe, A. Berzigotti, J. T. Heverhagen, L. Ebner, C. Gräni, A. T. Huber*; Berne/CH (adrian.huber@me.com)*

Purpose: To analyse liver and spleen native T1 relaxometry values to predict significant fibrosis and their additional value when normalised to the blood pool.
Methods and materials: 156 patients without solid liver lesions on routine liver multidetector CT scans underwent liver MRI with gradient-echo based MR elastography (MRE) and shortened modified Look-Locker inversion recovery (shMOLLI) based T1 relaxometry. T1 relaxation times were measured in the right liver lobe and in the spleen, in the aorta and in the vena cava. MRE liver stiffness was compared with T1 relaxation times alone, as well as T1 relaxation times normalised to the blood pool in the vena cava and in the aorta. Pearson correlation, students t-test, and receiver operation characteristics (ROC) analysis were used to investigate the usefulness of different T1 relaxometry values to predict significant liver fibrosis, using a cutoff value of 3.5kPa in MRE.
Results: Correlation between T1 relaxometry values and MRE liver stiffness was r=0.49-0.59 (p<0.001) for T1 of the liver and for T1 of the liver normalised to blood pool, while T1 of the spleen was less useful (r=0.11-0.17). Both normalised and not normalised T1 values of the liver allowed to significantly separate patients with significant liver fibrosis from those without significant liver fibrosis (p<0.001). In ROC-analysis, T1 relaxometry values normalised to the blood pool did not perform better than T1 values alone.
Conclusion: Native T1 relaxation times of the liver allowed to predict clinically significant liver fibrosis, while T1 relaxation times of the spleen were less useful. There was no additional value of liver and spleen native T1 relaxometry values to predict significant fibrosis when normalised to the blood pool.
Limitations: Retrospective design. MRE as non-invasive gold-standard, no histology.
Ethics committee approval: Yes.
Funding: No funding was received for this work.

RPS 601c-11 12:15

Iron measurement by quantitative MRI-R2* at 3.0T and 1.5T

J. Yamamura[1], S. Keller[1], R. Grosse[1], B. P. Schönnagel[1], Z. J. Wang[2], P. Nielsen[1], R. Fischer[3]*; [1]Hamburg/DE, [2]Dallas, TX/US, [3]Oakland, CA/US (j.yamamura@uke.de)*

Purpose: To investigate the suitability of a 3.0T imager for iron measurements in comparison to 1.5T in the liver.
Methods and materials: Patients with transfusional siderosis, hereditary hemochromatosis, DBA, and controls (n=249) underwent a MRI-R2* at 1.5T and 3.0T. In patients with severe liver iron burden (LIC>2000 µg/g_{liver}), shorter echo times were used (TE=0.65). In-vivo LIC was determined from the specific hemosiderin/ferritin magnetic susceptibility as non-invasively measured by SQUID. R2* was determined from a mono-exponential fit with constant signal level offset.

Results: In patients, LIC ranged from 130 to 9700 µg/g_{liver} and in controls from 176 to 377µg/g_{liver}. At 1.5 and 3.0T, R2*ranged from 31-2236s^{-1} and from 41-2344s^{-1}, respectively. From a direct comparison between R2* at 3.0T and 1.5T, a non-linear relationship was found between R2*(3T) and R2*(1.5T) due to the higher relaxivity at 3T. Below R2*(1.5T) < 600 s^{-1}, a linear relationship with a ratio of R2*(3.0)/R2*(1.5T) = 1.85±0.04 could be obtained in contrast to expected ratio of 2:1. In order to overcome the saturation effect of the 3T relaxivity for severe liver iron overload, one has to put constraints on the signal amplitude.
Conclusion: For liver iron measurements in patients with LIC>3000µg/g_{liver} or >18mg/$g_{dry\ weight}$, 1.5T imagers are better suited than 3.0T unless ultrashort echo times can be used. For R2* rates below that level, 3.0T systems with 3D data acquisition are more advantageous.
Limitations: Realtively small sampling size. In the future, this result must be further studied in a multi-centre study.
Ethics committee approval: Informed consent was obtained from all participants before examination and the local IRB approved the study.
Funding: No funding was received for this work.

Quantitative MRI characterisation of NASH in a dietary rodent model
M. Dioguardi Burgio[1], P. Garteiser[2], F. Julea[2], A. Abyzov[2], V. Paradis[1], V. Vilgrain[1], B. van Beers[1]; [1]Clichy/FR, [2]Paris/FR (marco_dioguardi@hotmail.it)

Purpose: To assess the diagnostic performance of quantitative MRI parameters for the diagnosis of early non-alcoholic steatohepatitis (NASH) in a dietary rodent model.
Methods and materials: We included 74 mice (C57bl6) with 2 control groups fed with normal diet (for 5 and 17 weeks, N=7), 3 dietary groups (5, 11, and 16 weeks, N=10) fed with high fat diet deficient in choline and supplemented with methionine and 3 dietary groups (5, 11, and 16 weeks, N=10) fed with high fat diet. The liver was scanned with a 7T system. Proton density fat fraction (PDFF), R2*, mechanical properties at 400, 600, and 800Hz including storage modulus (G'), loss modulus (G''), damping ratio, shear modulus (G*), and G* frequency dispersion coefficient were obtained with dedicated imaging sequences. At histopathology, the grade of steatosis, ballooning, inflammation, and the fibrosis stage were assessed. NASH was diagnosed according to the FLIP algorithm. ROC analysis, Spearman correlations, and multivariate regression were used to test the variables.
Results: 19 mice had NASH including 15 with stage 1 fibrosis. 32 had simple steatosis. G'' at 400Hz had the largest AUROC for NASH (0.84; p<0.01) and for diagnosing NASH versus simple steatosis (0.80; p<0.01). Cutoff of G''>0.38 kPa had 89% sensitivity and 79% specificity for NASH diagnosis. PDFF correlated with steatosis (rho 0.81; p<0.01). At multivariate analysis, inflammation was the main determinant of the frequency dispersion coefficient.
Conclusion: At quantitative MRI, the loss modulus had the best diagnostic performance for diagnosing early NASH. Frequency dispersion coefficient might be a marker of liver inflammation.
Limitations: Use of two different high fat diets might be a source of bias.
Ethics committee approval: Animal board approval was obtained.
Funding: No funding was recieved for this work.

The use of AI-based applications in radiology and the liability of the medical practitioner: a law and economics analysis of the incentives towards automation in diagnosis
A. Bertolini[1], G. Vatteroni[2], F. Episcopo[1], A. Chiti[3], L. Balzarini[2]; [1]Pisa/IT, [2]Milan/IT, [3]Pieve Emanuele/IT (andrea.bertolini@santannapisa.it)

Purpose: To assess the impact on the radiologist's behaviour of the diffusion of different AI-based imaging technologies (AIT), taking into account civil liability rules.
AIT increase cooperation between man and machine in diagnosis, allowing greater precision in lesion detection or reducing the involvement of the practitioner in the analysis of clearly negative cases. Machines possess some degree of autonomy, often supervised by the human user, in the assessment of the case. From a legal perspective, this entails a possible new apportionment of civil liability between (i) the medical practitioner, (ii) the manufacturer/programmer, and (iii) the hospital/structure that decided to adopt the given AI-based solution.
We intend to show how liability would be apportioned and what incentives this provides to radiologists in using specific AITs.
Methods and materials: Being a law and technology study, we began by providing a description of the specific applications considered, focusing on (a) the level of automation the system displays, (b) the possibility for it to adopt decisions (e.g. rule out what appears to be a certainly negative case), (c) its declared overall precision, and (d) the role of the human user.
The liability apportionment analysis was performed according to the principles of micro-comparative law, taking into account the European legal system and theoretical law and economics (game theory).
Results: By taking into account the different AIT, we will describe how liability is apportioned between the mentioned parties involved (i, ii, iii above).
Conclusion: The awaited liability apportionment affects the behaviour of the radiologist, in particular, the tendencies towards (1) using the application, (2) relying on its output, and (3) diverging from its conclusion, eventually leading to some defensive-medicine approaches.

Attitudes and perceptions of UK medical students towards artificial intelligence and radiology: a multicentre survey
D. S. Poon, C. Sit, A. Azam, A. Amlani, K. Muthuswamy, R. Srinivasan, L. Monzon; London/UK (daniel.poon@kcl.ac.uk)

Purpose: To explore the attitudes of UK medical students regarding AI, their understanding, and career intention towards radiology. We also examined the state of education relating to AI amongst this cohort.
Methods and materials: Students from UK medical schools were invited to complete a survey consisting of Likert and dichotomous questions.
Results: 484 responses were received from 19 UK medical schools. 88% of students believed that AI will play an important role in healthcare and 49% reported they were less likely to consider a career in radiology due to AI. 89% of students believed that teaching in AI would be beneficial and 78% agreed that students should receive training in AI as part of their medical degree.

Only 45 students received any teaching on AI; none received such teaching as part of their compulsory curriculum. Students that received teaching in AI were more likely to consider radiology (p=0.01). Despite this, a large proportion of students in the taught group reported a lack of confidence and understanding required for the critical use of healthcare AI-tools.
Conclusion: UK medical students understand the importance of AI and are keen to engage. Medical school training of AI should be improved. Realistic use-cases and limitations of AI must be presented to students so they will not feel discouraged from pursuing radiology.
Limitations: Not all UK medical schools were represented in the current study and response rates differed between different institutions, potentially introducing bias. Associated limitations relating to survey-based observational studies would apply. For example, potential misunderstanding or misintrepretation of questions by the respondents.
Ethics committee approval: Minimal risk ethical approval was obtained from the King's College London research ethics office (KCL-MRA18/19-11127).
Funding: No funding was received for this work.

The impact of artificial intelligence on the choice of radiology as a medical speciality by undergraduate medical students

G. Irene Brandes Garcia, A. Azzolini, U. Dos Santos Torres, E. A. S. Bretas, G. de Souza Portes Meirelles, G. D`ippolito*; Sao Paulo/BR (azzolini.anderson@gmail.com)*

Purpose: To evaluate the impact of artificial intelligence on the choice of radiology as a medical specialty by undergraduate medical students.
Methods and materials: In February 2019, an anonymous online survey was sent to Brazilian medical students from the city of São Paulo. The research contemplated questions such as how much students think they know about artificial intelligence (AI) technologies, how much AI discourages them from choosing radiology as a speciality, and if they believe that radiologist's job market is threatened.
Results: A total of 101 students answered the questionnaire, most enrolled in the internship years. More than half (52.5%) believed that the labour market for radiologists is threatened by AI and, even more surprisingly, among those students that had once considered radiology as a career, almost half (42.3%) discarded the speciality mainly due to the development of AI. At the same time, the majority of the overall participants (64.3%) claimed not to have good knowledge about these new technologies.
Conclusion: An expressive part of medical students believe that AI is a threat to the radiological practice and this perception may have an impact on their career choice. However, the majority claim to have insufficient knowledge about it.
Limitations: The main limitations of our study were the small number of participants, the fact that the students were from only one city, and that the majority of them were from the same university.
Ethics committee approval: This research was not registered on ethical boards since it was based on a voluntary online questionnaire and anonymity was reassured.
Funding: No funding was received for this work.

How do expectations and attitudes towards artificial intelligence applications differ between radiologists and IT experts?

F. Jungmann, T. Jorg, R. Natalie, C. Düber, J. Stefanie, P. Mildenberger*; Mainz/DE*

Purpose: To investigate the opinion of radiologists and IT experts on artificial intelligence (AI) and its future impact on radiological work.
Methods and materials: During a national meeting for AI, eHealth, and IT-infrastructure in 2019, a survey was conducted to obtain the participants' opinion on AI in radiology. 131 participants (42 radiologists, 89 IT experts/non-radiologists) took part in the survey. A 7-point Likert scale (1: "I disagree at all" to 7: "I totally agree") was used to assess the views of radiologists, IT experts in hospitals, and healthcare companies.
Results: All participants agreed that medicine will become more efficient with the use of AI (5.98) and that plausibility checks will be important to be able to understand the decisions of the AI (6.30). All participants stated that the validation of AI algorithms in clinical studies is mandatory (6.32).
Radiologists rated the statement that AI will lead to a change in the working environment of all physicians significantly higher than non-radiologists (6.38 vs. 5.85, p=.04). The need to inform patients about the use of AI (4.12 vs. 5.2, p=.009) was rated significantly lower among radiologists.
Conclusion: Radiologists and IT experts share various attitudes regarding future use on AI, especially with regard to the improvement in medical care and the need to validate algorithms in clinical studies. The views of radiologists and IT experts differ on some specific issues, such as the impact of AI on physicians' work and whether patients need to be informed prior to the use of AI.
Limitations: Not all participants of the meeting participated in the study, so a selection bias is possible.
Ethics committee approval: n/a

A European-wide needs assessment to prioritise technical procedures for simulation-based education in radiology

L. Nayahangan[1], E. Albrecht-Beste[1], L. Konge[1], B. Brkljacic[2], C. Catalano[3], B. B. Ertl-Wagner[4], K. Riklund[5], M. B. Bachmann Nielsen[1]*; [1]Copenhagen/DK, [2]Zagreb/HR, [3]Rome/IT, [4]Munich/DE, [5]Umeå/SE (leizl.joy.nayahangan@regionh.dk)*

Purpose: To identify and prioritise technical procedures that should be included in future simulation-based curricula for radiology trainees.
Methods and materials: A three-round Delphi process was initiated among key leaders chosen according to their leadership and educational role in the European Society of Radiology. Delphi round 1 identified all potential technical procedures that newly qualified radiologists should be able to perform. Round 2 explored and prioritised the procedures by investigating the frequency of procedures, the number of radiologists that should be able to perform the procedure, the feasibility for simulation training, and the risk and/or discomfort when performed by an inexperienced radiologist. Round 3 was an elimination and final ranking of the procedures. A consensus criterion of 2/3 was set a priori for inclusion in the final list.
Results: 71 key leaders across 27 countries agreed to participate and responded to round 1. Response rates for rounds 2 and 3 were 72% (51/71) and 82% (42/51), respectively. Round 1 identified 719 procedures; these were reduced to 34 procedures after removing duplicates and non-technical skills. In the final round, 8 procedures were eliminated, resulting in a final prioritised list of 26 technical procedures for simulation. The top 3 procedures include basic ultrasound (probe selection, image optimisation, and technical performance), ultrasound of the upper abdomen, and ultrasound of the kidneys, retroperinuem, abdominal wall, intestines, appendix, urinary bladder, pelvis, and scrotum.
Conclusion: This European-wide needs assessment promotes the development of simulation-based training programs targeted at current training needs. The prioritised list of technical procedures should guide the planning of future simulation-based education of radiology trainees.
Limitations: Although 27 countries participated, the selection process did not guarantee equal representation from every country.

Medicine in the digital age: artificial intelligence in medical education

F. Jungmann, K. Deutsch, S. Kuhn*; Mainz/DE*

Purpose: To introduce a curricular course for medical students which addresses artificial intelligence (AI) in medical education for the first time.
Methods and materials: "Medicine in the digital age" represents an interdisciplinary course in medical school that is taught in 5 modules on digital topics such as medical apps, augmented reality, big data, individualised medicine, and AI.
The course was held in 3 consecutive terms. All 32 participants were questioned in focus groups using guideline interviews. The questions of the guideline were first formulated structurally and then in terms of content, from which the 3 interview focuses emerged: fields of applications of AI, Work 4.0, and critical reflection. The interviews were evaluated using qualitative content analysis according to Philipp Mayring.
Results: 47% of the students' statements could be assigned to Work 4.0, 31% to critical reflection, and 22% to fields of application of AI. Within the category Work 4.0, the topic human-machine interaction accounted for the largest share of statements with 56%. The fears and worries of the students concerning AI played only a minor role with 12% of the statements in this category. The category critical reflection describes a holistic view of medicine in the digital age on the level of social abstraction and self-reflection (e.g. practical implementation, ethics).
Conclusion: The course conveys the knowledge of digital tools, the acquisition of skills, and the development of an attitude towards AI. The students become aware of the process of change through the increasing digitalisation and recognise the necessity to acquire new competencies for their future.
Limitations: Currently, the course is offered within the scope of the compulsory elective week. An expansion for all students is the aim.
Ethics committee approval: n/a
Funding: No funding was received for this work.

How scientific mobility can help the future of radiology research: a radiology trainee's perspective

F. Pesapane*; Milan/IT (filippopesapane@gmail.com)*

Purpose: To provide a perspective of radiology fellows about the current trends and policy tools for promoting mobility among young radiologists, especially in the EU and USA.
Methods and materials: Evidence-based medicine requires multicentre collaboration to identify a best practice, standardise it, and share it. Mobility helps to uniform techniques and terminology in different countries, which are crucial to develop widely-shared guidelines.
Results: While the EU has many talented and skilled researchers, they account for a significantly lower share of the labour force than is the case in the USA.
Given advances in communication technology, a core group of networked researchers may go a long way towards helping a country with modest scientific resources achieve the analogue world-class excellence of the richest countries, in a broader win-win situation. However, these new avenues will require strong leadership and enhanced institutional autonomy. International organisations such as the ESR and RSNA can play a role to involve local centres into global science projects. With the help of these societies, a radiology trainee can easily take advantage of the international training opportunities that are currently offered by public or private grants, enhancing the scientific mobility and the cooperation among research centres of different countries.
Moreover, the cultural-knowledge and the networks developed during mobility can be used by the trainees to advance their career.
Conclusion: Today, it is not just being a certified radiologist that matters, the place where training is held plays a role when applying for a high-level position. Mobility of trainees is an indispensable prerequisite to facing new challenges, including the application of artificial intelligence to medical imaging, which will require a large multicentre collaboration.
Limitations: n/a

Resident quality control (RQC): introducing a new method for monitoring residents' progress, strengths, and weaknesses, hence, tailoring and improving the residency program

H. Yashar, N. Leizarowitz, D. G. Shendler, D. G. Levy, D. Mercer, S. Adam, D. S. Barnes, A. Blachar*; Tel Aviv/IL (hilayashar1@gmail.com)*

Purpose: Residents' performance quality assurance and improvement is a priority for residency programs in all departments, let alone in radiology. There is a constant need for a general quality control system that covers all modalities in which residents are engaged.
Our radiology department implemented a residents' quality grading system (RQC). The goal of this system is to provide data that will demonstrate residents' progress and areas of strength and weaknesses, hence, tailoring the residency program individually.
Methods and materials: A computerised information system was developed and deployed. The system enables attending radiologists to grade residents' reports on a scale of 1-4, according to the following: 1) Complete agreement of the attending radiologist with the resident's report. 2) General agreement between reports, with minor changes. 3) Major changes without clinically significant impact. 4) Major changes with clinical significance that can gravely affect the patient.
The attending radiologist inserts the appropriate grade in the report and the resident is able to see it instantly.
Results: The RQC system has been implemented successfully in our department, with high compliance rates. Residents have been able to receive on-line feedback, understanding the clinical impact of their reports immediately. Moreover, the department is able to monitor a resident's progress and areas of weaknesses, thus directing his/her residency program accordingly.
Conclusion: RQC is a new system implemented by our radiology department with a high compliance rate, enabling constant feedback on residents' radiology reports. It continuously provides essential data that will impact residents' progress and quality of radiology reports, thus tailoring the residency program on an individual basis.
Limitations: Limitations include variability among evaluating radiologists, bias based on previous impression, shift workload, time of shift, and resident seniority.
Ethics committee approval: n/a
Funding: No funding was received for this work.

RPS 605c-9 12:03

Implementation of artificial intelligence: is the community ready? An international survey of 1,041 radiologists and residents

M. Huisman[1], E. R. Ranschaert[2], W. Parker[3], D. Mastrodicasa[4], M. Kočí[5], D. Pinto Dos Santos[6], T. Leiner[1], M. J. Willemink[7]*; [1]Utrecht/NL, [2]Turnhout/BE, [3]Vancouver/CA, [4]Stanford, CA/US, [5]Palo Alto, CA/US, [6]Cologne/DE, [7]Menlo Park, CA/NL (merel.huisman1@gmail.com)*

Purpose: Key opinion leaders predicting implementation issues will determine the course of AI (artificial intelligence) in radiology. The perception at large by radiologists and residents of AI remains unexplored. We investigated the existing knowledge and overall attitude towards AI by international radiologists and residents to help facilitate implementation.
Methods and materials: Between April-July 2019, a multi-language survey was accessible to radiologists and residents containing questions on awareness, knowledge, and attitude towards AI. Relationships of independent variables with an open and proactive attitude towards AI (readiness to use and learn about AI, to collaborate with data scientists, and agreement that radiologists should take the lead) were assessed using multivariable logistic regression.
Results: The survey was completed by 1,041 respondents from 54 countries (mean age 41 (range 24-74)). Most participants were male (n=670, 65%), radiologists (n=719, 69%), and working in non-academic centres (n=572, 55%) without formal research training (n=727, 70%). Over half had no knowledge of informatics/statistics (n=537, 52%). A minority had profound knowledge of AI (n=168, 16%). Almost half of the participants appeared to have an open and proactive attitude towards AI (n=501, 48%), which was significantly ($p<0.05$) associated with sex, age, working in an academic centre, having received formal research training, pre-existent knowledge on informatics/statistics, and professional social media use.

Conclusion: Almost half of the participants showed an open and proactive attitude towards AI, however, a substantial proportion had no knowledge of informatics/statistics. Pre-existent knowledge was independently associated with a positive attitude, indicating a need for additional training to facilitate implementation.
Limitations: Selection bias is presumably an issue in this survey, therefore the true percentage of the population having an open and proactive attitude is most likely lower.
Ethics committee approval: n/a

RPS 605c-10 12:09

Anticipated hurdles and incorporation into residency programs of artificial intelligence (AI): an international survey of 1,041 radiologists and residents

M. Huisman[1], E. R. Ranschaert[2], W. Parker[3], D. Mastrodicasa[4], M. Kočí[5], D. Pinto Dos Santos[6], T. Leiner[1], M. J. Willemink[7]; *[1]Utrecht/NL, [2]Turnhout/BE, [3]Vancouver/CA, [4]Stanford, CA/US, [5]Palo Alto, CA/US, [6]Cologne/DE, [7]Menlo Park, CA/NL (merel.huisman1@gmail.com)*

Purpose: Integration of AI education in residency programs is not yet common. As residency programs are already demanding, controversy exists as to what extent it should be incorporated, although it might accelerate the implementation of AI in radiology. We sought to explore the opinion of the radiology community and to identify commonly anticipated hurdles to implementation.
Methods and materials: Between April-July 2019, a multi-language survey was accessible to radiologists and residents including multiple-choice questions on the integration of AI in residency programs and the anticipated hurdles to implementation of AI in radiology.
Results: The survey was completed by 1,041 respondents from 54 countries, mean age 41 (range 24-74), mostly male (n=670, 65%), and radiologists (n=719, 69%). A majority (n=819, 79%) indicated AI should be incorporated in residency programs, the remainder indicated maybe (n=182, 18%) or disagreed (n=40, n=4%). A small majority indicated that AI should (n=241, 23%) or maybe should (n=359, 35%) become a radiology subspecialty, while almost half (n=437, 42%) disagreed. Indicated hurdles to implementation were mainly ethical/legal issues (n=630, 61%), limitations in digital infrastructure (n=356, 61%), lack of knowledge (n=584, 56%) of stakeholders (i.e. clinicians, radiology staff, or management), and generalisability of AI algorithms (n=400, 38%).
Conclusion: A large majority of responders favours incorporation of AI into radiology training. Anticipated hurdles to implementation were mainly ethical and legal issues, and a lack of knowledge and generalisability issues, which is in concordance with key opinion leaders. Based on these results, incorporation of AI training in residency programs seems highly advisable, including ethical and legal aspects as well as methodology to ensure safe and effective use of AI.
Limitations: Selection bias is present, therefore the opinion of the population will be more moderate.

The influence of AI-based computer-aided diagnosis systems on diagnosis confidence in medical experts with different levels of experience

J. F. M. Gawlitza[1], P. Fries[1], P. D. A. Heinzl[2], A. Bücker[1], E. Jussupow[2]; *[1]Homburg/DE, [2]Mannheim/DE (joshua.gawlitza@uks.eu)*

Purpose: With the current developments in artificial intelligence (AI), the future work of radiologists is likely to change as computer-aided diagnosis programs (CAiD) will be part of work-a-day life. We hypothesised that the diagnosis confidence of medical experts using CAiD systems will alter regarding their different experience levels.
Methods and materials: We developed a virtual diagnosing environment with a DICOM viewer, quantified computed tomography, and lung function parameters. 29 medical professionals (students to clinic directors) were exposed to 3 cases of either severe emphysema or lung fibrosis in a randomised order. The aim was a binary diagnosis: “COPD” or “not COPD”. After a first control case, a diagnosis was suggested to the reader from the CAiD (either “AI suggests: COPD” or “[…] not COPD”). The suggestion was experimentally manipulated, so it was once correct and once false. Besides accuracy, confidence in diagnosis was measured after every case.
Results: Medical students started with a-priori confidence in diagnosing COPD of 60%. Correct diagnosis suggestion of the AI system boosted confidence to 75%, while incorrect AI suggestion led to a significant drop in confidence to 50% ($p = 0.012$). No significant difference was found between the latter and a-priori confidence. A similar pattern was shown for medical students of higher semesters (ANOVA $p = 0.004$). No significant differences were found for medical doctors (ANOVA $p = 0.651$).
Conclusion: Our results suggest diagnosis confidence is more likely to be influenced in less experienced medical experts through AI-suggestions, either correct or false. Future education programs should address this problem and inform young residents about the pitfalls and benefits of AI-based CAiD systems.
Limitations: A small sample size due to a complex comprehensive setup. Binary diagnosis (low depth).

A simplified method to estimate the energy spectrum for megavoltage photon beams by monoenergetic depth dose library

P. Chakraborty, H. Saitoh; *Tokyo/JP*

Purpose: Although Monte Carlo simulation by using the specification of the linear accelerator (LINAC) is the most common method to determine the energy spectrum, it consumes a lot of computing time and the treatment head specification is not always easy to obtain. Therefore, a simplified method was discussed in this study to estimate the energy spectrum that can reproduce the depth dose agreed with the measured data. To estimate the energy spectrum, a monoenergetic depth dose library was provided. Characteristics of the energy spectrum as a function of distance from the central axis were also described in this study.
Methods and materials: The monoenergetic depth dose of 0.1MeV to 11MeV was simulated using the DOSRZnrc code with a history of 1000000000 to obtain better statistical accuracy. The energy spectrum was reconstructed using the monoenergetic depth dose library and a GRG (generalised reduced gradient) non-linear function was performed repeatedly until a good agreement between the calculated and measured depth dose was obtained.
Results: The total relative difference of the reconstructed and measured dose distribution was less than 1%, which provides good accuracy in the energy spectrum estimation.
Conclusion: A simplified method to estimate the energy spectrum incident on the surface of a water phantom was successfully implemented, which can be used as a fast energy spectrum estimation technique to obtain an accurate calculation of dose distribution.
Limitations: n/a

Reduction of microwave ablation needle-related metallic artefacts from virtual monoenergetic images using dual-layer detector spectral CT in rabbit VX2 hepatocellular carcinoma models
G. Wang[1], Z. Wang[1], X. Lu[2], Z. Jin[1]; [1]Beijing/CN, [2]Shenyang/CN (wangguorong_1022@163.com)

Purpose: To investigate the ability and the optimal energy level of virtual monoenergetic images (VMIs) to reduce microwave ablation needle-related metal artefacts by dual-layer detector spectral CT (DLSCT).
Methods and materials: A total of 20 rabbit VX2 hepatocellular carcinoma models that underwent DLSCT-guided percutaneous microwave ablation were analysed. Conventional 120 kVp polychromatic images and energy levels 40-200 keV (with increments of 20 keV) of VMIs were reconstructed. Two independent radiologists evaluated image quality objectively and subjectively (5-point Likert scale: 1=worst, 5=excellent). The CT value and standard deviation (SD) of the region of interest (ROI) on the chosen image were recorded, including the most significantly hypointense artefact (ROI_1), hyperintense artefacts (ROI_2), and distant liver tissue less affected by artefacts of the same slice (ROI_3). The image noise was defined as SD of ROI_1 (SD_1) and ROI_2 (SD_2). The metallic artefact-induced deviation of the attenuation value was defined as the variance in the absolute value of CT value (|CT1-CT3|, |CT2-CT3|). Statistical analysis was performed to compare the difference between 120 kVp conventional images and each energy level of VMIs.
Results: Compared with conventional images, VMIs showed significant lower SD_1 specifically at an energy level of 40 and 200 keV, and lower SD_2 when energy levels were at 140~200 keV ($P<0.05$). At 140~200 keV, the values of |CT1-CT3|, |CT2-CT3| were lower than those of conventional images ($P<0.05$). VMIs at 160~200 keV yielded higher subjective image scores than those of conventional images ($P<0.05$).
Conclusion: VMIs from DLSCT can obviously reduce microwave ablation needle-related metal artefacts in rabbit VX2 hepatocellular carcinoma models. Importantly, 200 keV may be the optimal energy level for reducing artefacts objectively and subjectively.
Limitations: The small sample size.
Ethics committee approval: Approval obtained from the animal board.
Funding: No funding was received for this work.

Missed lung cancers on radiographs and CT
Å. S. Lyslo, A. P. Parkar; Bergen/NO (aaselyslo@gmail.com)

Purpose: To retrospectively assess the rate of missed lung cancer on radiographs/CTs to identify the type of errors that occur and correlate the results to international guidelines for recommended miss rates for radiological lung cancer diagnosis.
Methods and materials: A manual search in PACS of CT thorax examinations from 01/10/2017-31/03/2019 was performed. CTs for cancer follow-up were excluded. Cases with lung cancers/indeterminate lesions were collected. Prior examinations (cut-off 2yrs) were searched for and each case classified:
1. Lesion not visible/no prior examinations/correct follow-up.
2. Lesion not reported.
3. Lesions reported but misinterpreted.
4. Lesions reported correctly but insufficiently conveyed to a clinician.
5. Lesions reported and conveyed correctly, but insufficient clinical follow-up.
6. Technical issues.
The time-lapse due to missed diagnosis was recorded.
Results: 2,266 CTs were initially reviewed and 50 were found to have lung cancer or indeterminate lesions.
The radiological diagnosis was correct in 41 (82%) cases.
35 (70%) were from group 1.
4 (8%) were from group 2.
5 (10%) were from group 3
6 (12%) were from group 5.
No cases were from group 4/6.
Of the 4 missed lesions, 2 were located in the left hilum and 1 each in the right and left upper lobe. Of the 5 misinterpreted lesions, 2 were considered an infection, 2 fibrosis, and 1 calcification.
Of the 6 without sufficient follow-up, 2 were elderly with advanced cancer and unable to undergo treatment, 2 postponed treatment themselves, and 2 were truly not followed up despite radiologists' recommendation.
The time-lapse ranged from 2-24 months.
Conclusion: The overall missed rate of lung cancer fulfilled international recommendations (>75%). Misinterpretation was a major issue as well as misses in the hilum. Education and training need to focus on that.
Limitations: As CT examinations for cancer follow-ups were excluded, new cancers occuring there could have been missed.
Ethics committee approval: Ethics committee review and data protection regulations were followed.
Funding: No funding was received for this work.

Fully automated quantification of left ventricular volumes and function in cardiac MRI: an evaluation of a deep learning-based algorithm
B. Böttcher, E. Beller, A. Busse, F. Streckenbach, M.-A. Weber, F. Meinel; Rostock/DE

Purpose: To investigate the performance of a deep learning-based algorithm for fully automated quantification of left ventricular volumes and function in cardiac MRI.
Methods and materials: We retrospectively analysed CMR examinations of 50 patients (74% men, median age 57 years). The most common indications were known or suspected ischaemic heart disease, myocarditis, or cardiomyopathies. Fully automated volumetric analysis of left ventricular volumes and function was performed using a deep learning-based algorithm. The analysis was subsequently corrected by a cardiovascular imaging expert as necessary. Manual volumetric analysis was performed by two radiology trainees. The time required for analysis was recorded. Volumetric results were compared using Bland-Altman statistics.
Results: The fully automated volumetric analysis was successfully completed in all patients in a median of 8.4 seconds. With expert review and corrections, the analysis required a median of 110 seconds. The median time required for manual analysis was 3.5 minutes for a cardiovascular imaging fellow and 9 minutes for a radiology resident. Compared with the expert-corrected results, the fully automated algorithm showed a mean deviation of -2.1% for end-diastolic volume, +3% for end-systolic volume, -10% for stroke volume, and -7.5% for ejection fraction. No corrections were necessary for 10 patients (20%). In the remainder, corrections were made on a median of 2 slices. The most common correction was related to inclusion or exclusion of slices at the apex or base of the left ventricle.
Conclusion: The deep learning-based algorithm allows for a fully automated analysis of left ventricular volumes and function with good accuracy. Although manual corrections are required in most patients for precise results, this approach is very time-efficient compared to manual analysis.
Limitations: A limited number of 50 cases.

The diagnostic accuracy of regadenoson perfusion cardiac magnetic resonance imaging in individuals with known or suspected coronary artery disease
A. Azcona[1], M. Roncal Redin[2], I. Soriano[2], A. Paternain Nuin[2], A. Ezponda Casajus[2], G. Bastarrika Alemañ[2]; [1]Zizur Mayor/ES, [2]Pamplona/ES (andoniazcona@gmail.com)

Purpose: To determine the accuracy and diagnostic performance of regadenoson-induced stress perfusion cardiac magnetic resonance (CMR) imaging in routine clinical practice.
Methods and materials: 403 consecutive individuals with known or suspected coronary artery disease underwent conventional stress/rest perfusion CMR in a 1.5-Tesla MR system (MAGNETOM Aera, Siemens Healthineers) for clinical indication. An intravenous bolus of regadenoson (0.4mg) was employed as a stressor. Stress perfusion CMR studies were visually assessed for perfusion deficits. CMR results were compared with invasive coronary angiography, considering positive 50% stenosis in at least one coronary vessel.
Results: A total of 402 individuals (305 males, mean age 64±11.8 years) were retrospectively evaluated. One patient could not complete the examination due to severe chest pain requiring nitroglycerin. Most frequently, the test was performed in patients with chest pain and prior coronary revascularisation (34.7%). Stress-CMR resulted as positive in 123 patients (30.6%) and negative in 279 (69.4%). Invasive coronary angiography was performed in 102

individuals. Compared with coronary angiography, regadenoson stress perfusion CMR showed a sensitivity of 94.5% (95% CI, 86.6%-98.5%), specificity of 82.8% (64.2%-94.1%), positive predictive value of 93.2% (86.1%-96.8%), negative predictive value of 85.7% (69.5%-94%), and accuracy of 91.2% (83.9%-95.9%).
Conclusion: Regadenoson stress perfusion CMR has a high diagnostic accuracy for the detection of significant coronary artery disease in routine clinical practice.
Limitations: A retrospective study.

The establishment of a student sonography course: from zero to over 1,000 in 2.5 years
L. Müller, J. Weimer*; Mainz/DE*

Purpose: Sonography is often the first imaging technique undergraduate medical students become familiar with. In German medical school, the curriculum is no defined space for practical skills training in imaging. Until 2017, there was only one available sonography device for training without any form of instruction for all medical students between year 3 and 6 at the Johannes-Gutenberg University Mainz. This was the motivation for establishing a new *peer-to-peer* student sonography course (*Sono-For-Klinik*, Mainz).
Methods and materials: In early 2017, we trained 22 student tutors with the help of the Departments of Radiology and Internal Medicine. Furthermore, we wrote a script with over 180 pages and created several teaching materials. Course rooms with electronic equipment and sonography devices were provided by the Rudolf-Frey-Lernklinik Mainz. Moreover, we linked in with external clinical partners who provided us with images and expertise. A standardised questionnaire was used for the evaluation of the course. The gained practical skills of the students were verified with objective structured clinical examinations.
Results: The first course was able to start in summer, 2017, with 60 students. The number of participants reached 151 in the next semester. Today, 1,040 students have participated in the course and 42 tutors have been trained. New sub courses (e.g. with a focus on echocardiography or FAST) have been created. We were certified as an official course by the *DEGUM* (German Society for Sonography) in 2018.
Conclusion: The need for practical imaging skills is huge among undergraduate students. Since the establishment of the course, all of our course capacities have been occupied. Due to self-motivation, it was possible to feed this need and to establish our educational project with over 1,000 participants in 2.5 years.
Limitations: The retrospective design.

Is gadolinium-enhanced imaging necessary in the surveillance of non-operated cranial meningiomata?
P. J. Shah, K. E. Twentyman, S. Currie, I. Craven*; Leeds/UK (kathryn.twentyman@hotmail.co.uk)*

Purpose: Gadolinium use is not without risk and economic cost. With patient safety of paramount importance and in this time of increasing health economic scrutiny, consideration must be given to alternative safer and less-expensive diagnostic and surveillance imaging techniques without sacrificing outcomes. This study's purpose was to evaluate whether T2-weighted imaging (T2-MRI) can provide an accurate alternative to gold-standard T1-weighted post-gadolinium imaging (Gd-MRI) in the assessment of non-operated cranial meningiomata.
Methods and materials: 90 meningiomata (30 skull base, 30 infratentorial, and 30 supratentorial) were identified from a tertiary neuroscience centre database. Two neuroradiologists independently measured the single maximal diameter of meningioma on either axial T2-MRI or Gd-MRI without reference to the other sequence. Observers were blind to previous measurements and clinical reports. This was repeated after a washout period (2 weeks) to permit intra and interobserver correlation. Bland–Altman plots evaluated the level of agreement (set at +/-1 mm) between meningioma measurements obtained on T2W-MRI and Gd-MRI.
Results: Neuroradiologists showed excellent intra and interobserver concordance on both Gd-MRI and T2-MRI (intra and inter ICC>0.9, irrespective of meningioma location). On Bland-Altman plots, the mean difference in measurements of supratentorial, infratentorial, and skull base meningiomata using T2-MRI and Gd-MRI were 0.46 mm, 0.78 mm, and 1.64 mm, respectively.
Conclusion: T2-MRI should be considered as an alternative to Gd-MRI in the surveillance of non-operated meningiomata located in the supra and infratentorial compartments. Change to the surveillance regime may provide health and economic benefits. Gd-MRI is still indicated in the assessment of skull base meningiomata. Skull base tumours are often intimately related to other complex anatomical structures and the use of Gd-MRI may enhance local soft-tissue contrast in order to better define tumour extent.
Limitations: A single-centre, consultant-only study with a small sample and differing protocols.

3D printed models: the new revolutionary tool in medical education
A. S. Constantinescu[1], E. Liciu[2]*; [1]Voluntari/RO, [2]Bucharest/RO (andconstef@yahoo.com)*

Purpose: The purpose of this study was to evaluate the efficiency of using different 3D-printed models and the CTs of the patients from which the models were created for teaching sectional anatomy to medical students. Our hypothesis was that in order to understand sectional or radiological anatomy one must first create a three-dimensional reconstruction of that structure in their mind. By creating a physical 3D reconstruction using the patient's own CT, we can make sure that the model we created is more accurate and that the learning process would, therefore, be much easier.
Methods and materials: Two 3D-printing technologies (Fused deposition modelling and stereolithography) were used to create the following models: scoliosis, pelvic bone, coronary arteries, 2 aorta models, heart, and a tumour model. During 5 hands-on workshops with a total of 50 student participants, we presented this subject and we also provided a 5 question questionnaire at the end that we used to interpret the results.
Results: 80% of the students completely agreed that the 3D-printed models were useful in understanding sectional anatomy. 76% would use a similar model of another structure for the same purpose. 82% would recommend using a 3D-printed model to another student or colleague. 76% of the students agreed that a lot of credibility to this study method was attributed to the models being an accurate representation of the patients anatomical structure and over 96% of them would like to see 3D-printed models being implemented in university courses.
Conclusion: In conclusion, the questionnaire results showed that 3D-printed models can be a learning bridge from conventional to sectional anatomy.
Limitations: This learning method is completely dependent on the lecturer's public speaking and teaching skills.

An application study of CT perfusion imaging in assessing metastatic involvement of perigastric lymph nodes in patients with gastric cancer
Z. Sun, S. Hu, L. Shao, L. Jin*; Wuxi/CN (qiong953780@163.com)*

Purpose: This study used CT perfusion imaging (CTPI) technology to evaluate the diagnostic efficacy in differentiating metastatic from inflammatory perigastric lymph nodes in patients with gastric cancer.
Methods and materials: A total of 115 perigastric lymph nodes of 60 patients with gastric cancer confirmed by gastroscopy underwent CTPI scan before an operation. The scan data was post-processed by using commercial software to calculate perfusion parameters including blood flow (BF) and permeability surface (PS), and to measure the size of lymph nodes. According to the postoperative pathology result, the lymph nodes were divided into two groups: metastatic nodes and inflammatory nodes. Perfusion parameters and the size of lymph nodes between two groups were respectively compared statistically, and a ROC analysis was used to determine the optimal cutoff value with sensitivity, specificity, and area under the curve (AUC).
Results: Examined perigastric lymph nodes were metastatic in 65 and inflammatory in 50. Mean values of perfusion parameters in metastatic and inflammatory lymph nodes, respectively, were BF of 90.05 versus 79.31 ml/100 mg /min ($p < 0.01$), and PS of 42.19 vs. 35.89 ml/100 mg /min ($p < 0.01$). Mean values of the size in metastatic and inflammatory lymph nodes were 1.34 cm versus 1.16 cm ($p > 0.05$). The sensitivity of 81.5%, the specificity of 66.0 %, and AUC of 0.784 for BF with a cutoff value of 80.76 ml/100 mg /min for differentiating metastatic from inflammatory nodes were higher than those of PS or the size of lymph nodes ($P < 0.05$).
Conclusion: BF might be a more effective marker than PS or the size of lymph nodes for differentiating metastatic from inflammatory nodes in gastric cancer patients.
Limitations: The unknown cardiac output of patients might influence CT perfusion values.

Virtual gastroscopy performed with stomach CT protocol and its role in the staging of gastric cancer: our experience

G. Fontanella[1], C. A. T. Manganiello[1], S. de Lucia[1], M. Mancinelli[1], A. Festa[1], B. Brogna[1], S. Borrelli[2]; [1]*Benevento/IT,* [2]*Avellino/IT*
(giovanni.fontanella@hotmail.com)

Purpose: To establish the role of our gastric CT protocol, with additional virtual gastroscopy navigation, in the staging of gastric cancer.
Methods and materials: Between August 2018 and September 2019, we selected 34 patients (mean age 64.2, 58.82% male) and scanned them in our 160 detector row system, using a dedicated CT protocol with standard gastric fluid distention obtained with a 2 litre diluted sodium amidotrizoate and meglumine amidotrizoate solution. The studies were reviewed by two radiologists with gastrointestinal and abdominal imaging experience, either in standard 2D or 3D navigation mode. The results were then compared for accuracy, specificity, and sensitivity with the pathology data.
Results: The lesions we detected were divided in three T groups: T1/T2 (44.11%), T3 (26.47%), and T4 (29.42%). Sensitivity values were 77.9% for T1/T2, 87.1% for T3, and 100% for T4 lesions. Specificity values were 100% for T1/T2, 83.2% for T3, and 92.3% for T4 lesions. Global accuracy values were 85.9% for T1/T2, 82.2% for T3, and 91.0% for T4 lesions. Nodal status was evaluated as well, with 23 N-positive patients (73.52%); nodal staging sensitivity, specificity, and accuracy values were 91.0%. 64.2%, and 75.7%.
Conclusion: Our CT protocol with fluid distention of the stomach and 3D virtual navigation has shown to have high sensitivity, specificity, and overall global accuracy in the staging of gastric cancer, especially for the T status in the early stages (T1/T2) and nodal status, allowing a more accurate therapeutic planning, especially concerning patients eligible for surgery.
Limitations: Our study is monocentric and based on a relatively small number of patients (34).
Ethics committee approval: All patients were orally instructed and signed written informed consent obtained.
Funding: No funding was received for this work.

Deep learning CT-based radiomics for prediction of treatment response to neoadjuvant chemoradiation in oesophageal squamous cell carcinoma

C. Xie[1], Y. Hu[2], L. Han[2], J. Fu[2], V. Vardhanabhuti[1], K. Chiu[1]; [1]*Hong Kong/HK,* [2]*Guangzhou/CN*

Purpose: Neoadjuvant chemoradiotherapy (NCRT) plus surgery improves long-term survival of patients with locally advanced esophageal squamous cell carcinoma (ESCC). Treatment response prediction remains a great challenge. We aimed to evaluate the value of deep learning radiomics models based on computed tomography (CT) for predicting pathologic complete response (pCR) in ESCC patients receiving NCRT.
Methods and materials: We identified 161 patients with ESCC (mean age: 58, male: 83.5%, pCR: 46.0%). A total of 2048 deep learning radiomics features were analysed by the convolutional neural network (Xception) from CT images. After feature selection, a radiomics signature was built with an extreme gradient boosting (XGBoost) algorithm. Two models were built. Model A, for post-NCRT evaluation, incorporates both pre-NCRT and post-NCRT CT images into the analysis, while Model B, for pretreatment assessment, was built based on pre-NCRT CT images only.
Results: Model A comprised 9 selected features and showed good discrimination performance in test set for treatment response to NCRT, with an accuracy of 0.78, area under the receiver operating characteristic curve (AUC) of 0.89, sensitivity of 0.70, and specificity of 0.96. Calibration curves demonstrated good agreement between the prediction probability and the observed pCR (Hosmer-Lemeshow test, P-value = 0.66). Decision curve analysis confirmed the clinical benefits. Model B was also found to have predictive potential, with an accuracy of 0.67, AUC of 0.73, sensitivity of 0.87, and specificity of 0.62.
Conclusion: Deep learning radiomics analysis based on CT demonstrated promising predictive value for NCRT treatment response in locally advanced ESCC. Both pretreatment and post-NCRT models could be potentially used for treatment strategy decision-making.
Limitations: Future studies in larger prospective cohorts are needed to further confirm clinical practicability.

Contrast MRI features in differentiating early invasive squamous cell cancer from mucosal high-grade neoplasia of the oesophagus

J. Qu[1], H. Zhang[1], X. Yan[2], S. Wang[3]; [1]*Zhengzhou/CN,* [2]*Shanghai/CN,* [3]*Xi'an/CN (qjryq@126.com)*

Purpose: To evaluate the diagnostic accuracy of contrast-enhanced MRI in the differentiation of mucosal high-grade neoplasia (MHN) from early invasive squamous cell cancer (EISCC) of the oesophagus.
Methods and materials: 32 study participants with MHN (n=18) and EISCC (n=14) of the oesophagus were enrolled in this prospective study. Postoperative histopathologic analysis was the reference standard. All participants underwent MRI (MAGNETOM Skyra, Siemens Healthineers, Erlangen, Germany). Two radiologists, blinded to participants' data, independently evaluated enhancement degree and enhancement pattern. Diagnostic performance of the two features was compared using the Chi-square test; kappa values were assessed for reader performance.
Results: Surgery was performed within 3.8+2.5 days after MR imaging. Inter-reader agreement on image quality was excellent (Kappa value=0.801~0.902 for three sequences, $P<0.001$), and the agreement on MR features was also excellent (Kappa value=0.831, $P<0.001$). All 4 mass-like MHN were "heart-shaped" in appearance. The combined two features provided the best sensitivity, specificity, and AUC of 100%, 94.1%, and 0.987, respectively. There was no significant difference between the degree of enhancement and the combination of the two features.
Conclusion: Contrast MRI can differentiate MHN from EISCC in oesophagus, with the presence of "heart-shaped" appearance favouring the diagnosis of MHN.
Limitations: Limited sample size, because most MHN was removed by EMR/ESD. Dynamic enhanced images features were not analysed in this study because it remains difficult to acquire good image quality of dynamic enhanced images of the chest.
Ethics committee approval: This study was approved by the Hospital Ethics Committee and all participants signed the written informed consent form.
Funding: No funding was received for this work.

Prognostic value of pretreatment computed tomography-defined tumour characteristics in patients with oesophagal neuroendocrine carcinoma: a preliminary result
Y. Zhou; *Zhengzhou/CN*

Purpose: To determine the prognostic significance of pretreatment CT-defined tumour characteristics in patients with oesophagal neuroendocrine carcinoma (NEC).
Methods and materials: A total of 89 patients who had confirmed oesophageal NEC were included in our database from September 2012 to July 2019. A baseline CT scan was obtained less than 1 week before treatment was performed. Basic morphological image features and clinical data including patients' age, gender, tumour length, location, the depth of wall thickness, clinical symptoms, immunohistochemical expressions, tumour invasion depth, lymph node metastasis, distant metastasis, treatment strategy, tumour margin, necrosis, calcification, morphological subtype, enhanced homogeneity, enhanced pattern, and enhanced degree were recorded. Potential prognostic factors of survival were evaluated using a univariate Cox proportional hazard model based on forward stepwise selection from the variables.
Results: The median overall survival was 45 (range, 24.6-65.4) months. Overall survival was censored in 18 patients. The univariate Cox regression analysis indicated that only the enhanced degree as an independent factor influenced the overall survival [Hazard Ratio, 0.53; 95% confidence interval (CI), 0.333-0.842] (P=0.007).
Conclusion: The CT enhanced degree on venous phase demonstrated improved predictive ability for predicting the overall survival of NEC after treatment.
Limitations: We created a prognostic model for 5-year overall survival, which is not the only interesting outcome variable. Pretreatment CT texture analysis and pathological response after treatment might be other variables of interest for future studies.
Ethics committee approval: This study was approved by the Institutional Review Board (IRB). All patients enrolled in this study provided informed consent.
Funding: No funding was received for this work.

RPS 701-7 14:30
Staging of duodenal adenocarcinoma with CECT
G. Litjens[1], S. Radema[1], L. Brosens[2], C. J. H. M. van Laarhoven[1], E. J. M. van Geenen[1], J. J. Hermans[1]; *[1]Nijmegen/NL, [2]Nijmegen/Utrecht/NL (g.litjens@radboudumc.nl)*

Purpose: To determine the accuracy of staging duodenal adenocarcinoma (DA) with contrast-enhanced CT. DA represents over 50% of small bowel adenocarcinomas. Patients usually present with aspecific symptoms, causing significant delays in diagnosis. Currently, it is unclear what would be the optimal diagnostic workup in DA.
Methods and materials: Retrospective evaluation of TNM-stage of DA on portal-venous CECT in 50 patients.
Results: The tumour was visible in 90% (45/50) of patients, isodens in 46% (23/50), hypodens in 30% (15/50), hyperdens in 2% (1/50), and of mixed density in 12% (6/50). Tumours were localised in all segments of the duodenum, but mostly in the pars descendens (22/50=44%). 35 patients underwent surgery with curative intent, 28 were resected, and 7 had unexpected metastases (N=4) or local invasion (N=3). The T-stage of the 28 resected patients was correct in 13 (13/28=46%), overestimated in 2 (2/28=7%), underestimated in 10 (10/28=36%), and in 3 patients the T-stage could not be determined. Of the 28 resected patients, 21 had suspicious lymph nodes (LNs), but only 13 of these had positive LNs at pathology. Of the 7 patients without suspicious LNs, 3 had positive LNs at pathology. In 12% (6/50), tumours in the duodenum were missed on endoscopy. In 27 patients with MRI, tumour visibility and extension could be better determined on the HASTE than on CECT.
Conclusion: CECT is probably not sufficient for staging DA. Compared to pathology, CECT underestimates the T-stage and cannot reliably detect LN metastases, which are highly prognostic. Future research concerning additional imaging modalities is needed to improve staging DA. We suggest that MRI could be a potential candidate.
Limitations: Retrospective and therefore non-uniform data.
Ethics committee approval: Informed consent waived and study approved by ethical committee.
Funding: No funding was received for this work.

The Oxford 1000 barium swallow study: our experience
M. Chen, H. F. D'costa; *Oxford/UK (d.mitch.chen@gmail.com)*

Purpose: A barium swallow is a fluoroscopic test of the upper gastrointestinal tract. It involves the use of ionising radiation and is operator dependent with respect to radiation exposure, which can be reduced with staff training.
In this observational study, 1004 barium swallow cases were evaluated for the relationship between radiation dose and staff level of training, and correlated with the final clinical/histologic diagnoses.
Methods and materials:
Data from 1004 barium swallows performed at our centre (M:F = 411:593) were retrospectively collected.
The radiation dose was first compared with the national diagnostic reference level (NDRL) and then with the operator training level, categorised as first-year residents, advanced radiographers, senior residents and consultants. At our centre, first-year radiology residents are trained by the advanced radiographers to perform barium swallows. Senior radiology residents perform the test independently in most cases.
40% of patients have subsequently had an oesophagogastroduodenoscopy (OGD). The patients were categorised by their final diagnoses.
Results:
The findings show 80% of the cases performed are within the NDRL and established statistically significant correlation ($p<0.05$) between radiation dose level and operator training level. There was no significant correlation between dose and final diagnosis. All histologically confirmed cases of malignancy were noted on the initial barium swallow tests apart from one, demonstrating the high sensitivity of the latter for malignancy.
Conclusion: This study demonstrates that radiation dose, though largely within the accepted range, is lowest for consultant GI radiologists with no difference in pathology identification. Re-visiting consultant supervised barium training will help further lower the radiation exposure to patients. Barium swallow study remains a valuable imaging modality for evaluating oesophageal pathologies in 21st century medicine.
Limitations:
Single-centre study.
Ethics committee approval: n/a

Utility of dynamic oesophagogram in the grading of achalasic patients: comparison with static x-ray barium swallow and correlation with clinical subtypes
G. Fontanella[1], C. A. T. Manganiello[1], M. Mancinelli[1], A. Festa[1], S. de Lucia[1], B. Brogna[1], S. Borrelli[2]; *[1]Benevento/IT, [2]Naples/IT (giovanni.fontanella@hotmail.com)*

Purpose: To establish the role of the dynamic oesophagogram in the grading of achalasia, in comparison with our standard static barium swallow protocol, and evaluate its correlation with clinical/manometric subtypes classification.
Methods and materials: Between June 2017 and June 2019, we selected 109 patients (mean age 61.4, 56.68% male) and evaluated them, both with our static (SBS) and dynamic barium swallow (DBS) x-ray protocol. The studies were reviewed in blind by two radiologists with gastrointestinal and abdominal imaging experience. The results were then evaluated for accuracy, specificity, and sensitivity, and compared with the manometric/clinical grading, our gold standard.
Results: The patients were divided into 4 radiological grades for both SBS and DBS, according to morphological criteria (I-IV), corresponding to three clinical subtypes (1-3; subtype 3 accomodating radiological grades III-IV). Sensitivity values ranged between 78.1-100% for SBS and between 96.3-100% for DBS. Specificity values were substantially similar for both SBS and DBS, ranging

between 58-97%. Subtype grading accuracy was significantly higher for DBS in Subtype I (82.3 vs 70.7%).
Conclusion: Our dynamic oesophagogram protocol, compared with our static dynamic swallow, has shown to have similar specificity, better sensitivity, and global accuracy for the diagnosis of achalasia. This has been linked to the much higher sensitivity in dysmotility detection shown by DBS. Grading definition accuracy is particularly high for DBS when compared with the manometric/clinical staging. These results are promising and DBS could help guide therapeutic choices through a more precise patient stratification.
Limitations: Our study is monocentric and the number of patients is limited (109).
Ethics committee approval: Our study received ethical committee approval and each patient signed informed consent before examinations.
Funding: No funding was received for this work.

A non-invasive model for predicting the malignant potential for gastrointestinal stromal tumours by using contrast-enhanced ultrasonography with gastric distention

T. Li, M. Lu*; Chengdu/CN (635598031@qq.com)*

Purpose: It is difficult to accurately identify the risk level of gastrointestinal stromal tumours (GISTs) without surgical pathological confirmation. The purpose of our study was to propose a non-invasive prediction model for diagnosing GISTs by using contrast-enhanced ultrasound (CEUS) with gastric distention.
Methods and materials: We retrospectively reviewed 36 GIST patients who underwent CEUS from May 2017 to August 2019. All lesions were certificated by pathology after surgery. The age of the patient, size of the lesion, necrosis, calcification in the lesion, perfusion parameters including arrival time (AT), peak intensity (PI), time to peak (TTP), and area under the curve (AUC) of the lesion and surrounding normal tissue were analysed. Logistic regression analyse were performed.
Results: Of the 36 GISTs, 19 were high-risk and 16 low-risk tumours, respectively. Compared with low-risk GISTs, high-risk GIST had faster AT (7.3s vs. 11.9s, $p < 0.001$), higher PI (15.2dB vs. 12.2dB, $p < 0.05$), and larger size (4.2cm vs. 2.2cm, $p < 0.001$). In multivariate logistic regression, AT (＜9.04s, odds ratio [OR] 34.26, 95% confidence interval [CI] 1.69–694.83), PI (＞15.21dB, OR 44.63, 95% CI 0.86–2323.87), and size (＞2.4cm,OR 47.11, 95% CI 2.64–840.55) were independent predictors of high-risk GIST and low-risk GIST.
Conclusion: The size, AT, and PI of the GISTs on CEUS can be used as parameters for a non-invasive risk level prediction model of GISTs. This model may be helpful in identifying different levels of GISTs before surgery.
Limitations: 36 GISTs were not sufficient enough, a larger sample size should be involved in the future study.
Ethics committee approval: This study was approved by the Institutional Review Board and Ethics Committee of Sichuan Cancer Hospital.

RPS 701-11 14:54

Differential diagnosis and mutation stratification of gastrointestinal stromal tumours on CT images using a radiomics approach

M. P. A. Starmans, M. J. M. Timbergen, M. Vos, M. Renckens, D. J. Grünhagen, G. J. van Leenders, S. Sleijfer, J. J. Visser, S. Klein*; Rotterdam/NL (m.starmans@erasmusmc.nl)*

Purpose: Gastrointestinal stromal tumours (GISTs) are rare mesenchymal tumours of the gastrointestinal (GI) tract and difficult to diagnose. Here, we evaluate radiomics for 1) distinguishing GIST from other GI tumours, and 2) predicting the GIST c-KIT mutational status and mitotic index.
Methods and materials: Patients treated at the Erasmus MC between 2004-2017 with GIST or non-GIST GI tumours with a venous phase CT scan were included. A clinician segmented the tumours from which 424 radiomics features were extracted. Sex, age, and tumour location were collected. Prediction models for GIST versus non-GIST, presence of c-KIT mutation and type (exon9 or exon11), and mitotic index (≤ 5/50 high power fields (HPF) vs. > 5/50 HPF) were created through an automated search amongst a variety of machine learning algorithms to find the combination that maximises performance. The evaluation was implemented through 100x random-split cross-validation, with 80% of the data used for training and model optimisation and 20% for testing. For comparison, a subset was scored by a radiologist.
Results: The dataset consisted of 122 non-GISTs (schwannomas, leiomyosarcomas, leiomyomas, gastric cancers, and lymphomas) and 125 GISTs. The GIST versus non-GIST radiomics model had a mean area under the curve (AUC) of 0.72; adding location improved the performance to 0.83; adding age and gender did not improve the performance. The radiologist had a similar performance (AUC of 0.72). The c-KIT mutation models (c-KIT, exon9, and exon11) only predicted the absence of mutations. The mitotic index model had an AUC of 0.60.
Conclusion: Our radiomics approach proved useful for distinguishing GISTs from other GI tumours, with a performance similar to a radiologist, but could not predict the GIST c-KIT mutational status or mitotic index.
Limitations: Potential location bias.
Ethics committee approval: Erasmus MC IRB (MEC-2017-1187).

Gastrointestinal stromal tumours (GISTs): an imaging perspective

P. Gupta[1], V. Choudhary[2]; [1]*Jammu/IN*, [2]*New Delhi/IN (puneetgupta619@yahoo.com)*

Purpose: To list the clinical features and imaging findings of GISTs and describe how GISTs can be diagnosed on the basis of the imaging findings.
Methods and materials: We reported 22 cases of pathologically and surgically proven GISTs at our hospital. The aim of this retrospective study was to review the imaging features of 22 GIST cases. We also describe the clinical and pathological findings of this well-recognised entity.
Results: Gastrointestinal stromal tumours (GISTs) are the most common mesenchymal tumours of the gastrointestinal tract. CT is the imaging modality of choice for diagnosing GIST at initial presentation, staging, and monitoring of the disease during and after the treatment. The aim of imaging is to locate the lesion, define its morphological characteristics, evaluate local invasion, and detect distant metastasis. CT is the imaging of choice for these purposes. Multidetector CT can pick up most lesions > 2 cm. CT is also superior for the staging of GISTs and monitoring the disease during and after treatment. Radiologists can often predict the correct diagnosis at presentation by the appearance of a large exophytic gastrointestinal mass without significant lymphadenopathy.
Conclusion: Gastrointestinal stromal tumours (GISTs), which arise from the interstitial cells of Cajal, are the most common mesenchymal tumours of the gastrointestinal tract. The increasing recognition of GISTs and prolonged survival of the patients with GISTs have made imaging increasingly important not only for diagnosis but also for monitoring the effects of treatment. Computed tomography (CT) is the imaging modality of choice for these purposes.

Development and validation of a nomogram based on CT images and 3D texture analysis for preoperative prediction of the malignant potential in gastrointestinal stromal tumors

C. Ren*; Shanghai/CN (rencaiyue@163.com)*

Purpose: The purpose of this study is to develop and validate a nomogram for preoperative prediction of the malignant potential in GISTs.
Methods and materials: A total of 440 patients with pathologically confirmed GIST after surgery were retrospectively analysed. They were divided into the training (n=308) and validation set (n=132). CT signs and texture features of each patient were analysed and a predictive model was developed using the lasso regression. Then a nomogram based on selected parameters was developed. The predictive effectiveness of the nomogram was evaluated by the ROC and AUC. C-index and calibration plots were formulated to evaluate the reliability and accuracy of the nomogram by bootstrapping based on internal and

external validity. The clinical application value of the nomogram was determined through the DCA.
Results: 156 GIST patients with low-malignant and 284 with high-malignant potential were enrolled. The prediction nomogram consisting of size, cystoid variation, and meanValue had an excellent discrimination both in training and validation sets (AUCs (95% CI): 0.935 (0.908, 0.961), 0.933 (0.892, 0.974); C-indices (95% CI): 0.941 (0.912, 0.956) , 0.935 (0.901, 0.982); sensitivity: 81.4%, 90.6%; specificity: 75.0%, 75.7%; accuracy: 88.0%, 88.6%, respectively). The calibration curves indicated a good consistency between the actual observation and nomogram prediction for differentiating GIST malignancy. DCA demonstrated that the nomogram was clinically useful.
Conclusion: This study presents a prediction nomogram which can be conveniently used to facilitate the preoperative individualised prediction of malignancy in GIST patients.
Limitations: This study was a single-centre retrospective study. The sample selection was biased in this retrospective study.

RPS 701-14 15:12
Development and validation of a risk model based on deep learning method for preoperative prediction of occult peritoneal metastasis in gastric cancer
D. Liu[1], Z. Huang[1], B. Wu[1], P. Yu[2]; [1]*Chengdu/CN*, [2]*Beijing/CN (18720998339@163.com)*

Purpose: To develop a risk model using a contrast-enhancement computed tomography (CECT) based on deep learning method to predict occult peritoneal metastasis (OPM) in patients with gastric cancer (GC).
Methods and materials: A total of 567 GC patients (training (OPM-positive n=55, OPM-negative n=340) and internal validation (OPM-positive n=24, OPM-negative n=148) cohort) were subject to develop the risk model based on deep learning method (Xception). All patients' OPM status was diagnosed as negative by CECT and later confirmed by laparoscopy or surgery (OPM-positive n=79, OPM-negative n=488). The region of interest was manually drawn along the margin of the primary tumour and extracted information reflecting phenotypes of the primary tumour. In the training cohort, we used 5-fold cross-validation and fuse for the prediction results obtained separately on the internal validation cohort. Receiver operating characteristics (ROC) and the area under ROC (AUC) were used to measure the model's discrimination and the decision curve analysis was used to compare the benefit of the model and all-laparoscopy and none-laparoscopy schemes on the internal validation cohort.
Results: The AUC yield was 0.8273 (median AUC, range in [0.8115-0.9950]), 0.7606 (median AUC, range in [0.7515-0.7727]) and 0.8558 for the cross-validation training cohort, cross-validation validation cohort and internal validation cohort. Decision curve analysis showed that if the threshold probability in the clinical decision was less than 50%, the patient would benefit more from our model than either of the all-laparoscopy or none-laparoscopy schemes.
Conclusion: Our model has an excellent prediction ability of OPM using only CECT and may have significant clinical implications in the early detection of OPM for GC.
Limitations: The region of interest was delineated in one single slice.
Ethics committee approval: This retrospective study was approved by the institutional review board of our hospital and informed consent was waived.
Funding: No funding was received for this work.

RPS 701-15 15:18
Gastrointestinal stromal tumours (GISTs): the relationship between preoperative imaging features on contrast-enhanced computed tomography (CECT) and pathologic risk stratification
S. Guerri[1], G. Danti[2], G. Grazzini[2], A. Masserelli[2], S. Pradella[2], V. Miele[2]; [1]*Bologna/IT*, [2]*Florence/IT*

Purpose: To evaluate the association between imaging features of gastrointestinal stromal tumours (GISTs) on preoperative contrast-enhanced computed tomography (CECT) and risk of relapse according to Miettinen's risk classification.
Methods and materials: The preoperative CECT of all patients with a pathologically proven diagnosis of GIST who underwent surgery between January 2008 and June 2019 were retrospectively reviewed. Exclusion criteria were recurrent GISTs, "paediatric-type" GISTs, and treatment with Imatinib prior to surgery. The following imaging features were analysed: growth pattern (exophytic/endoluminal/mixed), calcifications (presence/absence), necrosis (presence/absence), signs of ulceration or fistulisation (presence/absence), internal foci of haemorrhage (presence/absence), margins (irregular/well-defined), enlarged feeding or draining vessels (presence/absence), type of CE (homogenous/heterogeneous), degree of CE (marked versus mild and moderate), ascites (presence/absence), lymphadenopathy (presence/absence), peritoneal implants, and liver and other organs metastasis (presence/absence). The Chi-Square statistic was used to examine the correlation between different imaging features and pathologic risk classes of surgical resection specimens.
Results: 54 patients (29 men, 25 women; median age 65±11 years; range: 30-84 years) were included in the study for a total of 56 primitive GISTs: 5 (8.9%) no risk, 13 (23.2%) very low risk, 17 (30.4%) low risk, 8 (14.3%) moderate risk, and 13 (23.2%) high risk. Necrosis (p<0.001), ulceration or fistulisation (p=0.004), haemorrhage (p=0.007), margins (p=0.005), enlarged vessels (p<0.001), type of CE (p<0.001), and metastasis (p<0.001) were found to be associated with the Miettinen's risk group.
Conclusion: The presence of necrosis, signs of ulceration or fistulisation, internal foci of haemorrhage, irregular margins, enlarged vessels, heterogeneous CE, and metastasis were significantly associated with high risk of relapse and CECT imaging may be useful for risk stratification.
Limitations: Retrospective and observational study design.

Radiation therapists and occupational burnout: a national survey in Italy
P. Cornacchione[1], F. Fellin[2], C. Galdieri[3], D. Pasini[1], D. Lambertini[4], S. Durante[5], D. Catania[3], M. Zanardo[3]; [1]*Rome/IT*, [2]*Trent/IT*, [3]*Milan/IT*, [4]*Reggio Emilia/IT*, [5]*Bologna/IT (patriziacornacchione@gmail.com)*

Purpose: To investigate occupational burnout levels among radiation therapists (RTT) in Italy and the possible associations with socio-demographic factors.
Methods and materials: The Italian Association of Radiation Therapists (AITRO) and the Italian Federation of Scientific Radiographers Societies (FASTeR) proposed a national online survey including the Maslach Burnout Inventory to RTTs. Italian RTTs count around 2,000 individuals. Mann-Whitney U and c^2 tests were used.
Results: We obtained 246 answers, 106 (43%) respondents were men, RTT age was <30yo for 44 respondents (18%), 31-40yo for 73 (30%), 41-50yo for 63 (25%), and >50yo for 66 (27%), and 235 (95%) RTTs worked full-time. RTTs had an overall high median emotional exhaustion (EE) score (37, IQR 31-46), and high depersonalisation (16, IQR 13-21) compared to occupational burnout references (≥27 and ≥13, respectively). The median score of personal achievement (PA) (31, IQR 28-34) was comparable to the reference (≤31). Using a subgroup analysis, females had significantly higher levels of EE (p=0.003). Having sons and working with paediatric patients did not show an impact on occupational burnout (p>0.086). A total of 67 (27%) RTTs stated that a specific stress management course was available at their workplace and it appeared related to a reduced EE score (p=0.005), while 60 (24%) respondents declared that they relied on psychological support relating to a reduced EE (p=0.035). High levels of EE, depersonalisation, and low levels of PA were present in 235 (96%), 193 (78%), and 130 (53%) participants, respectively.
Conclusion: Italian RTTs' levels of burnout exceed the reference value, especially for EE and depersonalisation. Future interventions aimed at preventing burnout stressors should be implemented in the radiation therapy work environment
Limitations: An Italian survey.

RPS 714-2 14:06
Development of a training program for 3D CBCT image verification in prostate cancer
C. L. Coelho[1], S. Pinto[2], A. Dias[2], C. Castro[1]; [1]Porto/PT, [2]Aveiro/PT

Purpose: Cone-beam computed tomography (CBCT) is an important tool in patient position verification before radiotherapy treatment delivery. The purpose of this study was the development of a training program directed to therapeutic radiographers based on a 3D CBCT treatment verification in prostate cancer.
Methods and materials: An initial sample of 51 therapeutic radiographers answered a survey and performed the image verification of 10 clinical cases before integration into the training program. Participants performed the analysis of the same CBCT images and answered a survey of 4 closed questions and an open one related to their perception about the training program. To evaluate the shifts resulting from the image analysis, the t-test was used for paired samples, comparing the mean absolute deviation (MAD) in the 4 directions of the couch mechanical movements.
Results: A sample of 41 therapeutic radiographers completed all phases. No statistically significant differences were found in general and in subgroups of <2 years and >2 years' experience with CBCT (p>0.05). Professionals with more than 10 years of experience revealed an improvement in image analysis after the training program, with differences in the vertical shift before and after (p=0.001). No relation was observed between years of experience and the level of confidence.
Conclusion: This training program structure shows a level of effectiveness considered satisfactory for its implementation, as there is an educational need to update the programmatical contents related to the cross-sectional pelvic anatomy. Since decision-making is vital for treatment delivery, critical analysis of CBCT, and improving patient outcomes, it is important to include these contents in clinical practice.

RPS 714-3 14:12
Offline adaptive radiation therapy for prostate cancer: using daily CBCT and deformable image fusion for correct replanning
L. Capone[1], F. Lusini[1], L. Nicolini[1], F. Cavallo[2], D. Di Minico[2], G. Triscari[1], V. Forte[2]; [1]Rome/IT, [2]Mirabella Eclano/IT (caponel@upmc.edu)

Purpose: Modern radiotherapy equipment allows different strategies to be implemented online or offline. The purpose of this work is to define an offline ART procedure capable of guaranteeing a correct replanning in prostatic treatments according to objective evaluation parameters.
Methods and materials: The treatment protocol of prostate patients involves emptying the rectum and filling the bladder. Daily checks are performed using CBCT images. For this study, 18 prostate patients were selected (medium and low risk). The analysis was carried out using Velocity v4.0 software (Varian medical system) on patients subjected to replanning (group B) and others (group A). In order to allow an effective quantitative comparison, the Dice coefficient and statistical indices of dispersion and distribution were taken into consideration.
Results: Dispersion of percentages linked to the volume of the rectum is greater in the cases related to group A (IQR=5.72%; Q1=-3.98%; Q2=-0.66%; Q3=1.74%) than in group B (IQR=5.05%; Q1=-2.66%; Q2=0.02%; Q3=2.39%). The distribution of bladder percentage changes in group A produced IQR=11.80%(Q1=-10.12%; Q2=-5.49%; Q3=1.67%) while in group B IQR=9.07% (Q1=-3.57%; Q2=0.95%; Q3=5.51%). The Dice coefficient in group A showed a daily overlap of the bladder on average equal to 0.92±0.13, while in group B, 0.93 ±0.07. The volume of the rectum, in both groups, had an average Dice coefficient equal to 0.85±0.14.
Conclusion: The Dice coefficient is a useful index to establish whether localisation of the volumes is superimposable to CT sim data it considers only their geometrical overlapping. Volumes averages are important, especially for the bladder, which is more subject to changes of this type, rather than to variations in spatial localisation.
Limitations: Only prostate patients treated with 80Gy were selected for this study.

RPS 714-4 14:18
Radiation exposure levels used for planning and verification during prostate radiotherapy treatment
R. G. Monteiro, M. Mariano, J. Santos; Coimbra/PT
(raquelmonteiro--@hotmail.com)

Purpose: The significant advances in science, particularly in the radiation therapy (RT) field, have an important role in promoting and improving patient care and cancer treatments. During this, the patient is exposed to radiation related to the RT treatment but also to other examinations that must be quantified. The aim of this study is to characterise RT planning and verification of radiation exposure, excluding the dose values directly related to the treatment.
Methods and materials: The dose files related to computed tomography (CT) (Siemens®) and cone-beam computed tomography (CBCT) integrated on the linear accelerator TrueBeam (Varian Medical Systems®) of 60 patients with prostate cancer were analysed.
Results: A total of 1,252 exams were analysed and the mean values of DLP were 351.95 mGy for CBCT, 791.22 mGy for CT without current modulation, and 491.43 mGy for CT with current modulation.
Conclusion: The effective dose during the planning and verification of radiation therapy treatment is relevant. Optimisation of this imaging modality must be taken into account in order to reduce the patient risk.
Limitations: The results of this study are directly related to the radiotherapy equipment technology.
Ethics committee approval: Institution ethical approval obtained.
Funding: No funding was received for this work.

RPS 714-5 14:24
Analysis of radiotherapy performance using quality indicators derived from automated treatment pathways
L. Capone, F. Lusini, L. Nicolini, F. Cavallo, D. Di Minico; Rome/IT
(caponel@upmc.edu)

Purpose: Quality indicators and evidence-based measures of health care that can be used with administrative data to track performance and clinical outcomes are standardised. This study analyses the quality indicators needed in a cancer centre accredited by international JCI standards that use only electronic procedures for managing their patient workflow.
Methods and materials: Tasks and activities related to patient flow management have been identified and recreated digitally in the EMR according to the workflow carried out based on the JCI standards. The analysis was based on data from January 2019-August 2019. The quality indicators selected were staff compliance in the use of automated activities, percentages of completion with automatic care pathway activities, and waiting times between the different activities of the treatment paths from the first radiotherapy consultation to the treatment.
Results: Staff compliance in the use of automated activities was on average higher (91%) in the first 4 months compared to the second (80%), with a clear decline in July.
Percentages of completion of the activities show the adherence already acquired to the closure of some tasks such as the time out of radiotherapy treatments (92%) and the closure of the folder (43%).
The waiting times of the activities are on average always higher than our reference standard, but there is an improvement trend in all the activities analysed.

Conclusion: The EMR system allows you to accurately analyse the performance delivered in radiotherapy departments, creating versatile quality indicators which can be customised through the creation of adhoc care pathways, making it possible to achieve high-quality levels in the accreditation phase by international commissions and guarantee the monitoring of areas that need improvement.

Evaluation of the reproducibility abdominal compression with termoplastic mask in adrotherapeutic treatment with carbon ions and respiratory gating

L. Anemoni, A. Mancin, C. M. I. Diegoli, A. Vai, V. Vitolo, F. Valvo, S. Tampellini, A. Barcellini*; Pavia/IT*

Purpose: To evaluate the reproducibility over time of abdominal compression with a thermoplastic mask, identifying the position of the diaphragm on computed tomography (CT), and comparing the image dataset acquired in the simulation phase with those related to intra-treatment revaluations in the same respiratory phase.
Methods and materials: A group of 5 patients treated with carbon ions and respiratory gating was considered. The breathing signal was acquired through a pressure sensor placed between the patient and the thermoplastic mask. The 4D image datasets were reconstructed in at least 4 respiratory phases: (0% ex), 30% inspiration (30% in), 30% expiration (30% ex), and end-inspiration (100% in). The diaphragm was contoured on the dataset correspond to the maximum expirio phase. On a weekly basis, an intra-treatment CT revaluation was acquired for checking the consistency of the patient's anatomy and setup, acquired in the same way as the CT baseline. The difference between the positions of the mass centre of the diaphragm between CT planning and CT revaluation at the maximum expirio phase ($P_{diaframma}$ = √(x_diafr^2+y_diafr^2+z_diafr^2)) was used to evaluate the reproducibility of abdominal compression.
Results: A different position of the centre of mass was observed (1.3 ± 0.3 cm). During CT revaluation, there was a greater abdominal compression which cranially moves the diaphragm as happens during treatment.
Conclusion: Increase the time to be allowed to elapse (e.g. half/full day) between the mask packaging and CT acquisition.
Limitations: Patients who struggle to keep a constant breath for at least 20 minutes.
Ethics committee approval: n/a

Planning and verification of radiation exposure in head and neck radiotherapy treatment

M. F. N. Coelho, M. Mariano, J. Santos*; Coimbra/PT*
(joanasantos@estescoimbra.pt)

Purpose: During head and neck radiotherapy treatment, the patient is exposed several times to radiation in addition to the treatment dose. This exposure is related to the different stages of the radiotherapy workflow, the computed tomography (CT) planning, and the cone-beam CT (CBCT) used for the different verifications throughout the treatment. This study aims to quantify patient radiation exposure in different radiotherapy treatment stages, from diagnosis to the end of the process, excluding the treatment dose.
Methods and materials: The dose values of planned CT and CBCTs performed on adult patients with primary head and neck tumours from October 2018-March 2019 were directly collected on the scanners. The examination doses were analysed and compared with the tumour location and treatment fractionation clinical decisions.
Results: The majority of the patients performed 24 CBCT during the treatment and 33 treatment fractionations. In head and neck radiotherapy treatment, the planning CT was the procedure that involved the higher examination dose value in comparison with the total CBCT exposures.
Conclusion: If the obtained examination dose values from planning and verification imaging were included in the dosimetry calculations, no differences were found in treatment fractionation.
Limitations: The number of patients with head and neck tumours during the data collection period.
Ethics committee approval: Ethical approval was obtained from the centre.
Funding: No funding was received for this work.

Evaluation of radiation dose and image quality for comparison of state-of-the-art intraoperative cone-beam CT and preoperative MSCT for spine surgery navigation

M. Fujii[1], K. Doi[2], J. Miyagawa[1], N. Tamaru[1], M. Taniguchi[1], Y. Fujinaga[1]*;*
[1]Matsumoto/JP, [2]Willowbrook, IL/US (m_fujii@shinshu-u.ac.jp)

Purpose: To compare the patient dose and image quality of state-of-the-art intraoperative cone-beam CT (CBCT; Artis Pheno, SiemensHealthineers, Germany) and preoperative multi-slice CT (MSCT; Lightspeed VCT, GE, USA) for spine surgery navigation.
Methods and materials: Radiation dose measurements were performed using a torso anthropomorphic phantom (RAN-100; Phantom Laboratory, USA) with optically stimulated luminescence dosimeters (GD-352M; Chiyoda Technol, Japan). The dosimeters were attached to various landmarks on the phantom surface, in the centre-plane, in the breasts regions, and in other organs at risk. Dosimeter measurements were repeated 3 times each for CBCT and MSCT, and for each clinical protocol at our institution. Image quality was evaluated with modulation transfer function (MTF), noise power spectrum (NPS), and contrast-to-noise ratio (CNR) using a Catphan 700 phantom (Phantom Laboratory).
Results: The measured average dose for CBCT and MSCT was 42.4mGy and 46.4mGy, respectively. The spatial frequency at 10% MTF for CBCT and MSCT was 1.22cycle/mm and 1.09cycle/mm. NPS value at 0.5cycle/mm for CBCT and MSCT was 368 and 196, respectively. CNR for CBCT and MSCT was 16.9 and 29.0, respectively.
Conclusion: In our clinical protocols, CBCT was found to have a 9% lower radiation dose than MSCT, without significant degradation in image quality. Therefore, the CBCT protocol is recommended for use in spine surgery navigation when it is available.
Limitations: One paired equipment study of CBCT and MSCT. A one institutional, phantom study.

Safe administration of contrast media: adding shine to the shades of grey

R. Hassan, P. P. Wali, A. Chethan Kumar, S. Kanumukullakshminarayana, B. Singh, S. Gopalan, A. Nagadi, H. C. Chadaga, A. Kumar*;*
Bangalore/IN
(Rosmi.h@columbiaindiahospitals.com)

Purpose: To understand the proper guidelines regarding administration of iodinated and gadolinium-based contrast agents, particularly in patients with renal compromise, in pregnancy, and lactation, and to clarify misconceptions regarding the diagnostic usage of contrast media.
There is a lack of proper understanding among clinicians and radiologists about the guidelines and approach to contrast administration in various clinical scenarios, which can lead to unnecessary delay or avoidance of useful diagnostic studies. Contrast-induced nephropathy is grossly overestimated by both radiologists and clinicians. The risk of undergoing a non-diagnostic non-contrast CT is probably higher than the potential risk of developing CIN even in patients with eGFR <30 ml/min.
Methods and materials: We conducted an audit among the radiology departmental staff and clinicians regarding the basic principles of contrast administration with a questionnaire with 10 questions (1st audit). The response was assessed on the same day and results regarding awareness were analysed. Lectures were conducted for radiologists, technicians, and clinicians regarding

recent guidelines related to contrast administration following which a 2nd audit was conducted after 6 months. The response was assessed and the improvement in awareness and implementation in routine practice was reviewed.
Results: Significant improvement in awareness was observed in second audit results among radiologists (80% vs 100%), residents (70% vs 100%), technicians (50% vs 90%), and clinicians (30% vs 80%).
Conclusion: It is of utmost importance that radiology residents and radiologists have a good understanding of the basic principles of contrast administration.
It is essential to adequately educate and train the radiographers for the judicious utilisation and optimisation of radiological studies and to ensure smooth workflow.
Limitations: The attrition among the responders.

Systematic review and meta-analysis on risk factors and interventions to prevent contrast media extravasations in patients undergoing computed tomography
S. Ding, C. Campeanu, N. Richli, G. Gullo*; Lausanne/CH*

Purpose: To identify risk factors for contrast medium extravasation at the injection site and interventions to prevent or reduce damages.
Methods and materials: To find studies that included patients undergoing computed tomography performed with intravenous contrast, 9 databases were searched, including PubMed, CINAHL, and Embase. This review evaluated risk factors (patient demographics, comorbidities, and medication history) and interventions (e.g. contrast agent, injection per se, the material used for injection, and the healthcare professionals involved). Articles were assessed by two independent groups of reviewers for methodological validity using the Joanna Briggs institute system for the unified management (JBI SUMARI). In one case, quantitative data from two cohort studies was pooled in a statistical meta-analysis.
Results: 15/2,151 articles were selected. 2 were randomised controlled trials and 13 were quasi-experimental and observational studies. The quality of these studies was considered moderate to low. Being of female sex and inpatient status appeared to be risk factors for extravasation. Furthermore, the volume extravasated could be affected by the injection rate, venous access site, and catheter dwelling time. Preliminary studies seemed to indicate the potential of extravasation detection accessories to identify extravasation and reduce the volume extravasated. The other interventions either did not result in a significant reduction in the frequency/volume of extravasation or the results were mixed across the studies.
Conclusion: Potential risks were identified and areas for possible interventions such as the use of new catheters for injection. Further studies, however, should be conducted with solid methodological designs to allow the development of high-quality strategies to reduce the risks associated with extravasation.
Limitations: Statistical pooling was not always possible due to the heterogeneity of the studies.
Ethics committee approval: n/a
Funding: HES-SO.

The individualisation of CT-protocols for suspected pulmonary embolism: a national survey
A. Rusandu, B. Dymbe, E. V. Mæland, J. R. Styve*; Trondheim/NO (albertina.rusandu@ntnu.no)*

Purpose: Given the extensive use of CT in radiation-sensitive patient groups, such as pregnant and paediatric patients, and the importance of the CT-protocol tailoring for both radiation dose and image quality, the purpose of this study was to determine the extent to which individualisation of CT-protocols is practised across the country.
Methods and materials: The cross-sectional study involved collecting CT-protocols along with a mini-questionnaire in order to obtain additional information about how the CT-examination is individualised. All public hospitals performing CTs for detecting pulmonary embolisms were invited and 41% participated.
Results: Tailoring a standard protocol to different patient groups was more common than using dedicated protocols. Most of the available radiation dose reduction approaches were used. However, the implementation of these strategies was not systematic. Children and pregnant patients were examined without using dedicated CT-protocols or protocol adjustments focusing on a radiation dose reduction in 30% and 39% of the hospitals, respectively.
Conclusion: There is a need for practice optimisation, especially for developing dedicated CT-protocols or guidelines for tailoring the existing protocol to paediatric and pregnant patients.
Limitations: The senior CT-radiographer of the department who answered the questions might not always have extensive knowledge of all the adhoc protocol adjustments made by other radiographers. The extent of adjusting CT-protocols when examining children or pregnant patients might be higher than reported.
Ethics committee approval: The need for approval from The Regional Committee for Medical and Health Research Ethics and the Norwegian Centre for Research Data was waived as the project did not involve any health related or personal information. Participants were informed about the study's aim and that an e-mail reply containing attached CT-protocols would be regarded as implied consent to participation.
Funding: No funding was received for this work.

Stroke imaging: a multiphase CT angiography standard protocol for the improvement for hub-and-spoke hospital organisation
E. Stefani[1], M. Centenaro[2], L. Baldo[2], E. Delazer[2], M. Gambarotto[2], G. Molena[2], T. Nistor[2]*; [1]Conegliano/IT, [2]Treviso/IT*

Purpose: To create a standardised study protocol that can be applied to all CT scanners in a hub-and-spoke hospital organisation design to diagnose ictus cerebri and to promote training events for radiographers who work in the radiology department.
Methods and materials: A multi-professional working group has been created involving radiographers and radiologists with great experience in a hub centre and in 4 spoke hospitals in the same geographic area.
Data are from a 4-month long study and have been compared to literature of the same hospital design.
The technology available (6 CT scanners from 16-256 slice) has been analysed to define standard scanning techniques, reconstruction algorithms, window settings, and necessary reformations in order to produce comparable diagnostic images of the brain in all hospitals of the radiology department.
The multi-professional group planned a specific training for 60 radiographers working in CT imaging in order to share technical features of the new operating model.
Results: The new multiphase CT angiography protocol was defined.
2 major training events were realised with a 90% commitment to the project.
After that the new protocol has been adopted in the hub and in 3 out of 4 spoke hospitals, according to the technology available (with 16 slice-CT scanners, not all angiographic phases can be taken appropriately).
Reliability and reproducibility of diagnostic images produced in spoke hospitals increased and the repetition of unnecessary CT examinations, when patients with acute ischaemic stroke arrived at the hub hospital for treatment, has been largely avoided.
Conclusion: Multiphase CT angiography represents the gold standard when studying ictus cerebri in hub and spoke organisations. The use of standard protocol allows for a time-saving and widely available technique.

Good practices for radiographers: patient installation and centring for brain-CTs
V. Berclaz, C. Chevallier, C. Bruguier, J.-B. Ledoux; *Lausanne/CH (Virginie.Berclaz@chuv.ch)*

Purpose: The importance of patient centring when performing a CT is essential to provide good image quality and to ensure radioprotection. Because of time constraints, CT scans performed in the emergency department may have poor patient installation and centring, and thus lower quality.
Methods and materials: This retrospective study analysed brain-CT scans during a three-month period performed on various CT scanners in our institution. Centring was evaluated using DoseWatch. Straightness was assessed using SSDE view scout in the same software in order to identify the use of a head support (foam cushion or CT-head holder). The inclusion criteria was a brain-CT with at least native acquisition.
200 cases were randomly selected and subsequently divided into emergency-CT scans (100 cases) and routine/elective CT scans (50 cases each, performed during working hours). The same analysis was carried out after a workshop discussion with the CT radiographer's team concerning the preliminary results.
Results: After the workshop, we observed a change in practice. Radiographers adopted the use of the head support to improve centring. The preliminary results showed that centring was overall good, but still with outliers demonstrating a misuse of the chosen head support. Initially, 1% of cases were performed with a CT-head holder in the emergency-CT compared to 25% for the routine/elective CT. After the workshop, it increased to 5% and 35%, respectively. Straightness improved by 15% for the foam head cushion and a significant decrease in the number of outliers was observed after the workshop.
Conclusion: Radiographers performed CTs with better quality after the initial evaluation followed by a workshop, which is an effective and low-cost solution to improve CT image quality.
Limitations: n/a

RPS 714-14 15:18
CT scan anthropometric study of the frontal sinus for sexual diagnosis: first results from a documented osteological collection (Portugal, 19th-20th centuries)
P. M. Martins[1], R. C. M. C. R. Gaspar[2], A. Silva[1], B. Magalhães[2]; *[1]Aveiro/PT, [2]Coimbra/PT (pmartins@ua.pt)*

Purpose: A recent body of evidence from the literature around the world has shown that the human sinuses are sexually dimorphic, which may be very useful both in forensic and archaeological contexts. The main goal of the present study is to ascertain if this sexual dimorphism is also present in Portuguese individuals.
Methods and materials: The present study included 30 crania ([15 females, 15 males]; age-at-death ranges from 19-87 years old; $\bar{x}$=44.57, SD=16.85 [males $\bar{x}$=41.47, SD=15.51 and females $\bar{x}$=47.67, SD=18.09]) from the International Exchange Skull collection stored at the University of Coimbra (Portugal). CT scans were performed using a Siemens Somatom Emotion 16-CT scanner with a study protocol for imaging the paranasal sinuses. 6 linear measurements were taken in both right and left frontal sinuses (RF and LF weight; RF and LF height; RF and LF anteroposterior length) using RadiAnt DICOM Viewer 4.0.1 (64-bit). 3 volumetric measurements, the nasofrontal angle (NFA), and 3Dmeshes were obtained with ITK-SNAP software.
Results: 5 measurements resulted in higher means in males (one is equal in both sexes), although, no significant differences were found in all the linear measures and volumes taken in the frontal sinuses. Nevertheless, females had a significantly higher mean (Student's t=-2,453; d.f.=27; p=0.021) for NFA. Age at death does not seem to play a role in the present results (Student's t=-1.008; d.f.=28; p=0.322).
Conclusion: The present results question if dimorphic differences between sinuses may be specific to certain populations and show that NFA may be useful for sexual discrimination. In the future, the maxillary sinuses, as well as their morphology/shape, should also be considered as parameters of analysis for sexual discrimination. Also, a large sample size should be considered.

Values-based radiography: what patients, radiographers, and managers value in their examinations and treatments
A. Newton-Hughes[1], R. Strudwick[2]; *[1]Salford/UK, [2]Ipswich/UK (a.newton-hughes@salford.ac.uk)*

Purpose: While values-based practice is promoted in healthcare, little is known about stakeholder values in diagnostic and therapeutic radiography.
Methods and materials: This small project used audio-recorded focus groups and individual interviews in two geographically remote regions to identify the values of patients, radiographers, and managers.
Results: The results suggest that patients value the interpersonal elements of the examination e.g. smiles etc., and while they also value safety and efficiency, they assume that they will experience these. Patients particularly valued being able to see their images and have questions answered. Radiographers value giving the patient a good experience and enjoy learning from them. Radiographers assume that patients value their honesty and the care they show. Managers value a patient-centred approach and are also influenced by the need for service quality, while the radiographers believe that managers value and appreciate their staff.
Conclusion: While patients value seeing their images and having their questions answered, they advised that in diagnostic radiography they were seldom given access to their images. Conversely, in therapeutic radiography, the patients were able to review their images and valued this highly. Diagnostic patients reported being left with unanswered questions, which was not the case for radiotherapy. Both patient groups valued welcoming communication and diagnostic patients reported that this is not what they experienced.
Radiographers report that they value giving the patient a good experience and earning their trust, but in diagnostic radiography this is not always the patient experience.
While therapeutic and diagnostic patients shared the same values, their reported experiences were different.
Limitations: The small sample size.
Ethics committee approval: University and IRAS approval gained with participants providing signed consent.
Funding: This presentation details the findings of a research project funded by the College of Radiographers and Industry Partnerships Scheme.

Breast cancer detection in mammography using artificial intelligence: a large-scale retrospective evaluation
K. H. Kim, H.-E. Kim, H. Nam, B.-K. Han, H. H. Kim, E.-K. Kim; *Seoul/KR (khkim@lunit.io)*

Purpose: To assess the feasibility of artificial intelligence (AI) as an effective diagnostic-support tool for breast cancer detection in mammography in terms of overall diagnostic performance and false-positive-findings per image (FPPI).
Methods and materials: A total of 170,230 exams of 4-view digital mammograms were retrospectively collected from multiple institutions, where 36,468 were cancer, 59,544 were benign, and 74,218 were normal. An AI-based diagnostic-support tool was developed and evaluated on validation data from 3 countries: South Korea (KR; 619 cancer, 620 benign, 619 normal), the United States (US; 250 cancer, 250 benign, 250 normal), and the United Kingdom (UK; 218 cancer, 218 benign, 218 normal). Overall diagnostic performance was measured with area under the ROC curve (AUROC), sensitivity, and specificity.

Breast radiologists annotated biopsy-confirmed cancer lesions by referring to radiology and pathology reports, and FPPI was measured for cancer (FPPI-C), benign (FPPI-B), and normal (FPPI-N) breasts respectively to evaluate AI in terms of false-positive, which was known to be the fatal weakness of traditional CAD software.
Results: Per-exam, AUROC, sensitivity, and specificity was 0.970, 90.3%, and 91.7% for KR, 0.953, 93.6%, and 80.2% for US, and 0.938, 91.7%, and 76.8% for UK. For FPPI analysis, cancer-side, benign-side, both-side of breasts of cancer, and benign, normal exams were used. FPPI-C, FPPI-B, and FPPI-N were 0.353, 0.054, and 0.025 for KR, 0.370, 0.162, and 0.025 for US, and 0.320, 0.236, and 0.056 for UK.
Conclusion: The AI-based diagnostic-support tool developed from large-scale mammograms can be used for breast cancer detection on mammography. It achieved 0.94-0.97 of AUROC and >90% of sensitivity with low false-positive-findings per image, especially in normal exams.
Limitations: Real clinical value needs to be investigated via reader studies.
Ethics committee approval: Approved by IRB. Informed consent was waived.

RPS 702-2 14:16
Breast cancer detection in screening mammography using artificial intelligence: a multicentre retrospective reader study
H.-E. Kim[1], K. H. Kim[1], E. H. Lee[2], B.-K. Han[1], H. H. Kim[1], E.-K. Kim[1];
[1]Seoul/KR, [2]Bucheon/KR

Purpose: To assess the feasibility of artificial intelligence (AI)-based diagnostic-support software and whether it can be used to improve a radiologist's diagnostic performance in breast cancer screening under European double reading guidelines.
Methods and materials: A total of 320 exams of screening mammograms were retrospectively collected from two institutions; 80 cancer (proven by biopsy), 32 benign (proven by biopsy or follow-up imaging), and 48 normal exams respectively from each institution. A multi-reader multi-case study was conducted with 7 breast radiologists. Each radiologist read each case without and then with the assistance of Lunit INSIGHT MMG, an AI-based diagnostic-support software. Readers decided whether each case needed to be recalled in their first reading and then modified their decision by referring to the output of the software. Radiologist's performance was evaluated in terms of sensitivity and specificity as follows: 1) single reading (software-unaided), 2) double reading (majority voting of 3 readers, i.e. average of 35 possible combinations of 3 out of 7 readers), and 3) single reading (software-aided). Software standalone performance was also measured.
Results: Average sensitivity and specificity of radiologists based on their binary decision (i.e. recall or not) were 1) single reading (software-unaided): 80.0% and 72.3%, 2) majority voting of 3 radiologists (double reading simulation): 81.9% and 75.4%, 3) single reading (software-aided): 86.3% and 73.8%. Standalone performance of the diagnostic-support software was 88.8% (sensitivity) and 81.9% (specificity).
Conclusion: Radiologist's diagnostic performance was significantly improved; without vs with assistance of the software: 80.0% vs 86.3% (P<.001) in sensitivity and 72.3% vs 73.8% (P<.05) in specificity. Software-assisted performance in terms of sensitivity was better than the majority voting of multiple radiologists.
Limitations: Real clinical value needs to be investigated via prospective studies.
Ethics committee approval: Approved by IRB. Informed consent was waived.
Funding: Lunit Inc.

RPS 702-3 14:22
Reducing the radiologist's workload by detecting normal mammograms with an AI system
A. D. Lauritzen[1], A. Rodriguez-Ruiz[2], M. C. von Euler-Chelpin[3], E. Lynge[3], I. Vejborg[3], M. Nielsen[3], N. Karssemeijer[2], M. Lillholm[4]; *[1]København/DK, [2]Nijmegen/NL, [3]Copenhagen/DK, [4]Roedovre/DK (al@di.ku.dk)*

Purpose: To investigate whether an AI system can detect normal mammographies in a breast cancer screening cohort.
Methods and materials: This retrospective study analysed 18,020 doubly read studies from the Danish Capital Region breast cancer screening program, comprised of 143 screen-detected cancers and 447 non-cancer recalls (false-positives). Using the deep learning-based image analysis tool, Transpara v1.5, all studies were sorted into 10 categories based on findings from four views. A high category (10) indicated a high probability of malignancy, while a low category (1) indicated a very low probability of malignancy. Normal studies were identified as being in category 5 or less. This study examined the number of studies, and non-cancer recalls, that can possibly be avoided by detecting normal studies before radiologist reading.
Results: Using category 5 or less as a threshold, 10,545 (58.52%) studies were classified as normal. Included were 5 screen-detected cancers (3.5%) and 106 non-cancer recalls (23.71%). Category 1 and 2 comprised of 4,738 (26.29%) studies, 26 non-cancer recalls (5.82%), and 2 screen-detected cancers (1.36%). Category 1 comprised of 2,627 (14.58%) studies, 12 non-cancer recalls (2.68%), and 0 screen-detected cancers.
Conclusion: The results show that the AI system can successfully identify normal mammographies with very few missed screen-detected cancers. Furthermore, a substantial amount of false-positive studies were identified as normal. The results suggest that AI systems could potentially effectively and safely reduce the number of studies that radiologists would have to examine by a considerable amount, and several false-positives could be avoided.
Limitations: Transpara identifies a few screen-detected cancers as normal. Having radiologists examine missed cases, future improvements could be made. The number of cancer cases was limited. Results should be confirmed on a larger study.
Ethics committee approval: n/a

The value of 2D-AI-based CAD for second or third reading tested on 17,910 screening mammograms
S. H. Heywang-Köbrunner, A. Jänsch, C. Mieskes, M. Hertlein, A. Hacker;
Munich/DE (sylvia.heywang@referenzzentrum-muenchen.de)

Purpose: To test the capabilities of a new 2D-CAD program based on artificial intelligence and deep learning algorithms for systematic consecutive screen reading.
Methods and materials: For this purpose, 18,002 consecutive screening mammograms acquired in our screening unit between 1/2018-11/2018 were anonymised and processed by the CAD system (iCAD Inc.).
A call was considered positive if the case threshold exceeded 30 (which is a more specific threshold) and a hit was visible within the lesion on at least 1 view. Ground truth for benign lesions was a benign screening result (based on independent double reading), a benign consensus reading of cases considered suspicious by at least one reader, or a benign result after complete workup of cases considered suspicious at consensus reading. Malignancies were proven by percutaneous biopsy and surgery. We counted one diagnosis per patient. Patients with bilateral cancers obtained 1 diagnosis per breast.
Results: We excluded 45 drop-outs due to incomplete work-up (refused etc.), 40 cases with B3 lesions and 7 mammographically occult malignancies detected incidentally during assessment or preoperative staging. The evaluation was patient-based; only patients with bi-lateral cancers were evaluated breast-based. Using a case threshold of 30 CAD achieved a sensitivity of 91.5% (for 32 DCIS and 85 inv. cancers) and specificity of 80.2%; reader1: 84.6% and 91.6%; reader 2 89.7% and 91.5%.
Conclusion: Achieved results justify hopes to use novel CAD systems for a second (e.g. in countries with a shortage of readers) or third reading in the near future. Human consensus reading remains indispensable.
Limitations: n/a
Ethics committee approval: Not necessary since completely anonymised data was used.

Mammographic case conspicuity: a comparison between a radiologist's assessment and a masking index

S. Hickman[1], J. Mainprize[2], R. Black[1], J. Kaggie[1], Y. Huang[1], M. Yaffe[2], F. J. Gilbert[1]; [1]Cambridge/UK, [2]Toronto/CA
(sarah.hickman3@nhs.net)

Purpose: Cancers can be difficult to detect or even missed due to dense breast tissue. This study investigated the relationship between density, characterised using a masking index, lesion conspicuity, and evaluated subjectively, and cases found by only one reader in a double reading mammography screening system.
Methods and materials: Using the TOMMY trial dataset, the contralateral breast mammogram of 566 invasive cancer cases were analysed with a masking algorithm based on density and tissue arrangement. Two radiologists independently classified each cancer as either subtle or obvious, assigned a conspicuity score (1-3), and provided their decision to recall the case or not. Lesion size, radiological feature, and density as measured by a visual analogue score (VAS) was recorded. A generalised linear mixed-effects model was used to account for the non-negative skewed nature of the data to associate the masking index and the radiologist assessments. Size, density, and feature were fixed effects. Random effects included intercepts for subjects, the site of test, and lesion side.
Results: There were 58 subtle and 508 obvious invasive cancers (median age 62 years). Median lesion size was 13 mm [IQR 9-19 mm] with median density VAS 31 [IQR 20-50]. The masking index reduced by 25.9% (p <0.0001) from subtle to obvious cases. The reduction was 16.2% (p=0.017) after the adjustment for size, radiological feature, and density VAS. With lower density (VAS <50), the masking index reduced by 28.4% (p=0.0003) from subtle to obvious cases following adjustment. However, this was not demonstrated in cases with higher density (VAS >=50).
Conclusion: The masking index corresponds with the radiologist's assessment and could provide a quantitative measure to target supplemental imaging.
Limitations: Small subtle case sample size.
Ethics committee approval: Dataset from ethically approved TOMMY trial.
Funding: CRUK programme grant.

Acceptability of 3D printed breast models and their impact on the decisional conflict of breast cancer patients

L. Santiago, E. Arribas, B. E. Adrada, D. Black, C. Checka, J. Lee, R. Volk; Houston, TX/US
(Lumarie.Santiago@mdanderson.org)

Purpose: To evaluate the acceptability and impact of 3D printed breast models (3DM) on treatment-related decisional conflict (DC) of breast cancer patients.
Methods and materials: Patients with breast cancer were accrued in a prospective single-institution trial. All patients underwent contrast-enhanced breast MRI (MRI). A personalised 3D printed breast model (3DM) was derived from MRI. DC was evaluated pre and post 3DM review. Acceptability was assessed post 3DM review.
Results: Pre and post 3DM DC evaluation and 3DM acceptability assessment were completed by 25 patients. Bilateral 3DM was generated in 2 patients with bilateral breast cancer. The mean patient age was 48.8 years (28-72). Tumour stage was Tis (7), 1 (8), 2 (8) and 3 (4). The nodal staging was 0 (19), 1 (7), and 3 (1). Tumours were unifocal (15), multifocal (8), or multicentric (4). Patients underwent mastectomy (13) and segmental mastectomy (14) with (20) or without (7) oncoplastic intervention. 7 patients underwent neoadjuvant therapy. The mean pre and post 3DM DC scores were 16.6 (SD 15.3) and 10.0 (SD 13.2). There was a significant reduction in overall DC post 3DM review indicating patients became more assured of their treatment choice (p=0.001). DCS reduction post 3DM was also observed in the uncertainty (p=0.18), informed (p=.005), values (p=0.41), and effective (p=0.001) DCS subscales. No significant reduction was observed in the support of DCS subscale (p=0.148). 3DM acceptability was rated as good/excellent in understanding their condition, disease size, surgical options, encouraging to ask questions, 3DM detail, 3DM size, and 3DM impartiality.
Conclusion: 3DM are an acceptable tool to decrease decisional conflict in breast cancer patients.
Limitations: Small sample size.
Ethics committee approval: Institutional review board approval. Informed consent obtained.

Improving radiologist performance in breast cancer detection with the concurrent use of an artificial intelligence tool

S. Pacilè[1], J. Lopez[2], P. Chone[3], T. Bertinotti[4], P. Fillard[4]; [1]Valbonne/FR, [2]Newport Beach/US, [3]Oakland/US, [4]Paris/FR (spacile@therapixel.com)

Purpose: To demonstrate and estimate the benefits that an artificial intelligence (AI) tool could bring to the breast cancer detection performance of radiologists.
Methods and materials: The study was designed as a multi-reader multi-case investigation with fully-crossed design so that each case was read by each reader both with and without the aid of AI. It involved 14 participants who read a set of digital mammography (DM) images, half of them without AI and the other half with the help of AI during one first session and complementary cases during a second session. The used dataset included 240 cases (80 true positives, 40 false negatives, 80 true negatives, and 40 false positives).
The AI tool (MammoScreen v1.0.0, Therapixel) that was used is a system designed to identify suspicious regions for breast cancer on DM and assess their likelihood of malignancy. Area under the ROC curve and sensitivity were assessed as endpoints.
Results: Among readers, 11 (79%) increased their AUC using the AI system. The average AUC across readers was 0.769 when reading unaided and 0.797 when using the AI system. The average difference in AUC was 0.028 (95% CI: 0.002, 0.055 and p = 0035). Likewise, average sensitivity was shown to be increased by 0.033 when using AI support (p = 0.021). Figure 1-2 provide case examples where 9 radiologists detected small invasive cancers only using AI, avoiding making a false negative.
Conclusion: The overall conclusion of this study is that the performance of radiologists in reading mammograms is improved with the concurrent use of this new AI-based tool.
Limitations: n/a
Ethics committee approval: The investigation protocol was approved by an IRB.
Funding: The study was sponsored by Therapixel.

RPS 702-8 14:52

Validation of a deep learning-based breast density estimation tool on a Danish screening cohort in the context of personalised risk-based screening

A. D. Lauritzen[1], M. C. von Euler-Chelpin[2], E. Lynge[2], I. Vejborg[2], M. Nielsen[2], M. Lillholm[3]; [1]København/DK, [2]Copenhagen/DK, [3]Roedovre/DK
(al@di.ku.dk)

Purpose: To validate a fully automatic density estimation tool on a screening cohort in terms of agreement with radiologists' BI-RADS and cancer risk segregation.
Methods and materials: This study was based on the Danish Capital Region breast cancer screening program from November 1st, 2012, to December 31st, 2013. 4-view FFDMs were available for 53,956 women. The cohort's median age (IQR) was 59 (54-65) and the cohort comprised of 568 cancers. Radiologist's BI-RADS 4th edition scores were available from two readers. Using a deep learning-based fully automatic tool developed by the University of Copenhagen, all FFDMs were scored for planimetric percent mammographic density (PMD). The correspondence between two-reader consensus BI-RADS and PMD was evaluated in terms of Spearman correlation and, after categorisation of PMD, with weighted kappa statistics (WKS). The latter was compared to the readers' interobserver WKS. In terms of cancer risk segregation, the area under the ROC-curve (AUC) was compared for PMD and consensus BI-RADS, both with age as a covariate in a logistic regression model.

Results: The correlation between PMD and consensus BI-RADS was 0.85. The WKS between PMD and consensus BI-RADS was 0.693, and the radiologist inter-observer WKS was 0.692. The AUC for cancer risk was 0.60 (0.57-0.62) for PMD+age and 0.59 (0.56-0.61) for consensus BI-RADS+age.
Conclusion: PMD matched radiologists' BI-RADS in terms of the agreement between categorised PMD and consensus BI-RADS and the radiologists' interobserver agreement; both were substantial. For cancer risk segregation, there was no significant difference between consensus BI-RADS and PMD. Regarding personalised screening using mammographic density as a risk factor, the results suggest that automated PMD would work as well as consensus BI-RADS of two radiologists.
Limitations: The two readers work at the same clinic.
Ethics committee approval: n/a

Reproducibility of a semiquantitative scoring system to assess breast arterial calcifications (SSS-BAC) on mammography

A. Cozzi, R. M. Trimboli, M. Codari, C. B. Monti, C. Nenna, D. Spinelli, D. Capra, M. Alì, F. Sardanelli*; Milan/IT (andrea.cozzi@gmail.com)*

Purpose: To propose a semiquantitative score system for BAC assessment (SSS-BAC) and estimate its intra- and inter-reader reproducibility.
Methods and materials: In this retrospective study, consecutive women who underwent screening mammography at our centre from 01/01/2018 to 31/01/2018 were retrieved and included according to BAC presence. Two readers (R1 and R2) independently applied the SSS-BAC to both mediolateral oblique views, obtaining a score as the sum of: 1) number of calcified vessels (from 0 to n), 2) calcium burden (0 or 1), and 3) length of calcified vessels (from 0 to 4). R1 repeated the assessment two weeks later. Reading time was recorded for both readers on a subgroup of 10 subjects. Cohen κ statistics and Bland–Altman analysis were used to assess intra- and inter-reader reproducibility.
Results: Of a total 408 asymptomatic women who underwent mammography during the study period, 57 (14%) had BAC, so that 114 medio-lateral oblique views were assessed. Median final score was 4 (interquartile range [IQR] 3–4) for R1 and 4 (IQR 2–4) for R2 (P=0.417) while median reading time was 156 seconds (IQR 99–314 seconds) for R1 and 191 (IQR 137–292 seconds) for R2 (P=0.743). Bland–Altman analysis showed a 77% intra-reader reproducibility (bias 0.193, coefficient of repeatability [CoR] 0.955) and a 64% inter-reader reproducibility (bias 0.211, CoR 1.516).
Conclusion: SSS-BAC showed high reproducibility and was applied in about 2–3 min. It could be utilised in future studies to stratify cardiovascular risk and in trials for cardiovascular events prevention in the female population.
Limitations: Single-centre study. Only two readers.
Ethics committee approval: Ethics committee approval was obtained.
Funding: No funding was received for this work.

Deep learning-based calcification segmentation for imperfect mammography data

M. Jie[1], M. Xu[1], X. Lin[1], Y. Zhang[2], Z. Cao[2], S. Wu[1], L. Huang[1], M. Wu[1], Y. Wang[1]; *[1]Shenzhen/CN, [2]Palo Alto/US (majie688@hotmail.com)*

Purpose: Calcification detection from mammograms plays a vital role in early breast cancer diagnosis. We propose an automatic calcification segmentation solution based on deep learning framework and a series of novel pre-processing methods.
Methods and materials: We develop a series of novel pre-processing methods to normalise mammogram images and encourage the consistency of labels, and then a modified U-Net framework was applied to segment calcifications. Firstly, mammogram images were pre-processed, including window adjustment, breast region extraction, and artefact removal. Small patches with the size of 512*512 were extracted from original mammograms. Then, based on the size and shape, the calcification labels were classified as three types: dots, vessels, and clusters. To encourage the consistency of labels, the patches containing vessels were excluded from the training data. Then, a U-Net model with group normalisation was trained using the processed data. Finally, the obtained best two U-Net models were ensembled to segment calcifications. The training and evaluation were performed on an in-house dataset consisting of 1,776 mammograms with calcifications. Calcifications in this dataset were annotated by two experienced radiologists. The data was randomly split as training (60%), validation (20%), and test data (20%), respectively.
Results: In our evaluation, a predicted calcification is assumed as detected if more than 25% area is covered by the label. Recall at 1 false-positive per image for the three calcification types (dots, vessels, and clusters) are 0.691, 0.971, and 0.912. In comparison, recall at 5 false positives per image for these three calcification types reach 0.918, 1.00, and 0.988, respectively.
Conclusion: The developed pre-processing methods and the modified U-Net framework can effectively segment various types of calcifications.
Limitations: The size of the database is limited.

Workflow reduction and performance using an FDA cleared platform for mammography triage

A. Watanabe[1], V. D. Lim[2], L. N. Tanenbaum[3]; *[1]Manhattan Beach, CA/US, [2]La Jolla/US, [3]New York, NY/US (alyssa90266@gmail.com)*

Purpose: To assess performance and potential for workflow reduction using a deep learning triage algorithm.
Methods and materials: An FDA-cleared deep learning (DL) algorithm (cmTriageTM, CureMetrix, Inc.) was used to analyse two data sets of 2D mammograms. The first set was comprised of 400 biopsy-confirmed malignant cases and 855 negative cases from 4 institutions (with at least one-year follow-up as validation of benignity). The second set of 597 sequential screening mammograms was obtained at a single academic institution between July 1 and July 31, 2013.
Results: The overall AUC of the triage software is 0.95 (CI = [0.94, 0.96]). In the first simulation, at the default setting, cmTriage performed with a specificity of 77% and sensitivity of 93% (95% CI = [0.90,0.96]). At very high sensitivity of 99% with 95% CI = [0.97,1.00]), the specificity was 40% and 40% of the cases could have been removed from the worklist.
In the second study, there was a worklist reduction of 30% (at high sensitivity) to 63% (at default) of the screening mammograms.
There was 60% recall reduction at default and 32% reduction at high sensitivity (all false). There was a 11% reduction of benign biopsies at default. The recall rate would be reduced by 44% and 30% respectively with no loss in sensitivity at either operating point. There were no missed cancers at the high sensitivity setting.
Conclusion: Pre-analysis of mammograms using this triage software has the potential to significantly improve radiologist performance and enhance workflow and productivity without impairing sensitivity.
Limitations: This was a retrospective study. The sample size of the two data sets is limited and expansion to larger data sets is needed.
Ethics committee approval: n/a

Mammographic breast density assessment using deep learning especially for Asian women: clinical implementation

J. Liu[1], F. Yang[1], J. Tao[1], L. Shi[2], J. Lv[2]; *[1]Wuhan/CN, [2]Hangzhou/CN (liu_jie0823@163.com)*

Purpose: As high density in Asian women increases, the existing evaluation model of European and American women's breast density is not applicable in

China. The aim of this work was to investigate a deep learning (DL)-based breast density classifier to consistently distinguish the “dense” category.
Methods and materials: In this prospective study, we collected 2,548 digital mammograms from 637 women. An independent assessment of breast density was performed by four experienced radiologists to form a gold standard. We then used the gold standard to verify the performance of the existing AI model, which was based on the ResNet-18 neural network trained on the original interpretation of 80,156 digital screening mammograms.
Results: The DL model showed excellent accuracy (81%) and good agreement with radiologists in the test set (k = 0.67; 95% confidence interval [CI]: 0.64,0.70). The recall and precision were 49.42% and 66.15% in group A, 82.87% and 67.05% in group B, 86.00% and 87.83% in group C, and 67.65% and 96.72% in group D, respectively.
Conclusion: The proportion of each classification affects the accuracy of the training set. We got better performance in the test set of group D compared to other studies because of the higher proportion. Therefore our DL model is more suitable for Asian women (19% in training set and 12% in the test set of group D), which will help to establish the risk assessment models of breast cancer for Asian women.
Limitations: There is a lack of data for more regions in Asia, such as Korea and Japan, and we are going to do a multicentre study.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Deep learning-based mass segmentation in mammograms
M. Jie[1], M. Xu[1], X. Lin[1], Z. Cao[2], Z. Yang[2], S. Wu[1], L. Huang[1], M. Wu[1], Y. Wang[1]; [1]*Shenzhen/CN,* [2]*Palo Alto/US (majie688@hotmail.com)*

Purpose: Interpreting mammograms is an expertise-required task. We propose an improved encoder-decoder structured CNN model deeplab v3+ for automatic mass segmentation in mammography.
Methods and materials: We collected ~2,250 mammograms with mass lesions from three public datasets (CBIS-DDSM, INbreast, and Breast Cancer Digital repository (BCD) and 910 retrospective mammograms with mass lesions from an in-house dataset (Jan 2017 to May 2019). An encoder-decoder structured CNN, deeplab, integrated with atrous spatial pyramid pooling and atrous depth-wise convolution, was leveraged to segment masses. With Xception as the backbone, a novel pixel-wise focal loss was developed to further improve the detected mass contours. The CBIS-DDSM data and our in-house dataset were randomly split as training (60%), validation (20%), and test data (20%), respectively. The other two datasets (INbreast and BCD), along with the training subset of CBIS-DDSM, constituted the training set, while the validation and test subsets of CBIS-DDSM were the sole validation and test sets. The best model obtained using the public datasets was further fine-tuned on the in-house training data and then applied to the in-house validation and test data, respectively.
Results: The FROC curve of the deeplab model with Xception as the backbone and with the images downsampled by 3 was the highest. The baseline deeplab model reports 0.78 (Average Precision(AP)) and 0.883 (recall). Our best model reports 0.805 (AP) and 0.977 (recall) on the public test data, and 0.901 (AP) and 0.94 (recall) on the in-house dataset.
Conclusion: This study demonstrates a CNN-based segmentation model deeplab v3+, embedded with atrous spatial pyramid pooling and atrous depth-wise convolution, with Xception backbone, for effectively mass segmentation in mammography.
Limitations: The bias caused by race difference is not well considered.

RPS 703-1 14:00
4D-flow-derived mitral valve vortex ring: the relationship with left ventricular function
C. Kräuter[1], U. Reiter[1], C. Reiter[1], V. Nizhnikava[1], M. Masana[2], A. Schmidt[1], M. Fuchsjäger[1], R. Stollberger[1], G. Reiter[1]; [1]*Graz/AT,* [2]*Barcelona/ES*

Purpose: The mitral valve (MV) vortex ring is a swirling blood flow structure formed during diastole that is thought to store the kinetic energy of blood entering the left ventricle (LV). Cardiac magnetic resonance four-dimensional phase-contrast (4D-flow) imaging allows for the analysis of the MV vortex ring. The aim of this study was to investigate the relation of absolute and relative vortex ring kinetic energy with systolic and diastolic LV function parameters.
Methods and materials: 21 healthy subjects (male/female 7/14; age 59±7 years) underwent realtime-cine and 4D-flow imaging at 3T. LV volumetric function parameters (ejection fraction, ventricular volumes, and peak filling rates) were determined from realtime-cine series with routine software. Pre-processing of velocity data as well as the measurement of peak early-(E) and late-(A)-diastolic transmitral velocities were performed by prototype software (4DFlow, Siemens Healthcare). MV vortex rings were automatically detected and evaluated by in-house software. Dependencies of early- and late-diastolic peak absolute and relative kinetic energy ($Ekin_{abs,E}$, $Ekin_{rel,E}$, $Ekin_{abs,A}$, and $Ekin_{rel,A}$) on LV function parameters were assessed by correlation analysis.
Results: Early- and late-diastolic MV vortex rings were detected in each subject. While LV volumetric function parameters did not correlate significantly with vortex ring kinetic energy, early- and late-diastolic peak transmitral velocities (E=74±12cm/s, A=67±13cm/s) showed strong correlations with the respective peak kinetic energies ($Ekin_{abs,E}$=1.48±0.66mJ, r=0.86; $Ekin_{rel,E}$=67.7±24.4J/m^3, r=0.90; $Ekin_{abs,A}$=1.09±0.55mJ, r=0.89; $Ekin_{rel,A}$=57.8±23.3J/m^3, r=0.93). Furthermore, the E/A ratio (E/A=1.14±0.23) correlated strongly with the ratio of peak kinetic energies ($Ekin_{abs,E}/Ekin_{abs,A}$=1.61±0.87, r=0.80; $Ekin_{rel,E}/Ekin_{rel,A}$=1.32±0.64, r=0.84).
Conclusion: MV vortex ring kinetic energy demonstrated a strong relation with peak transmitral inflow velocities, suggesting the MV vortex ring as a promising structure for studying LV diastolic function.
Limitations: A small number of subjects.

Quantitative assessment of left ventricular regional myocardial strain changes in patients with coronary chronic total occlusion using cardiac magnetic resonance: a pilot study
K. Liu, Z. Li, C. Xia, K. Diao; *Chengdu/CN*
(634270986@qq.com)

Purpose: To investigate the differences of regional strain parameters between myocardial segments dominated by the occlusive and non-occlusive vessels in patients with coronary chronic total occlusion (CTO) using cardiac magnetic resonance (CMR).
Methods and materials: 42 patients (30 men, 66.5±8.2 years) with CTO confirmed by coronary angiography (CAG) were enrolled and underwent bSSFP cine CMR on a Siemens 3.0T MRI scanner. 3D regional strain parameters of left ventricular (LV) myocardial segments were measured using tissue tracking procedure on CVI42 software, based on a standardised 17-segment model of AHA. These parameters included regional radial, circumferential and longitudinal peak strain (PS), peak systolic strain rate (PSSR), peak diastolic strain rate (PDSR), and peak displacement (PD). The occlusive vessel was

determined by CAG results and a two-independent t test was used to analyse the difference of strain parameters between myocardial segments dominated by the occlusive and non-occlusive vessels.
Results: Compared with myocardial segments dominated by non-occlusive vessels, the above strain parameters of myocardial segments dominated by occlusive vessel all decreased. There were significant differences on radial PS [(33.52±15.13) % vs. (20.64±10.51)%, P=0.007], circumferential PS [(-17.48±4.89) % vs. (-14.45±6.72) %, P=0.037], radial PSSR [(2.95±2.32) s-1 vs. (1.36±0.98) s-1, P=0.04], circumferential PSSR [(-1.05±0.39) s-1 vs. (-0.85±0.38) s-1, P=0.034], radial PD [(6.15±2.13) mm vs. (4.60±2.01) mm, P=0.003], and longitudinal PD [(6.15±3.87) mm vs. (4.43±2.59)mm, P=0.034].
Conclusion: Strain analysis by CMR can quantitatively evaluate LV myocardial deformation and detect early cardiac regional dysfunction, which has potential clinical value for identifying ischaemic myocardial segments in CTO patients.
Limitations: A lack of studies on the diagnostic performance of strain parameters.
Ethics committee approval: This study was approved by Institutional Medical Ethics Committee of our institute. Written informed consent was obtained from all patients.

Academic challenge meets reality: the transfer of a cardiac ventricle segmentation algorithm to clinical data

C. Anastasopoulos[1], P. Full[2], T. Akıncı D'antonoli[1], F. Isensee[2], P. Haaf[1], K. Maier-Hein[2], J. Bremerich[1], B. Stieltjes[1], G. Sommer[1]; [1]*Basel/CH,* [2]*Heidelberg/DE*

Purpose: To investigate the predictive power of an award-winning deep-learning ventricle segmentation (DLVS) trained on a publicly available data-set if applied to a clinical data-set without further training.
Methods and materials: 899 cardiac MRI data-sets with short-axis steady-state free precession cines that had been semi-automatically segmented for clinical reading were retrospectively included. Reported left/right ventricular (LV/RV) volumes and ejection fraction (EF) served as ground truth. Parameters were recalculated using a fully automatic DLVS, which won the MICCAI Automated cardiac diagnosis challenge. Cases were classified as normal or pathologic using established thresholds for indexed end-diastolic volume (EDVi), EF, and mass.
Results: DLVS showed good correlation to reported values for LV-EDVi (R^2 0.95), LV-EF (R^2 0.83), and mass (R^2 0.82). For RV-EDVi (R^2 0.62) and RV-EF (R^2 0.29), prediction deviated from reported values. According to the reports, 485/899 cases had reduced LV-EF (<57%), which was predicted by DLVS with a 79% accuracy, 7% false-positive, and 33% false-negative rate (FPR/FNR). Reduced RV-EF (≤50%; 231 cases) was predicted with a 75% accuracy, 18% FPR, and 48% FNR. LV dilatation (EDVi males >105, females >96mL/m^2; 233 cases) was predicted with a 94% accuracy, 7% FPR, and 3% FNR. RV dilatation (EDVi m>121, f>112mL/m^2; 42 cases) was predicted with a 91% accuracy, 7% FPR, and 31% FNR. LV hypertrophy (m>176, f>140g/m^2; 208 cases) was predicted with a 89% accuracy, 2% FPR, and 40% FNR.
Conclusion: Automatic segmentation of a large clinical sample delivered satisfactory results, especially for LV-EDVi. Nevertheless, deviations for other parameters were substantial and consequently led to a prominent number of clinical misclassifications. This indicates a need for more clinically representative data in challenges.
Limitations: Clinical reading volumetric results might not be suitable as ground truth.
Ethics committee approval: Ethics committee approval obtained.
Funding: No funding was received for this work.

Retro-gated compressed sensing cardiac cine imaging: sharper borders and accurate ventricular quantification in 60 seconds

B. Longere[1], L. Grenier[1], J. Pagniez[1], V. Silvestri[1], A. Simeone[1], M. Schmidt[2], C. Forman[2], F. Pontana[1]; [1]*Lille/FR,* [2]*Erlangen/DE (fpontana@gmail.com)*

Purpose: To evaluate a newly developed segmented retro-gated compressed sensing (CS-RG) cine sequence in comparison with conventional segmented retro-gated multi-breath-hold balanced SSFP (SSFP-REF) and real-time single-breath-hold compressed sensing cine (CS-RT).
Methods and materials: 30 adult patients referred for CMR underwent a protocol on a 1.5T scanner (MAGNETOM Aera, Siemens Healthcare) including at least a short-axis stack and one vertical and one horizontal long axis slice using (a) the reference retro-gated multi-breath-hold cine SSFP-REF, (b) the single-breath-hold CS-RT cine sequence, and (c) the 3-breath-hold CS-RG prototype sequence. Two readers independently assessed LV and RV end-diastolic volume (EDV), end-systolic volume (ESV), ejection fraction (EF), and LV mass for each sequence. Image quality was objectively compared using edge-sharpness measurements and subjectively rated with a 4-point scale.
Results: The mean scan time of SSFP-REF was 485.4 ±83.3s with a mean of 15.0 ±1.2 breath-holds vs 23.9 ±5.2s with CS-RT and 58.3 ±15.1s with CS-RG (p<0.0001). Analysis of variance demonstrates no significant difference regarding mean LV and RV volumes (EDV, ESV), or EF and LVM (p >0.17). All images were rated as diagnostic with a similar subjective image quality between CS-RG and SSFP-REF mainly rated as excellent (p=0.31), higher than the score mainly rated as good, with CS-RT (p=0.0008). CS-RG demonstrated a significantly better edge sharpness than CS-RT (0.083 ± 0.013pixel^{-1}vs 0.070 ±0.011 pixel^{-1}; p=0.0004) and no significant difference with SSFP-REF (0.075 ± 0.016pixel^{-1}; p=0.0516).
Conclusion: CS-RG cine provides an accurate quantification of LV and RV functional parameters in 3 breath-holds and in around one minute without compromising the sharpness of myocardial borders and image quality.
Limitations: No major limitation except sample size.
Ethics committee approval: Each patient gave informed consent.

The role of strain analysis in patients with suspicious arrhythmogenic cardiomyopathy

G. Muscogiuri[1], F. Ricci[2], L. Fusini[1], M. Guglielmo[1], A. Baggiano[1], A. I. Guaricci[3], G. Cicala[4], M. Pepi[1], G. Pontone[1]; [1]*Milan/IT,* [2]*Rome/IT,* [3]*Bari/IT,* [4]*Parma/IT (g.muscogiuri@gmail.com)*

Purpose: To evaluate biventricular strain in the early diagnosis of AC.
Methods and materials: We retrospectively evaluated 38 patients who underwent cardiac magnetic resonance and myocardial biopsy suggestive for AC between 2016 and 2019.
MR images were transferred to an off-line dedicated workstation and global longitudinal (GLS), circumferential (GCS), and radial (GRS) strain were calculated using a dedicated tool. After the evaluation of volumes and function, the population was divided based on MR imaging criteria for the diagnosis of AC (Model 1). Model 2 divided the population into two parts, using EF of left ventricle (LV EF)≥55% as a cut-off value. Model 3 identified patients with a positive biopsy and the absence of imaging criteria for AC plus LV EF≥55%.
All the MR parameteres were compared with a healthy population who underwent cardiac MR for other purposes. A p value < 0.05 was considered statistically significant.
Results: In Model 1, a statistically significant difference (p<0.01) was observed for GLS, GCS, and GRS of LV between the normal population and the population with a positive biopsy. Similarly, significant results of Model 1 were observed for RV in terms of GCS and GRS.
In Model 2, a significant difference of left ventricle GLS and GRS was observed between patients with a positive biopsy and LV EF ≥ or < 55%.
In Model 3, the GRS (p: 0.02) and GCS (p: 0.003) resulted in statistically significant differences compared to the normal population.

Conclusion: An analysis of strain could be extremely helpful for the identification of patients that do not satisfy the criteria for diagnosis of AC.
Limitations: The population was composed exclusively by patients with a positive biopsy. It would be interesting to include patients with a negative biopsy.
Ethics committee approval: In process.
Funding: No funding was received for this work.

Compressed sensing 4D flow assessment of parameters of left ventricular diastolic function
G. Reiter[1], C. Reiter[1], N. Jin[2], F. Testud[3], C. Kräuter[1], D. Giese[4], A. Triebl[1], M. Fuchsjäger[1], U. Reiter[1]; [1]*Graz/AT,* [2]*Chicago/US,* [3]*Malmoe/SE,* [4]*Erlangen/DE (gert.reiter@siemens-healthineers.com)*

Purpose: Cardiac magnetic resonance four-dimensional (4D) flow imaging is a potential technique for the characterisation of left ventricular (LV) diastolic function, which could substantially benefit from a reduction of scan times. The purpose of the present study was to investigate if the acceleration of whole-heart 4D flow imaging by compressed sensing (CS) could be employed to derive standard parameters of LV diastolic function.
Methods and materials: 11 adult cardiac patients with regular heart rhythm were prospectively recruited for 3T (Magnetom Skyra, Siemens Healthcare, Erlangen, Germany), ECG- and navigator-gated whole-heart 4D flow imaging with CS (acceleration-factor=7.6), and without CS (parallel acquisition acceleration-factor=3). Protocols of the prototype sequence were matched for spatial resolution and the number of reconstructed frames. For both data sets, early- (E) and late diastolic (A) transmitral peak velocities, systolic (S) and diastolic (D) pulmonary venous peak velocities, as well as early-diastolic peak mitral annular velocity (e'), were evaluated using a prototype software (4DFlow, Siemens Healthcare, Erlangen, Germany). The corresponding parameters of LV diastolic function E/A, S/D, and E/e' were calculated. The relationships of the velocity-ratios derived with and without CS were investigated by means of correlation and Bland-Altman analysis.
Results: CS acquisition reduced scan time significantly (369±92 s vs. 618±119 s, p<0.01). Velocity-ratios from CS measurements (E/A=1.35±0.31; S/D=1.11±0.33; E/e'=11.7±4.7) exhibited no significant bias compared to respective results without CS (E/A=1.44±0.31, p=0.15; S/D=1.16±0.29, p=0.13; E/e'=11.8±4.8, p=0.92), demonstrated small standard deviations of errors (0.17, 0.10 and 2.6 for E/A, S/D and E/e', respectively), and correlated strongly (r=0.85, 0.96 and 0.85 for E/A, S/D and E/e', respectively).
Conclusion: Compressed sensing allows substantial acceleration of whole-heart 4D flow imaging without a significant impact on the evaluation of standard parameters of LV diastolic function.
Limitations: A small subject number.

Extra-cellular volume (ECV) of the left and right ventricle as a marker to triage diastolic dysfunction
A. Kapoor, G. Mahajan, A. Kapoor; *Amritsar/IN (masatulak@aim.com)*

Purpose: To evaluate the role of extracellular volume estimation to triage left ventricle diastolic dysfunction.
Methods and materials: Informed consent was taken from 100 consecutive new patients with stage II diastolic dysfunction tissue doppler echocardiography with preserved ejection fraction > 50%. Pro BNP levels, demographic data, and treatment details were noted.
ECV of the left and right ventricle (LV and RV) was determined on cardiac MR (Siemens 1.5T Amira) using T1 MOLLI plain and contrast study. Patients were categorised into three groups: Group I) with normal ECV of RV and LV (<27%), Group II) with abnormal ECV of LV and normal ECV of RV, and Group III) with raised ECV of RV and LV.
Patient follow-up was for one year to determine the occurance of readmission or mortal event.
Results: There were 67 males and 43 females with a mean age of 67 years. 32 patients were in group I, 48 in group II, and 20 in group III. The mean pro BNP levels raised in group II in 72% patients and in 100 % in group III (p value 0.5). The mean ECV of LV and RV in groups I, II, III were 22%, 32%, and 37%, and 23%, 24%, and 35%, respectively (p<0.05). The one-year readmission was 6%, 15%, and 40% in group I, II, and III patients (p<0.01).
Conclusion: ECV estimation of LV and RV can triage patients of LV diastolic dysfunction, which has a significant effect on first-year hospital readmission. Pro BNP levels show a poor correlation with ECV.
Limitations: A small cohort of patients with left ventricle dysfunction, short follow-up of one-year, and the non-use of other serum fibrotic markers.

Age and sex-related influences on left atrial phasic function in type 2 diabetes mellitus patients from a Chinese population: a feature tracking cardiovascular magnetic resonance imaging
M.-T. Shen, Z.-G. Yang; *Chengdu/CN*

Purpose: Left atrial (LA) phasic function is tightly linked to T2DM and confers key prognostic information. The influences of age and sex on LA phasic function using FT-CMR in T2DM patients is unclear. Therefore, we used FT-CMR to assess LA phasic function in T2DM patients based on age and sex.
Methods and materials: 150 T2DM patients (64% men; mean age, 53.43±11.02 years) were eligible for FT-CMR analysis. LA longitudinal strain and strain rate at systolic were εs and SRs, early diastolic were εe and SRe, and late diastolic were εa and SRa, which reflected reservoir, conduit, and pump function, respectively. All parameters were analysed by CVI42 and compared in terms of age and sex.
Results: Women demonstrated higher conduit function (εe: 13.36±3.63% vs. 11.77±3.23%, p=0.014; SRe: -1.50±0.41 vs. -1.32±0.44, p=0.023) and lower pump function (εa: 9.75±2.83% vs. 10.90±2.81%, p=0.048; SRa: -1.16±0.41 vs. -1.41±0.42; P=0.002) than men, while the reservoir function was similar. Women showed age-dependent more pronounced reservoir functional decay and pump functional augment than men (P for interaction, <0.05). Increasing age was independently associated with deteriorated conduit function and augment pump function, even after accounting for baseline clinical covariates in multivariable models that incorporated LA volume, LAEF, LVEF, LV global strain, and LV mass/end-diastolic ratio (all P<0.001).
Conclusion: Our findings suggest that women with T2DM demonstrated higher conduit and lower pump function than men with T2DM, and aging deteriorated conduit and increased pump function in both sexes, being more prominent in women at advanced ages, and was independent of baseline characteristics.
Limitations: A limited sample size.

Myocardial mass corrected strain yields high diagnostic performance to differentiate between health and disease
M. C. Halfmann, S. Benz, T. Leckebusch, T. Klimzak, M. Michael, M. Larisch, C. Düber, K.-F. Kreitner, T. Emrich; *Mainz/DE (Moritz.Halfmann@gmx.de)*

Purpose: Correction of feature tracking (FT) derived strain values to myocardial mass lead to an improvement in the diagnostic power in acute myocarditis and hypertensive heart disease. The purpose of this study was to evaluate this concept in a large cohort of various cardiomyopathies in comparison to healthy volunteers.
Methods and materials: This study incorporated 444 data sets of healthy volunteers (n=127) and various cardiac diseases with and without depressed ejection fraction (n=317). CINE images in typical short- and long axis orientation were used to calculate traditional parameters of cardiac function and volumes, as well as FT derived strain values. Subsequently, strain values were corrected

to myocardial mass (strain-ratio). For post-processing, a dedicated cardiovascular software tool was used (cvi42, Circle, Calgary, Canada). ROC-Analysis was used to compare the diagnostic power to differentiate between health and disease.
Results: Global longitudinal rStrain showed the highest diagnostic power to differentiate between health and disease with an AUC of 0.904, resulting in a sensitivity and specificitiy of 82.8% and 82.6%. For differentiation of health and disease, rStrain clearly outperformed EF (ΛAUC: 0.20), EDV (ΛAUC: 0.43), myocardial mass (ΛAUC: 0.04), and "naked" longitudinal strains (ΛAUC: 0.15).
Conclusion: Myocardial mass corrected strains are a powerful method to discriminate between health and various acute and chronic cardiomyopathies.
Limitations: A single-centre study and retrospective study design.
Ethics committee approval: All patients provided written informed consent. The study was approved by the local ethics committee (2018-13520/837.196.13/837.477.14).
Funding: No funding was received for this work.

Global myocardial strains in pulmonary hypertension: association with severity of the disease

V. Nizhnikava, G. Reiter, U. Reiter, C. Reiter, C. Kräuter, G. Kovacs, H. Olschewski, M. Fuchsjäger*; Graz/AT (volha.nizhnikava@gmail.com)*

Purpose: Pulmonary hypertension (PH) is associated with left (LV) and right ventricular (RV) functional and myocardial alterations. Cardiac magnetic resonance (CMR) cine-imaging is used not only for the assessment of volumetric function but also for the determination of myocardial strain parameters.
The aim of the study was to compare associations of feature-tracking derived myocardial strain parameters with mean pulmonary arterial pressure (mPAP) and volumetric function in patients with PH.
Methods and materials: 34 patients with PH underwent right heart catheterisation for mPAP assessment (mPAP=44±11mmHg) and CMR cine realtime free-breathing imaging at 3T (Skyra, Siemens Healthcare) within 1±3 days. LV and RV volumetric parameters were evaluated from short-axis slices (Argus, Siemens Healthcare). Global radial (GRS), circumferential (GCS), and longitudinal (GLS) LV and RV strains and strain rates (GRS_{rate}, GCS_{rate}, and GLS_{rate}, respectively) were assessed from short-and four-chamber series (cvi42, Circle Cardiovascular Imaging) using a two-dimensional approach. Relations between parameters were analysed by regression and correlation analysis.
Results: Significant correlation with mPAP was found for the following strain parameters: RV-GRS (r=-0.43), systolic RV-GRS_{rate} (r=-0.41), RV-GCS (r=0.41), systolic LV-GRS_{rate} (r=0.42), and systolic LV-GCS_{rate} (r=-0.42).
All strain parameters correlated more strongly to respective ejection fraction (EF) than to mPAP: RV-GRS (r=0.62), systolic RV-GRS_{rate} (r= 0.45), and RV-GCS (r=-0.62) with RV-EF; systolic LV-GRS_{rate}(r=0.63) and systolic LV-GCS_{rate} (r=-0.54) with LV-EF. With the respective EF as the covariate, only partial correlations of LV strain parameters with mPAP remained significant (r=0.46 for systolic LV-GRS_{rate}, and r=-0.46 for systolic LV-GCS_{rate}).
Conclusion: In PH patients, global LV and RV strain parameters are more strongly associated with ventricular function than with the severity of PH. Consistent correlations of LV systolic strain rates with mPAP might be related to septal bowing.
Limitations: A single-centre study.
Ethics committee approval: NCT01725763.

Feasibility and value of right atrial strain in patients with inoperable chronic thromboembolic pulmonary hypertension (CTEPH)

V. Bethke, A. Hasse, M. Richter, A. Brose, C. Liebetrau, C. B. Wiedenroth, K. Tello, G. Krombach, F. Roller*; Giessen/DE*

Purpose: Ventricular strain analysis showed promising results in patients with pulmonary hypertension. In contrast, right atrial (RA) strain is not yet well investigated. Therefore, the aim of this study was to assess the feasibility and value of RA strain in patients with inoperable chronic thromboembolic pulmonary hypertension.
Methods and materials: MRI at 1.5 Tesla and right heart catheterisation were performed before and 6 months after BPA in 30 consecutive CTEPH patients (mean age 63.4±10.6 years; 17 female). RA feature tracking strain analysis was performed (global longitudinal (GL) and global radial (GR)) and compared to 30 control patients (mean age 56.6±9.5 years; 19 female). Results were also correlated to right ventricular function (RVEF) and measures of pulmonary haemodynamic (mPAP and PVR).
Results: RVEF, mPAP, and PVR significantly decreased after BPA (all p<0.0001). Moreover, RA strain parameters decreased significantly after BPA (GL -15.1±6.9 to 18.5±4.8, p < 0.0005; GR 27.7±12.2 to 37.0±12.8, p=0.0001) and were significantly lower compared to the controls (GL -21.7 ± 5.2 and GR 49.3±19.5; p<0.0001). GR strain revealed a moderately significant correlation to RVEF (before BPA r=0.35; after BPA r=0.42, p=0.019), whereas only slight correlation trends to pulmonary haemodynamic (mPAP, PVR) were present.
Conclusion: RA strain was significantly lower in CTEPH patients compared to controls. Beside significant improvement of RV function and pulmonary haemodynamic, BPA also significantly improved RA strain. Moreover, RA strain showed a moderate correlation to RVEF. In addition to ventricular strain analysis, RA strain might enable new insights regarding atrioventricular coupling, therapy-effects, and monitoring and prognosis in CTEPH.
Limitations: A small study cohort.

U-Net convolutional neural network and B-spline deformable image registration for fully-automated strain calculation is feasible in the study of health in Pomerania

F. C. Laqua[1], P. L. Madsen[2], N. Hosten[1], R. Bülow[1]; *[1]Greifswald/DE, [2]Copenhagen/DK*

Purpose: To assess the feasibility of fully-automated myocardial strain estimation in a large epidemiological study since manual segmentation and strain estimation is time-consuming and prone to interoperator-variability.
Methods and materials: From the study of health in Pomerania (SHIP), 1,519 subjects from the general population (median age 52 years, 54.9% men) underwent steady-state-free-precession cine-CMR. A U-Net convolutional neural network (U-Net) was trained with 4-chamber, 2-chamber, and short-axis images of 991 probands from SHIP-TREND and used to predict left ventricular (LV) segmentation in end-diastole for the independent SHIP-CORE cohort. Time-series images were registered using deformable B-spline registration. In this manner, a set of indicator-points, derived from segmentation, was warped through the cardiac cycle. The movement of the indicator-points was visually assessed by two CMR experts. Global and segmental circumferential and longitudinal and radial myocardial strain curves were calculated following Green-Lagrangian formulation.
Results: Predicted segmentation was robust for LV myocard and cavity except for very apical and basal slices, with minor errors in the presence of banding-artefacts. In the vast majority of the assessed time-series, the indicator point-set followed wall motion and biologically plausible strain curves were calculated. Minor segmental tracking errors occurred with underlying motion and chemical-shift artefacts.
Conclusion: Fully-automated myocardial strain estimation combining deformable B-Spline registration with U-Net is feasible in a large population-based CMR study and presents a promising approach for even larger CMR studies like the German National Cohort and UK Biobank. Future research is needed for validation and comparison to manual software.

Limitations: No quantitative comparison with a reference-standard was undertaken. Comparison with commercially available software is ongoing.
Ethics committee approval: All individuals gave written informed consent. The study was approved by the Ethics Committee of the University of Greifswald.
Funding: This study is supported by the German Federal State of Mecklenburg-West-Pomerania.

RPS 703-13 15:12

Pressure-volume relationship by stress cardiovascular magnetic resonance: feasibility and clinical implications

A. Meloni[1], A. de Luca[2], C. Nugara[3], C. Cappelletto[2], G. Aquaro[1], C. Grigoratos[1], G. Todiere[1], A. Barison[1], A. Pepe[1]; [1]*Pisa/IT,* [2]*Trieste/IT,* [3]*Palermo/IT (alessia.pepe@ftgm.it)*

Purpose: The variation between rest and peak stress end-systolic pressure-volume relation (ESPVR) is obtained during routine stress echocardiography and is an index of myocardial contractile performance.
This is the first study assessing the delta rest-stress ESPVR (DESPVR) by dipyridamole stress cardiovascular magnetic resonance (CMR).
Methods and materials: 100 consecutive patients (24 females, 63.76±10.17 years) who underwent dipyridamole stress-CMR were considered.
The ESPVR was evaluated at rest and peak-stress from raw measurement of systolic arterial pressure by sphygmomanometer and end-systolic volume by the biplane Simpson method. Wall motion and perfusion at rest and after dipyridamole were analysed. Macroscopic fibrosis was detected by the late gadolinium enhancement technique.
Results: The mean ESPVR at rest and peak stress was, respectively, 4.84±2.47 and 5.33±3.16 mmHg/mL/m2; mean ΔESPVR was 0.48±1.45 mmHg/mL/m2.
ΔESPVR was significantly lower in males.
ΔESPVR was not correlated to baseline left ventricular end-diastolic volume index or ejection fraction.
43 patients had myocardial fibrosis and showed significantly lower ΔESPVR values.
An abnormal stress CMR was found in 25 patients. The ΔESPVR was significantly lower in patients with abnormal stress CMR.
During a mean follow-up of 56.34±30.04 months, 24 cardiovascular events occurred. At receiver-operating characteristic curve analysis, a ΔESPVR<0.02 predicted the presence of future cardiac events with a sensitivity of 0.79 and a specificity of 0.68.
Conclusion: The noninvasive assessment of the ΔESPVR index during a dipyridamole stress-CMR exam was feasible. The ΔESPVR was independent from baseline LV dimensions and function, so it can be used for a comparative assessment of patients with different diseases. ΔESPVR by CMR can be a useful marker for additional prognostic stratification.

Effectiveness of cardiovascular magnetic resonance combined strain value in the determination of ejection fraction

I. A. Abidoye[1], M. C. Halfmann[2], S. Benz[2], T. Leckebusch[2], T. Klimzak[2], M. Larisch[2], C. Düber[2], K.-F. Kreitner[2], T. Emrich[2]; [1]*Ado-Ekiti/NG,* [2]*Mainz/DE (ibukunabidoye@yahoo.com)*

Purpose: Strain parameters reflect cardiac deformation by analysing longitudinal and circumferential shortening as well as radial thickening of the myocardium. Theoretically, optimal myocardial contraction should be a result of all three deformation patterns. Therefore, we propose a new method (combined strain) to link strain values to cardiac function.
Methods and materials: In this retrospective cross-sectional study, we evaluated 444 subjects, both healthy (n=127) and diseased (n=317), with varying degrees of ejection fraction (EF) using CMR imaging at 3T (MAGNETOM Prisma, Siemens Healthineers, Erlangen, Germany). Left ventricular volumes and EF, as well as global strain values [radial (RS), circumferential (CS), and longitudinal (LS)], were acquired for the left ventricle using dedicated software (cvi42, Circle, Calgary, Canada). Combined strain (CoS) was calculated by the following equitation: CoS=RS+Absolute(CS+LS).
Results: Overall, absolute combined strain was found to have a higher correlation to EF than absolute longitudinal and radial strain, and a comparable correlation as absolute circumferential strain. The correlation was much stronger in patients with depressed EF than in those with normal EF. Sensitivity and specificity to predict reduced EF was higher in combined strain than in longitudinal or radial strain (AUC for CoS: 0.91 vs LS: 0.86 vs RS: 0.86).
Conclusion: In our large collective of healthy volunteers and magnitude of cardiomyopathies with and without depression of left ventricular function, the proposed concept of a combined strain outperformed radial and longitudinal strain in the evaluation of left ventricular function. The prognostic implications of these parameters have to be determined in prospective studies.
Limitations: A single-centre, retrospective study.
Ethics committee approval: All patients provided written informed consent. The study was approved by the local ethics committee (2018-13520/837.196.13/837.477.14).

Left atrial strain imaging: a comparison between conventional and highly accelerated cine imaging

G. Bisso[1], C. Reichhardt[1], S. Altmann[1], I. A. Abidoye[2], C. Düber[1], K.-F. Kreitner[1], T. Emrich[1]; [1]*Mainz/DE,* [2]*Ado-Ekiti/NG (sebastian.a.altmann@web.de)*

Purpose: Feature-tracking (FT) derived strain imaging of the left atrium is a promising method for the detection of atrial function and (subclinical) dysfunction in cardiomyopathies (REF). FT relies on sufficient spatial and temporal resolution that allows corrects tracking of endo- and epicardial contours. Compressed sensing (CS) is a relatively new method to accelerate image acquisition by incoherent sub-sampling of k-space, transformation of sparsity, and iterative reconstructions. The aim of this study was to compare left atrial strain by FT between a conventional (Conv) and a CS-based CINE sequence.
Methods and materials: This prospective study included 32 healthy volunteers. Imaging was performed at 3T (MAGNETOM Prisma, Siemens Healthineers, Erlangen, Germany). CINE images (Conv and CS) in typical long axis orientations were used to calculate left atrial FT strain. Both sequences were comparable in regard to temporal and spatial resolution. Post-processing was performed with a dedicated cardiac imaging software (cvi42, Circle, Calgary, Canada).
Results: Left atrial reservoir, booster, and conduit strain differed significantly between CONV and CS (e.g. reservoir strain (Conv vs CS): 42.9 vs 27.6%, p<0.0001) (Table 2). Nevertheless, there was an almost linear correlation for reservoir and conduit strain, and a weaker correlation for booster strain.
Conclusion: FT strain parameters of the left atrium differ significantly between Conv and CS-based CINE images. These differences could be explained by different diastolic reference phases for FT and thin atrial walls for contour detection. Further research is needed to establish a potential correction factor and validate this in a larger cohort with normal and impaired atrial function.
Limitations: A single-centre study.
Ethics committee approval: All volunteers provided written informed consent to participate. The study was approved by the local ethics committee (2018-13520).
Funding: No funding was received for this work.

Purpose: To compare the diagnostic accuracy of dynamic contrast-enhanced computed tomography (DCE-CT) and ^{18}Fluorine-Fluorodeoxyglucose Positron Emission Tomography/Computed Tomography (PET/CT) for the diagnosis of solitary pulmonary nodules.
Methods and materials: In this prospective multicentre trial, 380 participants with an incidentally detected solitary pulmonary nodule (8-30mm), and no recent history of malignancy, underwent DCE-CT and PET/CT. All patients underwent either biopsy with histological diagnosis or completed 2 years of CT follow-up. PET/CT was considered positive if it met one of the following criteria: nodule tracer uptake equal to or greater than the mediastinum with irregular/spiculate morphology on CT or evidence of distant metastases. DCE-CT was considered positive if the degree of nodule enhancement was ≥20 Hounsfield units. The primary outcome measures were the comparative diagnostic accuracies of DCE-CT and PET/CT.
Results: Of 380 participants recruited, 312 (47% female, 68.1±9.0 years-old) completed the study. The median pulmonary nodule diameter was 14mm (IQR 11-19), with a 61% rate of malignancy. The sensitivity and specificity for DCE-CT was 95.2% (95%CI 91.2;97.5) and 29.3% (95%CI 22.0;37.8), and for PET/CT was 72.5% (95%CI 65.7;78.4) and 80.5% (95%CI 72.6;86.5). The area under the receiver operator characteristic curve (AUROC) was 0.63 (95%CI 0.58;0.67) for DCE-CT and 0.76 (95%CI 0.72;0.82) for PET/CT (p<0.001). Combining the tests resulted in a significant increase in the diagnostic accuracy over PET/CT alone (AUROC=0.89 (95%CI 0.86;0.93),p<0.001).
Conclusion: PET/CT has a superior diagnostic accuracy to DCE-CT for the diagnosis of solitary pulmonary nodules. However, combining the two techniques improves the diagnostic accuracy over either test alone.
Limitations: Results may not be generalisable to screening detected nodules.
Ethics committee approval: REC-12/SW/0206.
Funding: NIHR-HTA (09/22/117).

Visibility of interval cancer on previous screening mammograms: comparison of digital mammography and digital breast tomosynthesis in population-based screening
P. Skaane, S. B. Brandal, S. Y. Yanakiev, E. E. Eben, T. Lie, R. Gullien*; Oslo/NO (PERSKA@ous-hf.no)*

Purpose: Review baseline screening examinations of interval cancer (IC) in a population-based program comparing DM and DM+Digital Breast Tomosynthesis (DBT).
Methods and materials: Oslo Tomosynthesis Screening Trial (OTST) (ClinicalTrials.gov NCT01248546) was a prospective study comparing DM and DM+DBT. The trial had a paired design with four arms for independent double reading 2D and 2D+DBT and a common consensus meeting before decision to recall. 24,301 women (50-69 years) were included. Four radiologists retrospectively reviewed baseline screening examinations of all interval cancers using the same breast-based 5-point rating scale applied in the screening program, and gave individual scores for each breast and for CC- and MLO-view, and separately for DM and DBT. A consensus meeting grouped the analysis as normal, nonspecific, and significant minimal signs, and false negative ("missed"). The two latter categories were defined as "actionable", i.e., potential detectable cancer.
Results: Screen-detected cancer was found in 230 women (four bilateral) and 51 IC (IC rate 2.1/1000) during a two-year follow-up period. Two IC developed among 938 women were recalled for reasons other than cancer. Of 14 IC among 2,856 women dismissed at consensus, 8 had a positive score for IC, and 5 at 2D, and 7 at DBT among dismissed were classified as actionable. 35 IC among 20,507 women had negative score in all four arms (none actionable at DM, 5 actionable at DBT). Totally 5 IC were considered actionable at 2D compared with 12 at DBT. Correct diagnosis of these 12 exams might have reduced the ICR for DBT-screening from 2.1/1000 to 1.6/1000.
Conclusion: More IC had the potential to be correctly detected at baseline DBT-screening compared with DM, probably due to both perception and characterisation errors.
Limitations: The material, including screening examinations, was enriched with cancers (and relatively few normal and benign cases) which might have increased the readers awareness for malignancies. Only one of the four reviewers was reader of the OTST.
Ethics committee approval: Oslo Tomosynthesis Screening Trial (OTST): Clinical Trials.gov nr.: NCT 01248546. Regional Ethics Committee reference number: 2010/144.
Funding: None.

Multicenter prospective comparison of the TROcar versus SELdinger technique for percutaneous Cholecystostomy: the TroSelC Trial

N. A. Arkoudis[1], L. Reppas[1], S. C. Spiliopoulos[1], M. Theofanis[2], P. M. Kitrou[2], K. Katsanos[2], K. Palialexis[1], D. Filippiadis[1], E. Brountzos[3]; [1]Athens/GR, [2]Patras/GR, [3]Haidari/GR (nick_arkoudis@hotmail.com)

Purpose: To compare the safety and efficacy of bed-side ultrasound-guided (US) Trocar versus US/fluoroscopy-guided Seldinger techniques for percutaneous cholecystostomy (PC).
Methods and materials: This is a prospective, two-center, non-inferiority study comparing bed-side US-guided Trocar PC (group T; 53 patients, mean age:74.31±16.19 years, male:28) versus US/fluoroscopy-guided Seldinger PC (group S; 52 patients, mean age: 79.92±13.38, male:26) in consecutive patients undergoing PC in two large tertiary university hospitals. Primary endpoints were technical success and procedure-related complications rates. Secondary endpoints included procedural duration, pain assessment, and clinical success in up to 3 months of follow-up.
Results: PC was successfully performed in all 105 patients (100%). Clinical success was similar between the two study groups (86.8% group T vs.76.9% group S; p=0.09). Mean procedural time was significantly lower in group T (1.77±1.62min vs. 4.88±2.68min group S; p<0.0001). Significantly more procedure-related complications were noted in group S compared to group T (11.5% vs. 1.9%; p=0.02). In group S, bile leak was 7.7%, abscess formation 1.9%, and gallbladder rupture 1.9%. No procedure-related death was noted. Minor bleeding occurred in one patient (1.9%) in group T, which auto-resolved. At 12 hours, pain score was significantly lower for patients in group T (0.78 ± 1 vs. 3.12 ± 1.36; p=0.0001).
Conclusion: Bed-side, US-guided Trocar PC was equally effective with less procedure-related complications, required less procedural time, and resulted in decreased post-procedural pain, compared to fluoroscopically-guided PC using the Seldinger technique.
Limitations: Relatively small number of patients included. Each center performed only one method for PC. Patients were not blinded to the study's method.
Ethics committee approval: Institutional board approval was obtained and an informed consent explaining the risks and benefits of the procedure was obtained in all cases.
Funding: No funding was received for this work.

Building an advanced medical image anonymisation system by integrating open-source tools in a large multi-center cross-modality AI imaging project

Y. Huang[1], W.-J. Lee[1], Y.-C. Chen[1], T.-D. Wang[1], C.-M. Chen[1], C.-Y. Lee[2], W.-C. Wang[1], C.-Y. Chou[1], Y.-C. Chang[1]; [1]Taipei/TW, [2]Miaoli/TW (squll1peter@gmail.com)

Purpose: Proper de-identification of medical images while maintaining research-relevant information and connection between cross-modality image studies is complex and cumbersome. We aimed to develop a medical image anonymisation system that integrates currently available open-source tools to overcome the de-identification difficulties in a large multi-center cross-modality AI imaging project.
Methods and materials: Cardiovascular images including cardiac CT, nuclear myocardial perfusion images, invasive coronary angiography, coronary fractional flow reserve, coronary optical coherence tomography, and intravascular ultrasound from eight institutes were retrospectively collected to build the database. The images were de-identified with an on-site standalone anonymiser then sent to the Core Lab for main de-identification process. The main de-identification processor is composed of an open-source DICOM server with a custom server-side script, a MIRC clinical trial processor with custom pipelines, and python scripts for special anonymisation and processing needs. Each component runs in a separate container but connect to the same virtual network. De-identification profile and server settings are versioned and tested in a separate container before publishing.
Results: A total of 12 million multi-center cross-modality cardiovascular images from 2000 patients were de-identified successfully while preserving research-relevant information and connection between cross-modality image studies. A special de-identification process for specific type of image annotation was developed and integrated into the main de-identification process.
Conclusion: We successfully built a medical image anonymisation system in a multi-center cross-modality cardiovascular imaging database by integrating available tools.
Limitations: (1) Lack of real time progress monitoring and feedback for end users. (2) Requires manual manipulation to redo de-identification with new profile.

Abbreviated MRI randomised study in breast cancer survivors: does it impact patient anxiety?

M. Mohallem Fonseca[1], T. Alhassan[2], D. Koszycki[1], B.-A. Schwarz[1], R. Segal[1], A. Arnaout[1], T. Ramsay[1], J. Lau[1], J. M. Seely[1]; [1]Ottawa, ON/CA, [2]Dubai/AE (jeseely@toh.on.ca)

Purpose: To determine if the addition of abbreviated breast MRI (A-MRI) to surveillance mammography (MG) impacted patient anxiety and if it improved cancer detection rate (CDR) in breast cancer survivors.
Methods and materials: A prospective parallel unblinded controlled trial was performed in a tertiary care academic center on women with a personal history of breast cancer who were randomised into two groups: surveillance with MG or MG plus A-MRI. The primary outcome was anxiety measured via four validated questionnaires at the time of enrollment, after notification of imaging results, and 6 months later, and compared between the two groups. Other parameters including recall, biopsy rates, and CDR were compared between MG and A-MRI.
Results: 199 patients were included, 105 women in A-MRI plus MG and 94 in MG groups. MRI recall rate was 26.6% (28/105), biopsy rate was 20% (21/105), with CDR 5.7% (6/105) - 6 cancers found by MRI alone. Compared to MRI alone, the rates of MG recall, biopsy and CDR were significantly lower: 4.5% (9/199, p<0.00001), 3.0% (6/199, p<0.00001), 0.5% (1/199, p<0.0039) respectively - 1 DCIS found in a patient who had MG only. Penn State Worry Questionnaire scores were similar for both groups and did not change over time, both moderately severe.
Conclusion: Compared to mammography alone, A-MRI had significantly higher cancer detection in breast cancer survivors. MRI was not associated with a "reassuring effect", but showed no increase in anxiety despite a higher rate of recalls and biopsies. Further work is needed to ensure an acceptable benefit-to-harm ratio.
Limitations: Potential for selection bias due to oncologist preference.
Ethics committee approval: Approved by the institutional review board and written informed consent was obtained.
Funding: Support was provided in part by the Ottawa Hospital Cancer Program.

Diagnostic performance of ultrasound in patients with pancreatic ductal adenocarcinoma: a multi-centered population-based observational study
J. Kang, M. Abdolell, A. Costa*; Halifax, NS/CA (jessie-dain@Dal.Ca)*

Purpose: To evaluate the performance of ultrasound (US) in diagnosing patients with pancreatic ductal adenocarcinoma (PDAC) in our region.
Methods and materials: Patients diagnosed with PDAC between 2014-15 were identified by the Cancer Registry data. Their US requisitions, images, and reports were reviewed independently by a radiology resident and abdominal radiologist, and finalised via consensus. Examinations were excluded if a pancreatic lesion was known at the time of US.
The following data elements were extracted: clinical suspicion of PDAC, comment on image quality, detection of tumour, location, size, detection of secondary signs and liver metastases, suspicion of neoplasm raised, and follow-up recommendations. US were graded as true-positive, indeterminate, or false-negative. One-way ANOVA and chi-square tests were performed according to these subgroups.
Results: 113 US examinations on 107 patients (53 men, 54 women; mean 70 +/- 13 years) were included. Cancer was suspected clinically in 49 patients. 35/113 (31.0%) examinations commented on image quality, however only 49/113 (43.4%) visualised the tumour. There were 50 true-positives, 40 indeterminates, and 23 false-negatives. There was no difference in age, weight, tumour location, or size across subgroups. However, sex distribution, clinical suspicion of PDAC, comment on US quality, visualisation of tumour, detection of secondary signs, and liver metastases were significantly different ($p<0.005$). The number of examinations reporting suspicion of neoplasm or recommending follow-up also varied significantly ($p<0.0001$).
Conclusion: Assessment of PDAC with US is unreliable in our region, with a large proportion of indeterminate and false-negative studies. These results have important implications for radiologists reporting US and referring physicians relying on US for patient work-up.
Limitations: Retrospective study. Operator dependent nature of US.
Ethics committee approval: REB approval, PHIA adherence.
Funding: No funding was received for this work.

Dynamic ^{18}F-FET PET as an independent prognostic factor in de-novo oligodendroglioma
M. Unterrainer, F. Vettermann, B. Suchorska, J. Herms, W. G. Kunz, M. Niyazi, P. Bartenstein, J.-C. Tonn, N. Albert*; Munich/DE (marcus.unterrainer@med.uni-muenchen.de)*

Purpose: Within the updated WHO classification, gliomas are stratified into molecular genetic subgroups. Among these, IDH-mutant, 1p/19q-codeleted gliomas (oligodendrogliomas) exert a favourable outcome compared to IDH-wildtype tumours such as glioblastoma. Therefore, the individual risk of treatment-associated morbidity has to be weight up. ^{18}F-FET PET increasingly gains clinical importance for glioma imaging, however, its prognostic value in de-novo oligodendroglioma is unclear and was evaluated.
Methods and materials: Patients with histologically verified de-novo oligodendroglioma (IDH-mutant and 1p/19q-codeleted) underwent MRI and dynamic ^{18}F-FET PET prior to therapy. ^{18}F-FET PET parameters (maximum/mean tumour-to-background ratio [TBR_{max}, TBR_{mean}], minimal time-to-peak [TTP_{min}], biological-tumour-volume [BTV]), contrast-enhancement, Karnofsky-Performance-Score (KPS) and subsequent treatment were assessed and correlated with the progression-free survival (PFS) as defined by Response-Assessment in Neuro-Oncology criteria (RANO) using Kaplan-Meier estimates and uni-/multivariate analyses.
Results: Seventy-six patients with de-novo oligodendroglioma (WHO grade II n=58, WHO grade III n=18) were included. During a median follow-up time of 67.5 months, 43/76 patients experienced tumour progression with a median PFS of 57.0 months. In univariate analyses, WHO grade (WHO grade II vs. III: median PFS 64.0 vs. 39.0 months, $p=0.035$) and TTP_{min} on dynamic PET (≤25 vs. >25 min: median PFS 50.0 vs. 104.0 months, $p=0.021$) were associated with PFS, whereas age, contrast enhancement, KPS, $TBR_{max/mean}$ and BTV were not ($p>0.05$). In multivariate analysis, both WHO grade (hazard ratio 2.4 (CI: 1.2–4.9), $p=0.019$) and TTP_{min} (hazard ratio 2.4 (CI: 1.1–5.2), $p=0.021$) were significant prognostic factors for PFS.
Conclusion: Within the molecular genetic subgroup of oligodendroglioma, TTP_{min} on dynamic ^{18}F-FET PET represents an independent prognostic imaging biomarker for PFS. Therefore, dynamic ^{18}F-FET PET in addition to histological and molecular genetic features might help to individualize the clinical management and decision making.
Limitations: Retrospective study.
Ethics committee approval: Approved by the ethics committee LMU.
Funding: No funding for this study was received.

Comprehensive functional evaluation of the spectrum of multi-system atrophy with 18F-FDG PET/CT and 99mTc TRODAT-1 SPECT: 5 years experience from a tertiary care centre
R. Verma, R. Ranjan, H. Mahajan, E. Belho, V. Gupta, N. Seniaray, N. Gupta, V. Mahajan*; New Delhi/IN (drharshmahajan@yahoo.com)*

Purpose: To elucidate the patterns of characteristic hypometabolism on 18F-FDG PET/CT in various subtypes of MSA and correlation with the patterns of uptake on Dopamine transporter imaging with 99mTc TRODAT-1 SPECT.
Methods and materials: A retrospective analysis of 65 patients of clinically suspected MSA was done. All the subjects underwent 99mTc TRODAT-1 SPECT study and 18F-FDG PET/CT scan on two separate days, between 2013 and 2018. The scans were analysed both qualitatively (visually) and semi-quantitatively. The FDG uptake patterns were recorded, and areas of hypometabolism that were two standard deviations from the mean were considered abnormal.
Results: All the subjects had an abnormal pattern of FDG uptake on PET scan, both on a visual inspection and semiquantitative analysis. In MSA-P subjects (n=22), diffuse predominant hypometabolism of the globus pallidus-putamen complex was noted with relative sparing of the caudate nuclei. In MSA-C subjects (n=23), characteristic hypometabolism was noted in the cerebellum and brainstem. In mixed subtypes (n=10), variable involvement of the basal ganglia, cerebellum, and brainstem was noted with frontoparietal hypometabolism. TRODAT scan was abnormal in all and showed pronounced asymmetry with prominent rostrocaudal gradient seen in the MSA-P subtype.

Conclusion: Dopamine transporter imaging agent 99mTc TRODAT-1 SPECT not only helps in the confirmation of Parkinsonian disorders but also demonstrates varying patterns of distribution in different subtypes of MSA. Characteristic patterns of hypometabolism may help in the differentiation of the subtypes of MSA in the presence of clinically overlapping symptoms.
Limitations: Retrospective design and semiquantitative assessment are the major limitations of this study.
Ethics committee approval: IRB approval was not required as it was a retrospective study.
Funding: No funding was received for this work.

^{18}F-choline PET-CT in the localisation of parathyroid adenomas

A. Mazurek[1], M. Dziuk[1], A. Gizewska[1], S. Piszczek[1], N. Papachristodoulou[2]; *[1]Warsaw/PL, [2]Budapest/HU (andrzej_mazurek@wim.mil.pl)*

Purpose: The aim was to evaluate the usefulness of ^{18}F-choline (^{18}F-FCH) PET-CT for parathyroid adenoma detection in patients with hyperparathyroidism in comparison with neck ultrasound (US) and parathyroid 99mTc-MIBI scintigraphy.
Methods and materials: The 50 patients (45F/5M) underwent neck US, 99mTc-MIBI scintigraphy (subtractive and dual-phase planar and SPECT-CT imaging) and ^{18}F-FCH PET-CT within 6 months. The findings were classified as positive, inconclusive or negative in terms of images typical for parathyroid adenoma in each imaging modality. The localisation of possible parathyroid adenoma in subsequent surgical operation was performed based on the ^{18}F-FCH PET-CT images. The results were compared to the surgical and pathological findings and the follow-up evaluation. Additionally, laboratory tests were performed (plasma calcium and parathormone levels).
Results: Primary hyperparathyroidism was diagnosed in 46/50 and secondary in 4/50 patients. The mean radioactivity of ^{18}F-FCH was 215 MBq and the average time from radiotracer injection to scan was 67 minutes. 44 patients scanned with ^{18}F-FCH PET-CT were classified as positive, 3 as inconclusive and 3 as negative. In the neck US results, 6 patients were scored as positive, 8 as inconclusive and 36 as negative. The results of 99mTc- MIBI scintigraphy were as follows: 8 patients positive, 4 inconclusive, 38 negative. Thirty-five patients underwent surgery, in 30 out of them (85,7%) surgical treatment was effective. Among 35 patients, 11 had previously undergone unsuccessful surgery (none of those patients had previously performed ^{18}F-FCH PET-CT).
Conclusion: The ^{18}F-FCH PET-CT method demonstrates high accuracy in the detection of parathyroid adenomas compared to neck US and 99mTc-MIBI parathyroid scintigraphy, increasing the efficacy of surgical operation in patients with hyperparathyroidism.
Limitations: Not all patients underwent surgery.
Ethics committee approval: The ethics committee approved this study.

RECIL vs Lugano for response assessment in FDG-avid Non-Hodgkin lymphomas: a head-to-head comparison in 54 patients

D. Leithner[1], A. Haug[2], D. P. B. Staber[2], M. Raderer[2], D. B. Kiesewetter[2], P. D. U. Jaeger[2], D. C. Kornauth[2], P. D. I. Simonitsch-Klupp[2], D. Berzaczy[2]; *[1]Frankfurt am Main/DE, [2]Vienna/AT (doris.leithner@gmail.com)*

Purpose: To compare the recently proposed RECIL classification to the established Lugano response classification for treatment response assessment in FDG-avid lymphomas, with a particular focus on the provisional response category of RECIL, termed "minor response" (MR).
Methods and materials: In 54 patients with FDG-avid Non-Hodgkin lymphomas (41 with diffuse large B-cell lymphoma and 13 with follicular lymphoma), [18F]FDG-PET/CT-based response according to RECIL (five response categories: complete remission (CR); partial remission (PR); minor response (MR); stable disease (SD); or progressive disease (PD)) and Lugano (four response categories: CR; PR; SD; or PD) was determined at the interim restaging after three immunochemotherapy cycles, and at the end-of-treatment (EOT) restaging after six immunochemotherapy cycles. Following the recording of MR, absolute and relative rates of agreement, as well as kappa (κ) coefficients were calculated.
Results: At the interim restaging, MR was observed in 8/54 patients (14.8%), all of which showed a responding disease according to Lugano. At EOT, MR was observed in only 3/54 patients (5.6%). When MR was recoded as PR, the overall agreement between RECIL and Lugano was 83.3% at the interim restaging (45/54 patients; κ=0.69, P<0.0001), and 90.7% at EOT (49/54 patients; κ=0.79, P<0.0001). When MR was recoded as SD, the overall agreement between RECIL and Lugano was 79.6% at the interim restaging (43/54 patients; κ=0.63, P<0.0001), and 90.7% at EOT (49/54 patients; κ=0.79, P<0.0001).
Conclusion: The RECIL and Lugano classifications yield comparable information about lymphoma treatment response in the majority of patients with FDG-avid lymphomas, especially at EOT. Minor response at the interim restaging according to RECIL is a common finding and generally indicates a favourable EOT outcome.
Limitations: Only two lymphoma subtypes were included.
Ethics committee approval: The study was approved by the local Ethics Committee; informed consent was waived.
Funding: No funding was received for this work.

Metabolic tumour volume as a prognostic biomarker in melanoma patients undergoing baseline ^{18}F-FDG-PET/CT: a comparison with serologic tumour markers and acute phase proteins

C. P. Reinert, S. Gatidis, D. H. Dittmann, C. Pfannenberg, K. Nikolaou, A. Forschner*; Tübingen/DE (christian.reinert@med.uni-tuebingen.de)*

Purpose: In this study, we investigated the correlation of serologic tumour markers and acute-phase proteins with whole-body metabolic tumour volume (MTV) in melanoma patients undergoing ^{18}F-FDG-PET/CT and the role of MTV as an imaging predictor for overall survival.
Methods and materials: A patient cohort with malignant melanoma undergoing ^{18}F-FDG-PET/CT between 04/2013 and 01/2015 was evaluated. Whole-body MTV was quantified using 50%-isocontour volumes of interests (VOIs) and then correlated with serum levels of LDH, S-100 protein, c-reactive protein (CRP) and alkaline phosphatase (AP), which were tested close to the timepoint of PET/CT. Overall survival (OS) between PET/CT and death was compared between patients with MTV above or below the cohort's median and pathological or non-pathological serologic parameters.
Results: 107 consecutive patients (65±13.1y) were included. ^{18}F-FDG-PET/CT revealed a median whole-body MTV of 2.74 [0–66.3] cm^3. We observed a strong correlation between LDH and MTV (r_P=0.73) and between S-100 and MTV (r_P=0.54), whereas CRP and AP showed a less significant or no correlation with MTV (r_P=0.66;r_P=0.30). For the differentiation between MTV above/below patient median, ROC analysis derived 212 U/l as cut-off value for LDH (AUC 0.82;sensitivity 0.77;specificity 0.70). MTV above the patient median was associated with reduced OS (43.1±2.7months) compared to MTV below the patient median (55.7±2.8months, p=.02). Correspondingly, elevated LDH was accompanied with reduced OS (39.3±5.1months) compared to normal LDH (50.1±2.3months, p=.03).
Conclusion: Whole-body MTV in ^{18}F-FDG-PET/CT appears to be an imaging biomarker for the disease progression in malignant melanoma which correlates well with established serologic parameters and proves to be a feasible imaging predictor for OS.
Limitations: Retrospective design.

Impact of ^{18}F-FDG-PET/CT on clinical management in patients with cholangiocellular carcinoma
L. S. Kiefer, J. Sekler, B. Gückel, C. La Fougère, K. Nikolaou, S. Gatidis, C. Pfannenberg*; Tübingen/DE (lena.kiefer@med.uni-tuebingen.de)*

Purpose: To determine the impact of ^{18}F-FDG-PET/CT on clinical management in patients with cholangiocellular carcinoma (CCA).
Methods and materials: Patients with CCA undergoing clinically indicated PET/CT between 04/2013-08/2018 were prospectively included in the local PET/CT registry study. Questionnaire data from referring physicians regarding PET/CT indication (diagnosis/staging/suspected recurrence) and intended clinical management (non-treatment (watchful-waiting/additional tests)/palliative/curative treatment) were recorded before and after PET/CT. Post-PET/CT changes in clinical management were analysed. The outcome was determined using Kaplan-Meier-analysis.
Results: 27 patients (mean age: 60 years (IQR: 51.5-67.5 years), 56% males) with altogether 43 PET/CT-examinations were included. PET/CT indications were mainly "suspected recurrence" and "staging" (95.3%). Intended clinical management changed in 35 cases (81.4%) after PET/CT. Major changes (between non-treatment and treatment strategies) occurred in 27 cases (62.8%). Minor changes in non-treatment and among therapies were documented in 8 cases (18.6%). Additional tests (further imaging and/or biopsy) were intended in 21 (48.8%) and 9 (20.9%) cases before PET/CT. After PET/CT, imaging was performed in 1 (2.3%) and biopsy in 8 (18.6%) cases. In only one case biopsy was already planned before the PET/CT and performed afterwards, whereas in 8 cases, biopsy became unnecessary based on PET/CT results. Patients with intended curative treatment after PET/CT showed a mean survival of 2.21 years (95%-CI: 0.76-3.66 years), whereas patients with intended palliative or non-treatment showed a mean survival of 1.21 years (95%-CI: 0.72-1.69years) and 2.08 years (95%-CI: 1.27-2.89years).
Conclusion: ^{18}F-FDG-PET/CT influences clinical management in patients with CCA. It guides the decision for reasonable additional tests and helps to avoid unnecessary imaging and biopsy. Thus, a more appropriate and individualised treatment may be possible based on PET/CT results.
Limitations: Small cohort.
Ethics committee approval: The study was approved by the local institutional review board and ethics committee. Informed consent was obtained from all patients.
Funding: No funding was received.

RPS 706-7 14:46
Diagnostic efficiency of whole-body ^{18}F-FDG PET/MRI, MRI alone, and SUV and ADC values in the staging of primary uterine cervical cancer
A. Kiviniemi[1], S. Narva[1], I. Rinta-Kiikka[2], S. Hietanen[1], J. Hynninen[1], J. Virtanen[1]*; [1]Turku/FI, [2]Tampere/FI (aikast@utu.fi)*

Purpose: To assess the diagnostic performance of PET/MRI and MRI alone in the local and whole-body staging of cervical cancer, and to evaluate the benefit of standardised uptake value (SUV) and apparent diffusion coefficient (ADC) in staging.
Methods and materials: Consecutive patients with biopsy-proven cervical cancer and whole-body ^{18}F-FDG PET/MRI obtained before the definitive treatment were retrospectively identified. Local tumour spread, nodal involvement, and distant metastases were evaluated using PET/MRI or MRI dataset alone. Histopathology or clinical consensus with the follow-up imaging were used as reference standard. Tumour SUVmax and ADC were measured and the SUVmax/ADC ratio calculated. The area under the curve (AUC) was determined to predict diagnostic performance and Mann-Whitney U test was applied for group comparisons.
Results: In total, 33 patients who underwent surgery (n=23) or first-line chemoradiation (n=10) were included. PET/MRI resulted in higher AUC compared with MRI alone in detecting parametrial (0.89 vs 0.73), vaginal (0.85 vs 0.74), and deep cervical stromal invasion (0.96 vs 0.74), respectively. PET/MRI had higher diagnostic confidence than MRI in identifying patients with radical cone biopsy and no residual at hysterectomy (sensitivity 89% vs 44%). PET/MRI and MRI showed equal AUC for pelvic nodal staging (both 0.73), whereas AUC for distant metastases was higher using PET/MRI (0.80 vs 0.67). The tumour SUVmax/ADC ratio, but not SUVmax or ADC alone, was significantly higher in the presence of metastatic pelvic lymph nodes (P<0.05).
Conclusion: PET/MRI shows higher accuracy than MRI alone for determining not only distant metastasis but also local invasive tumour spread. Tumour SUVmax/ADC ratio may predict pelvic nodal involvement.
Limitations: No evaluation of interobserver variability.
Ethics committee approval: This study was approved by the institutional ethics committee and informed consent was waived.

The role of histopathological and biochemical parameters in predicting metastatic disease in Ga68 PSMA PET for prostate cancer
U. Aydos, Ü. Ö. Akdemir, S. Çetin, F. Ç. Budak, S. Gülbahar, M. Y. Koparal, T. S. Sozen, L. Ö. Atay*; Ankara/TR*

Purpose: The aim of this study was to evaluate the role of histopathological and biochemical parameters in the prediction of the presence and number of PSMA positive lesions consistent with the metastatic spread of prostate cancer on Ga68 PSMA PET images.
Methods and materials: Biochemical, histopathological, and imaging data of 302 prostate cancer patients who underwent Ga68 PSMA PET/CT or PET/MR imaging for primary staging were retrospectively analysed. Patients were divided into two groups as "PET-positive" and "PET-negative" according to the presence of pathologic extra-prostatic PSMA involvement. "PET-positive" cases were additionally divided into three groups: Group A (N1+, M0), Group B (1-3 distant metastases), Group C (>3 distant metastates).
Results: The mean age of patients was 66.8 ± 7.6 years. Imaging modality was PET/MR in 223 (73.8%) and PET/CT in 79 (26.2%) patients. Total PSA, PSA density (PSAD), and tumour tissue ratio were found to be higher in Group C compared to both groups. PSMA PET positivity was observed in 3.8% of the low-intermediate risk groups (ISUP 1-3 and total PSA≤20 and PSAD<0.15). This ratio was 46% (p<0.001) in the high-risk group (ISUP 4-5 or total PSA>20 or PSAD≥0.15) with a relative risk of 12. The logistic regression model to predict the presence of distant metastasis had an accuracy of 89.7%; with ALP, total PSA and ISUP Gleason grade as significant predictors (p<0.05).
Conclusion: In this study, Ga68 PSMA PET positivity was significantly higher in the high-risk patient group than in the low-intermediate risk groups. The regression model used for predicting the presence of distant metastasis on PET imaging was successful with high accuracy.
Limitations: This study was retrospective.

Prostate cancer heterogeneity in high b-value DWI correlates with ^{68}Ga-PSMA PET/CT: preliminary results
M. Mottola[1], F. Ferroni[2], D. Barone[2], M. A. Turci[1], M. Celli[2], F. Matteucci[2], G. Gavelli[2], G. Paganelli[2], A. Bevilacqua[1]*; [1]Bologna/IT, [2]Meldola/IT (margherita.mottola@unibo.it)*

Purpose: To investigate whether radiomic features computed on high b-value DWI sequences referring to tumour cellularity correlate with the ^{68}GA-PSMA PET/CT ligand, highly specific for the diagnosis of prostate cancer (PCa).
Methods and materials: This study retrospectively enrols 17 patients belonging to a multi-cohort investigation for the clinical impact of 3T-mpMRI and ^{68}GA-PSMA PET/CT in PCa diagnosis and staging. PCa lesions were contoured in consensus by two experienced radiologists in either DWI or T2w sequences, depending on where they were more visible. 40% of SUV_{max} was used as the threshold to contour lesions on PET images and, on these regions, the median of the last decile of SUV (SUV_{M90th}) was computed. Instead, 84 radiomic features were computed on b-2000 DWI lesions and their value was correlated to SUV_{M90th} through the absolute Spearman index (ρ).
Results: Several radiomic features showed excellent correlations with ^{68}GA-PSMA-SUV_{M90th}. In particular, the radiomic feature performing as the best is related to local tumour heterogeneity and showed ρ≥0.7 in 82% of patients, ρ≥0.5 in just two cases, and one-only patient yielded ρ=0.3.
Conclusion: The outcome reveals a rank correlation between the degrees of PCa cellularity heterogeneity and ^{68}GA- PSMA -SUV_{M90th}. In other words, a wider expression of membrane receptors for PSMA seems corresponding to an over-proliferation of cells, which theoretically is suggestive of tumour onset and malignancy progression.
Limitations: A wider cohort of patients is needed to better understand this correlation and to deepen the physiological and biomolecular causes of such behaviour.
Ethics committee approval: IRB approval, written informed consent was waived.

RPS 706-10 15:04

Assessment and evaluation of the significant role of 18F-FDG-PET/CT in determining the cause of fever of unknown origin (FUO) and inflammation of unknown origin (IUO)

S. M. Shaikh; *Hyderabad/IN (idrsikandar@gmail.com)*

Purpose: Fever of unknown origin (FUO) and inflammation of unknown origin (IUO) are becoming diagnostically challenging conditions with relevance to various medical advances and newer techniques. Diagnosis of these underlying disease conditions may be significantly improved by 18F-fluorodeoxyglucose positron emission tomography (18F-FDG-PET).
Methods and materials: Retrospective study to test the diagnostic utility of 18F-FDG-PET/CT in a large cohort of patients with FUO or IUO and to define parameters to increase the likelihood of diagnostic 18F-FDG-PET/CT. Patients under the FUO or IUO category underwent 18F-FDG-PET/CT scanning in addition to the standard diagnostic work-up. 18F-FDG-PET/CT results were classified as helpful or non-helpful in establishing the final diagnosis. Binary logistic regression was used to identify clinical parameters associated with a diagnostic 18F-FDG-PET/CT.
Results: 60 patients underwent FDG PET-CT, 18 with FUO, 35 with IUO and 7 had FUO or IUO previously (exFUO/IUO). The diagnosis was established in 24 patients (79.2%). The leading diagnoses were Tuberculosis (15.3%) in the FUO group, large vessel vasculitis (21.1%) and polymyalgia rheumatica (18.3%) in the IUO group and IgG4-related disease (15.4%) in the exFUO/IUO group. In 34 patients (56.7% of all patients and 71.6% of patients with a diagnosis), 18F-FDG-PET/CT was positive and helpful in finding the diagnosis. Predictive markers for a diagnostic 18F-FDG-PET/CT were an age over 50 years (p=0.019), C-reactive protein (CRP) level over 30 mg/L (p=0.002) and the absence of fever (p=0.001).
Conclusion: 18F-FDG-PET/CT scanning is helpful in evaluating the correct diagnosis in more than 50% of the cases presenting with FUO and IUO. Absence of intermittent fever, higher age and elevated CRP level increase the likelihood for a diagnostic 18F-FDG-PET/CT.
Limitations: Differentials of malignant foci cannot be ruled out.
Ethics committee approval: n/a

RPS 706-11 15:10

Initial evaluation of 18F-FDG biodistribution in healthy and oncology subjects scanned using the uEXPLORER total-body PET/CT

Y. Abdelhafez, N. Omidvari, B. Spencer, R. D. B. Badawi, S. Cherry, L. Nardo; *Sacramento, CA/US (yabdelhafez@ucdavis.edu)*

Purpose: EXPLORER is a new generation PET/CT scanner with unprecedented sensitivity and total-body coverage. Its clinical implementation changes the way PET/CT is interpreted and the radiologist needs to gain familiarity with the new way that the functional anatomy is seen. This work aims to characterise aspects of the impact of this new technology on the visualisation of small structures through a semiquantitative evaluation.
Methods and materials: PET data from 19 subjects (healthy subjects, n=5, and oncology patients with limited disease, n=14) were acquired on the EXPLORER scanner for 20 min at 90-min post-injection of 18F-FDG. Data were reconstructed in 1-mm isotropic voxels using an OSEM iterative algorithm with 4 iterations and 20 subsets. At least 1-cm volumes of interest (VOIs) were placed on the liver (Lbkg), ascending aorta (AAbkg) and bone marrow at L3 vertebral body (L3), and smaller structures such as spinal cord (SC), adrenals (AG) and pituitary gland (PG). Semiquantitative values including the SUVmean, SUVmax and SUVpeak were recorded.
Results: SUVmean values for larger structures were: Lbkg=2.5±0.70; AAbkg=1.61±0.39; L3=2.39±1.33. For smaller structures, SUVmax & peak were: for SC, 4.13±0.1.42 & 2.70±0.59 (varied by region); for PG, 5.54±1.60 & 3.26±0.88; and for AGs, 4.64±2.14 & 2.73±0.92. When PG and AG values were normalised for Lbkg, their ratios were: 2.4 & 1.9 for SUVmax and 1.4 & 1.1 for SUVpeak, respectively. No significant differences were seen between healthy and cancer patients.
Conclusion: Initial EXPLORER scans in healthy and oncology subjects demonstrated that biodistribution values in small structures are higher than that usually seen from standard scanners. For example, the adrenals and pituitary gland uptake are higher than the liver background. This notion is critical to correctly interpret total-body PET/CT scans.
Limitations: Small sample size.

RPS 706-12 15:16

Evaluation of the first integrated PET/dual-energy CT system in patients with lung cancer

S. S. Martin[1], M. van Assen[2], P. Burchett[3], J. G. Ravenel[3], A. Varga-Szemes[3], T. J. Vogl[1], U. J. Schoepf[3], C. N. de Cecco[4]; [1]*Frankfurt am Main/DE,* [2]*Groningen/NL,* [3]*Charleston, SC/US,* [4]*Atlanta, GA/US (simartin@outlook.com)*

Purpose: The aim of this study was to prospectively evaluate the first integrated positron emission tomography (PET)/dual-energy computed tomography (DECT) system in patients with lung cancer.
Methods and materials: In this single-center HIPAA compliant prospective trial, we included 25 patients (age range, 41-84 years; mean age, 62±12.8) with NSCLC (n=21) or SCLC (n=4) who were referred for a PET study between May 2017 and June 2018. All patients received contrast-enhanced imaging on a clinical PET/DECT system. Data analysis included PET-based standard uptake values (SUV_{max}) and DECT-based iodine densities of tumour masses and lymph nodes.
Results: SUV_{max} and iodine density parameters were measured in 33 malignant lung masses (18.0 and 2.3 mg/mL, respectively) and 56 enlarged mediastinal or hilar lymph nodes (8.4 and 2.2 mg/mL, respectively). A moderate correlation was found for SUV_{max} and iodine density values in tumour masses (r=0.53). SUV_{max} and iodine density values of lymph node metastases showed a weak correlation (r=0.36). Additionally, iodine quantification analysis provided no added value for the differentiation of malignant from benign lymph nodes with an area under the curve (AUC) of 0.52 using PET-based SUV_{max} analysis as the reference standard.
Conclusion: The integration of PET/DECT in lung cancer staging can provide additional insights in the assessment of primary lung cancer and on the correlation between tumour vascularisation and metabolic activity, offering an alternative for tumour characterisation improvements.
Limitations: This is a pilot study with a small study size of 25 participants. The histological subtypes at various stages were not investigated in our study.

Ethics committee approval: This prospective, single-center study was approved by the ethics committee of our university hospital. All study participants provided written informed consent.
Funding: This study was supported by a research grant from Siemens Healthineers.

RPS 706-13 15:22
Prostate cancer lymph node metastasis assessment by artificial intelligence-based PET/CT detection
P. Borrelli[1], M. Larsson[1], J. Ulén[2], O. Enqvist[2], E. Trägårdh[2], H. Kjölhede[1], P. Hoilund-Carlsen[3], L. Edenbrandt[1]; [1]Gothenburg/SE, [2]Malmö/SE, [3]Odense/DK (pablo.borrelli@vgregion.se)

Purpose: First experience with automated artificial intelligence (AI)-based ^{18}F-choline-PET/CT detection of prostate cancer (PCa) lymph-node metastases.
Methods and materials: Cloud-based annotation (RECOMIA) was used by two nuclear-medicine specialists, who manually segmented lymph-node metastases in scans from 407 biopsy-proven PCa patients, 325 (80%) of which were used for training of a convolutional neural network (CNN), while 81 (20%) made up a validation group. Reader A annotated the total material blinded to training/validation designation. Reader B annotated the validation group blinded to Reader A and AI-based segmentation. CNN classified high tracer uptake suggesting lymph-node metastasis. A CNN-tool from prior studies was used to mask organs already segmented in the system.
Results: The AI-based tool failed in 1 validation patient weighing 123kg. In 18 of the remaining 80 validation patients both readers detected ≥1 lymph-node lesion and in 53 they agreed that no lesion was present. Inter-reader reliability, expressed by kappa, was 0.72 (95% CI 0.56-0.89). A total of 87 lymph-node lesions were detected by both readers; the AI-based tool detected 80 (92%) of these. Fifty-four were detected by one reader only; the AI-based tool detected 28 (52%) of these. The AI-based tool identified 219 suspicious lymph-nodes not detected by the readers or 2.7 per patient. Thus, the AI-based tool made 327 detections, of which 108 (33%) were considered lymph-node lesions by at least one reader.
Conclusion: Automated AI-based detection of lymph-node metastases is feasible and reproducible. The discrepancy between AI- and reader-based detection should be further investigated in prospective studies of PCa patients recognising the challenges of lymph-node detection and verification. The AI-based tools developed are available on request at (www.recomia.org) for research purpose.
Limitations: Further studies are needed.

Coronary calcium scoring at 100 kV with tin filtration using a kV-independent reconstruction kernel
R. H. Savage[1], A. F. Abadia[1], S. S. Martin[2], A. Varga-Szemes[1], A. Fischer[3], U. J. Schoepf[1], C. Tesche[4], P. Sahbaee[1], V. Vingiani[5]; [1]Charleston, SC/US, [2]Frankfurt am Main/DE, [3]Charleston/US, [4]Munich/DE, [5]Rome/IT (SavageRo@musc.edu)

Purpose: To investigate the feasibility of a protocol for coronary artery calcium scoring (CACS) at 100kV with tin filtration (Sn100kV) to provide accurate Agatston scores and to asses its potential for radiation dose reduction using a software-based correction algorithm and a kV-independent kernel compared to the standard 120kV acquisition.
Methods and materials: We analysed image data of 114 patients who underwent a clinically-indicated CACS acquisition using the standard 120kV protocol and an additional Sn100kV CACS research scan. Datasets of the Sn100kV scans were reconstructed using a kV-independent kernel, which produced images with Hounsfield units equivalent to 120kV for bone and calcium. This enabled Agatston scoring without changing the original weighting threshold of 130HU, regardless of the original tube voltage chosen for image acquisition. The Agatston scores and radiation dose values were calculated and compared between the two protocols.
Results: Median Agatston scores derived from the standard 120kV and the Sn100kV protocol with the kV-independent kernel were 24.7 (IQR:0-171.1) and 21.4 (IQR:0-173.8), respectively (p=0.18). We found an excellent correlation for Agatston scores derived from the two different protocols with a Pearson's correlation of r=0.99. The dose-length-product was 11.4±4mGycm using the Sn100kV and 50.4±24.9mGycm using the standard 120kV protocol (p<0.01), resulting in significantly lowering the effective radiation dose by 77% (0.16±0.06mSv vs 0.7±0.35mSv, P<0.01) for scanning at Sn100kV. Additionally, 99% of patients were classified into the same risk category using the Sn100kV protocol.
Conclusion: CACS at Sn100kV using the kV-independent kernel is feasible and shows a high correlation compared to standard 120kV scanning. Furthermore, the radiation dose was significantly reduced using the low-kV protocol.
Limitations: A single-centre study with images read by only one radiologist.

Evaluation of a tube voltage-tailored contrast media injection protocol for coronary CT angiography
R. H. Savage[1], V. Vingiani[2], U. J. Schoepf[1], A. F. Abadia[1], A. Fischer[1], M. van Assen[3], P. von Knebel Doeberitz[4], A. Varga-Szemes[1], S. S. Martin[5]; [1]Charleston, SC/US, [2]Rome/IT, [3]Groningen/NL, [4]Mannheim/DE, [5]Frankfurt am Main/DE (SavageRo@musc.edu)

Purpose: To evaluate a tube voltage-tailored contrast media (CM) application protocol utilising software support for patient-specific injection during coronary CT angiography (CCTA).

Methods and materials: In this HIPAA-compliant single-centre study, 120 patients referred to CCTA were prospectively assigned to a tube voltage-tailored CM injection protocol. Automated tube voltage selection (ATVS), which automatically adjusts kV to the patient's body habitus, ranged from 70-130kV by applying 10kV intervals. The iodine delivery rate (IDR) was adapted to the tube voltage level using dedicated software (Bayer/Medrad, Indianola, PA). The administrated CM volume ranged from 33mL at 70kV (IDR, 0.8gI/s) to 65mL at 130kV (IDR, 1.9gI/s). Attenuation measurements were performed in the aorta and coronary arteries to calculate quantitative signal-to-noise (SNR) and contrast-to-noise (CNR) ratios. Five-point scales were used to evaluate the overall image quality. Radiation metrics were assessed (Radimetrics™, Bayer) and compared between the protocols.
Results: The mean age of the study patients was 62.5±11.9 years. Image quality was rated as diagnostic in all patients. Contrast enhancement peaked at 7 kV ($p<0.001$), while SNR and CNR parameters showed no significant differences between the tube voltages ($p=0.085$). Additionally, no significant differences were found for subjective image quality parameters between the different protocols ($p=0.139$). The lowest radiation dose values were observed in the group of patients assigned to the 70kV protocol with a median effective radiation dose of 1.1mSv ($p<0.001$).
Conclusion: The proposed tube voltage-tailored injection protocol allows for an individualised scanning of patients undergoing CCTA with significant reductions of CM and radiation dose while simultaneously maintaining a high diagnostic image quality.
Limitations: The diagnostic accuracy of different tube voltage-tailored CM protocols was not investigated. The vendor-specific parameters for CM administration.
Ethics committee approval: IRB-approved, all subjects provided informed consent.

Interventional cardiology: patient exposure to radiation and interoperator variability — a healthcare group investigation

J. Anderson[1], M. Zanardo[2], B. Smith[3], M. Maher[3], L. Fox[3], A. Anderson[3], L. A. Rainford[3]; [1]Balbriggan/IE, [2]Di Milano/IT, [3]Dublin/IE
(joseph.anderson@ucdconnect.ie)

Purpose: To evaluate both retrospective and prospective radiation exposure data in a cohort of patients undergoing IC examinations performed by different operators to analyse factors impacting radiation dose with a special focus on operator dependency and to seek operator perceptions on radiation protection training.
Methods and materials: Retrospective and prospective data collation and analysis of radiation parameters from 179 DCAs and 43 PCIs performed in a single centre (Sept 2018-June 2019) by 3 interventional cardiologists within a Siemens Artis imaging suite were conducted. The radiation parameters available for all patients were dose area product (DAP), total fluoroscopy time (FT), the number of cine runs, and the cumulative air kerma. Data collated for retrospective examinations included D.O.B, gender, previous cardiac history, operator, procedure type, access route, contrast agent, and contrast dose. In addition, patient BMI and the total examination duration and complexity was recorded for prospective data. Dose reference levels were calculated at the 3rd quartile. Operators compared against each other and with national/international standards. Cardiologists with consistently low DRLs were followed up with a semistructured interview.
Results: DRLs were determined by gender, patient BMI, previous cardiac history, type of IV approach, contrast dose, and the operator, and were within Irish and European DRLs. Significant interoperator variability ($p<0.001$) was noted. The cardiologist acknowledges his trainer and mentor who influenced him a lot with his technique, decision making, efficiency, and low radiation levels.
Conclusion: Radiation safety in interventional cardiology procedures is operator dependent. Further research is warranted in the standardisation of operator training with evolving technologies.
Limitations: The retrospective data collection, discontinuous sampling, procedure-specific rather than patient-specific statistical analysis, and the non-availability of occupational dosimetry.
Ethics committee approval: Ethics approval from UCD School of Medicine and Departmental with permission from Bon Secours Hospital, Dublin.

Scattered radiation in mobile chest AP in ICU

M. Antikainen, M. Sarjanoja, K. Tuomivaara, T. S. Schroderus-Salo, A. Henner; *Oulu/FI*

Purpose: To investigate scattered radiation in the mobile chest at different distances and heights around the patient's bed with varying kV values.
Methods and materials: The study utilised a MobileArt evolution high power type 32kW (manufactured 2010) mobile x-ray unit. Measurements were taken with a phantom laying supine and half-sitting on a bucky table for an AP chest x-ray. The mAs value was 1.2mAs, while the tube potential varied from 95kV-125kV. Scattered radiation was measured both from the phantoms side and caudally with RaySafe i2 dosimeters (868.3MHz). The distances were measured from the centre of the radiation field at 0.5 m, 1 m, 1.5 m, and 2 m. At each distance, doses were measured at 70 cm (bed level), 100 cm, 130 cm, and 160 cm from the floor.
Results: The amount of scattered radiation increased when kV was raised in both patient positions. With the patient supine with 95kV, the dose rate was 3,222mSv/h, while at 125kV, it was 5,154mSv/h. Scattered radiation decreased significantly when the distance increased. For example, with 125kV and measuring at 160 cm, with 0.5 m distance, the dose rate was 6,244mSv/h, but at 2 meters only it was 0,944mSv/h. The highest dose rates for both supine (5,154mSv/h) and half-sitting (6,244mSv/h) positions were measured at 0.5 m and 160 cm from the floor.
Conclusion: As expected, the higher the tube potential, the more and further radiation scatters in both positions. The highest dose rates were measured at 160 cm from the floor (radiographers neck-head level) and the lowest doses were at the patient's bed level. Noting the direction of scattering radiation is important to protect the surrounding patients and personnel.

Convolutional neural network-based volumetric segmentation of the liver compared with semi-automatic and manual methods

B. Budai, P. Borsos, P. Magyar, V. Bérczi, P. N. Kaposi; *Budapest/HU*
(bettinabudai.95@gmail.com)

Purpose: The manual segmentation of CT images for volumetric analysis of the liver can be time-consuming. Alternatively, partially, or fully computer-aided methods can reduce labour and processing time.
Methods and materials: 62 CT scans from patients examined for diffuse or focal liver diseases were retrospectively collected. The portal venous phase scans were reconstructed with a slice thickness of 5 mm and without an interslice gap. The area of the whole liver was manually segmented as the ground truth with 3D Slicer software. A grow-from-seeds method was used for semi-automatic three-dimensional segmentation of the livers. Either every third or pre-selected five axial slices were used in the grow-cut process, followed by an automatic hole filling, extrusion removing, and surface smoothing of the predicted volume. We developed in-house a volumetric, fully convolutional neural network (V-net) for automated liver segmentation. The network was trained on 51 scans after image preprocessing and data augmentation. The remaining 11 scans were used in the test set and prediction accuracy was estimated after 10-fold cross-validation.
Results: The predicted volume of 62 livers in semi-automatic segmentation where the area of the whole liver was manually delineated on every third slice showed a Dice coefficient of (DSC)=mean±SD=0.96±0.007, Hausdorff average distance of (Hd)=0.95±0.22 mm, and a Jaccard coefficient of (Jc)=0.93±0.012.

The accuracy of the semi-automatic segmentation using only five manually contoured slices was also excellent: DSC=0.94±0.013, Hd=1.83±0.67 mm, and Jc=0.88±0.023. Meanwhile, the V-net based segmentation has achieved DSC=0.87±0.024, Hd=4.25±0.76 mm, and Jc=0.77±0.043.
Conclusion: We conclude that a V-net model can be used for liver segmentation with similar accuracy to manual and semi-automatic methods, thus, expediting the clinical workflow.
Limitations: The size of the training and validation cohorts should be increased before a clinical application can be introduced.
Ethics committee approval: Approval obtained from the research ethics committee of our institution.

Split-bolus and single-pass CT of the abdominal district
A. Missere, N. Raiano*; Naples/IT*

Purpose: To compare the various standard CT protocols and those performed with split-bolus and single-pass techniques, emphasising the advantages and differences in the abdominal district.
The several demonstrated protocols which have used split-bolus and single-pass techniques have the purpose of underlining a decrease of the radiation dose to the patient compared to the standard protocols. The optimisation of the protocol to reduce radiation dose becomes more remarkable considering the new 2013/59 EURATOM directive.
Methods and materials: The illustrated protocols referring to the abdominal district evaluate the diagnostic accuracy of patients with non-traumatic acute or inflammatory bowel disease, the detection and characterisation of focal liver lesions in oncologic patients, the detection of FNH, the pre-operative assessment of HCC, the evaluation of the resectability of pancreatic tumours, and the synchronous nephrographic and excretory phase in the uro-CT.
Results: The diagnostic efficacy of split-bolus and single-pass CT techniques is comparable to that of the multiphasic protocol CT.
Conclusion: The comparison between split-bolus and single-pass CT with multiphasic protocol CT is in terms of noise and CNR, with a reduction in radiation dose and in the number of images to film and store. This comparison demonstrates the diagnostic efficacy and the reduction of radiation dose with the split-bolus and single-pass CT protocols.
Limitations: The amount of contrast in some split-bolus CT protocols.
Ethics committee approval: Local ethics committee approval was obtained.
Funding: No funding was received for this work.

Vascular activity in rotator cuff tendinopathy: evaluation with conventional Doppler ultrasound and superb microvascular imaging (SMI)
C. C. Ooi, K. Q. Teng, S. K. Wong, G. M. Tan, V. C. Ma, S. N. Mohamed, P. C. Mohan, T. S. Howe, M. A. Png*; Singapore/SG*
(1602085@sit.singaporetech.edu.sg)

Purpose: Superb microvascular imaging (SMI) is an innovative Doppler technique for imaging minute vessels with slow velocity. The primary aim of this study was to elucidate the application of SMI in comparison with conventional colour Doppler (CD) and power Doppler (PD) in detecting neovascularity in the supraspinatus tendon. The secondary aim was to investigate the association between neovascularity and shoulder pain and functional disability.
Methods and materials: The supraspinatus tendon of consecutive patients presented with clinical suspicion of rotator cuff problems were evaluated with grey-scale (tendon enlargement, homogeneity, and hypoechogenicity), CD, PD, and SMI. Two radiologists independently graded the images. The relationship between neovascularity (on CD, PD, and SMI) and pain/disability as determined by a visual analog scale (VAS) and the Oxford shoulder score (OSS) was established.
Results: 59 patients (mean age 53, 39 females) were recruited. 34 (34/59: 58%) patients demonstrated no flow in all Doppler techniques while in 22 (22/59: 37%) patients, vascularity was detected in SMI but not with CD or PD ($p<0.01$). SMI positively correlated with hypoechogenicity on grey-scale ($p<0.01$), VAS ($p<0.001$), and OSS scores ($p<0.001$), while CDU and PDU did not show a significant relationship. The Kappa-coefficients of grey-scale, CD, PD, and SMI between the two reviewers were 0.87, 0.79, 0.74, and 0.85, respectively.
Conclusion: Neovascularity on SMI is associated with a hypoechogenic alteration of the supraspinatus tendon and is more related to shoulder pain and functional deficit compared to CD and PD. SMI is a feasible and reliable clinical tool. The supplementation of SMI to conventional ultrasound may increase the performance for diagnosing painful rotator cuff tendinopathy.
Limitations: A single-centre study with a small sample size.
Ethics committee approval: Approved by the Singapore Institute of Technology (SIT) Institutional Review Board.
Funding: No funding was received for this work.

Body composition in elderly lung transplantation recipients assessed by pre-transplantation computed tomography scans predicts the outcome after lung transplantation
D. Kifjak, H. Prosch, S. Schwarz, A. Benazzo, P. Jaksch, M. Weber, W. Klepetko, K. Hoetzenecker, T. Schweiger*; Vienna/AT*
(daria.kifjak@meduniwien.ac.at)

Purpose: To predict the clinical outcome in elderly lung transplantation (LuTx) recipients after transplantation by semi-automated quantification of body composition in preoperative chest CT scans.
Methods and materials: This retrospective study included 114 patients ≥60 years who received LuTx at the Medical University of Vienna from December 1998-December 2018 and who underwent a chest CT within one year before transplantation. The mediastinal fat areas at the level of the carina and the dorsal muscle group (DMG) areas at the level of the 12th thoracic vertebral body were calculated semi-automatically using OsiriX (Pixmeo, Switzerland). The adjusted and normalised data was correlated with clinical parameters.
Results: The mean age at transplantation was 63±2.7 years. Fibrosis (40.4%) and COPD (50.9%) were the most common diagnoses. We identified three groups of patients according to body composition ("low risk": high muscle mass and low mediastinal fat (n=8), "high risk": low muscle mass and high mediastinal fat (n=12), and "intermediate": any other combination (n=94)). The "high risk" group patients compared to the "low risk" group patients had a significantly increased risk for wound infections (p=0.001), delirium (p=0.042), and tracheostomy (p=0.032). The time of ventilation (p=0.022; 480 vs 43 hours), the stay in the ICU (p=0.001; 38 vs 5 days), and the stay in hospital (p=0.001; 66 vs 19 days) were significantly longer in the "high risk" group compared to the "low risk" group.
Conclusion: The body composition in pre-transplantation chest CT scans of LuTx candidates is an objective and easily applicable tool for the identification of patients with a poor outcome after LuTx. In addition, it accentuates the pivotal importance of physical activity and rehabilitation in LuTx.
Limitations: The small sample size and single centre.
Ethics committee approval: Ethics committee approval obtained.

The value of diffusion-weighted MRI in differentiating benign from malignant rectal tumours and assessing the grading of the malignant tumours

A. H. Albu Mohammed, D. A. Al-Hilly*; Baghdad/IQ (ali_dawai@yahoo.co.uk)*

Purpose: To evaluate the value of the apparent coefficient of diffusion in the differentiation between benign and malignant rectal tumours and to assess the histological grading of the malignant tumours.
Methods and materials: A cross-sectional study was conducted in Medical City Complex. Forty patients with rectal tumours were included, and an MRI exam was done for all patient with diffusion weighted imaging as a part of the exam. All patients were followed up for a final histopathological result.
Results: A total of 40 patients, with 21 female and 19 male, their age range from 19-75 years with the mean age of 52.37 ± 14.14 years. All malignant rectal tumours showed restricted diffusion with lower ADC values in comparison to benign tumours (0.814 ± 0.14 vs 1.433 ± 0.27 * 10^{-3} mm^2 / sec). Also, there were statistically significant differences between grades of malignant tumours (well, moderate and poor differentiated) in which the poorly differentiated tumours have lower ADC value than moderate and well-differentiated tumours. In addition to that, the diffusion-weighted imaging revealed an increase in the number of detected lymph nodes when compared with conventional MRI exam without DWI (5.76 ± 3.26 vs 4.42 ± 1.95 lymph nodes).
Conclusion: Diffusion-weighted MR imaging is a valuable tool in the differentiation of benign from malignant rectal tumours with high sensitivity and specificity with the aid of ADC values calculated from the maps obtained by DWI and also in assessing the grading of malignancy.
Limitations: The susceptibility artefact of the diffusion-weighted imaging in addition to artifacts from the air and other contents of the bowel. Small tumours less than 1.5 cm.
Ethics committee approval: n/a

Role of 18F-FDG PET-CT in detection and staging of hepatocellular carcinoma

H. Abdelhalim, M. Houseni, M. Elsakhawy, N. Abd Elbary, O. Elabd*; Shebeen El-Kom/EG (heba.abdelhalim@liver.menofia.edu.eg)*

Purpose: To evaluate the role of fluorine18-fluorodeoxyglucose positron emission tomography/computed tomography (18F-FDG-PET/CT) in detection of hepatocellular carcinoma (HCC), its regional and distant metastasis.
Methods and materials: A prospective study on 100 patients referred to our centre due to presence of hepatic focal lesions. As a part of investigation, 18-F-FDG PET/CT was done. Sensitivity of 18-F-FDG PET/CT to detect HCC, its nodal and distant metastasis was calculated.
Results: 18F-FDG-PET/CT has shown high sensitivity for the detection of primary HCC (93.4%), regional lymph nodal metastases (91.3%) and pulmonary deposits (88.2%). It demonstrated high specificity for detection of pulmonary deposits (95.2%). Metabolically active HCC lesions were detected in only 70% of cases with poorly differentiated HCC in 32 patients, moderately differentiated HCC in 23 patients and well-differentiated HCC in only 8 patients with P-value <0.001. We detected a significant difference in SUVmax value between the different grades of HCC (P-value < 0,001) with mean SUVmax 3.0±0.53 for well-differentiated HCC, 5.3±2.6 for moderately-differentiated HCC & 10.6±4.2 for poorly differentiated HCC.
Conclusion: 18F-FDG-PET/CT has high sensitivity in detection of high pathologic grades of HCC, lymph nodal as well as pulmonary deposits.
Limitations: Histopathology for HCC metastases was not available in all cases. The presence of enlarged reactive regional lymph nodes in cirrhotic patients caused increased false-positive nodal metastasis.
Ethics committee approval: The research programme and the informed consent have been approved by the ethics committee of the National Liver Institute, Menofia University, Egypt.
Funding: No funding was recieved for for this work.

Whole-body low-dose CT scan imaging quality and radiation dose in multiple myeloma: a comparison between 128-slice and 64-slice scanners

A. Ahmed, P. Kiely, J. Saunders*; Limerick/IE (a.ahmed2@nuigalway.ie)*

Purpose: Imaging is crucial for staging and monitoring multiple myeloma patients. Radiation exposure from these imaging is of particular concern in this patient group as they require repeated imaging of the whole body. The aim of this study is to assess the difference in radiation dose and objective image quality in multiple myeloma patients, comparing 64-slice and 128-slice CT scanner for whole-body imaging.
Methods and materials: This was a retrospective, single centre study involving patients who have histologically proven multiple myeloma and have had whole-body CT imaging on 128-slice and 64-slice CT scanner at University Hospital Limerick, evaluating image quality objectively and radiation exposure. Image quality analysis was performed by measured the signal to noise ratio and contrast to noise ratio. Radiation dose was automatically calculated for 32-cm body phantom by the CT scanner.
Results: Our study demonstrated that image quality is improved while using the 128-slice CT scanner, with significantly reduced radiation dose when compared to 64-slice scanner (9.57 mSv with 64-slice scanner vs 4.93 with 12-slice scanner). The improvement of image quality was statistically significant in two, out of the three anatomical sites measured.
Conclusion: Due to the improved image quality and reduced radiation dose, we recommend using the 128-slice CT scanner for staging and monitoring multiple myeloma patients.
Limitations: The main limiting factors of this study are the low sample size used and the fact this was a single centre study. Objective image quality was measured at three anatomical sites. More anatomical site comparisons would have led to a more comprehensive study.
Ethics committee approval: Study was approved by the local ethics committee.
Funding: No funding was recieved for this work.

Predicting response to therapy of locally advanced rectal cancer: radiomic analysis from MR imaging

M. Micilotta[1], G. Cappello[2], V. Giannini[2], A. Defeudis[2], S. Mazzetti[2], S. Cirillo[1], D. Regge[2]*; [1]Turin/IT, [2]Candiolo/IT (monicamicilotta@gmail.com)*

Purpose: To predict the response to neoadjuvant therapy in patients with locally advanced rectal cancer (LARC) using texture features of MRI staging examination, to customise therapeutic management.
Methods and materials: The dataset is composed of 52 patients acquired in two different institutions with different MR scanners and protocols. All colorectal cancers were manually segmented on the T2-w images. CRCs were classified as non-responders (R-) if their TRG score was >=3 and responder (R+) otherwise. 39 quantitative features were extracted from the largest segmented slice, including volume, mean, standard deviation, percentiles, skewness, kurtosis, and texture parameters from GLCM and GLRLM matrices from both T2w and ADC maps. Patients from institution A and B were randomly used as training and testing dataset. A stepwise logistic regression model was created using 70% of lesions (36) as a training set and 30% as testing set (16) randomly selected.
Results: The dataset included 21 R- and 31 R+ tumours. Accuracy on the training set was 98% (35/36), with sensitivity and specificity of 100% (21/21) and 95% (14/15), respectively. Accuracy on the testing set was 87% (14/16), with sensitivity, specificity, NPV and PPV of 86% (8/9), 89% (6/7), 89% and 86% respectively.
Conclusion: This study demonstrates the possibility to recognize, analyzing MRI staging examination, patients that will not respond to conventional neoadjuvant therapies, to customize treatment and avoid the use of ineffective therapies, preventing unnecessary toxicity and costs.
Limitations: This study is limited by a manual segmentation with consequent interobserver variability and an external validation dataset.

Ethics committee approval: Ethics committee approval obtained.
Funding: AIRC5x1000 - Ref. 9970, FPRC5x1000 Ministero Salute 2013, FPRC5x1000 Ministero Salute 2015.

Pre-operative CT staging of borderline pancreatic cancer patients after neoadjuvant treatment: its accuracy in the prediction of vascular invasion and resectability
S. Ahmed*; Assiut/EG (shimaaabdalla@aun.edu.eg)*

Purpose: To assess the utility of MDCT-tumour vascular interface criteria for predicting vascular invasion and resectability in borderline pancreatic cancer (BRPC) patients after neoadjuvant therapy.
Methods and materials: Eighty-six patients with BRPC who finished neo-adjuvant therapy, showed no progression in preoperative CTs and underwent surgery were included. Two radiologists assessed preoperative CTs to predict vascular invasions and resectability status; the comparison was done with surgical and pathological findings.
Results: At preoperative MDCT, combined criteria of circumferential interface ≥ 180^0 and venous contour deformity (teardrop appearance, unilateral/ bilateral narrowing or occlusion) correctly predicted (89.4%) of venous invasions with an accuracy 93.2%. Combined criteria of circumferential interface ≥ 180^0 with contour deformity (narrowing, teardrop appearance, occlusion) or length of tumour contact > 2cm correctly predicted (71.4%) of arterial invasions with an accuracy 90.7%. Preoperative CT correctly predicted (94.4%) of R0 resections. In cases with no pathologic vascular invasion, criteria of preserved tumour vascular intervening fat/pancreas parenchyma, or lost intervening fat/parenchyma but with circumferential interface ≤ 90^o, preserved normal venous contour and patent lumen correctly predicted (96%) of R0 resections with an accuracy 94.1%. In cases with vascular invasion, combined criteria of circumferential interface < 180^o with preserved normal venous contour and patent lumen correctly predicted (93.3%) of R0 resections with an accuracy 85.1%.
Conclusion: Tumour vascular interface criteria are accurate in the prediction of vascular invasion after neo-adjuvant therapy. MDCT was helpful in the prediction of R0 resection in cases with no pathologic vascular invasion and cases with only venous involvement.
Limitations: We analysed only cases with no progression on pre-operative CT based on RECIST criteria, it may underestimate the number of R0 resections.
Ethics committee approval: IRB approval was obtained.

MyT3 8-6 16:20
Measurement of the volume of a metabolically active tumour by PET/CT with 18F-FDG: a new criterion for the status of the disease in patients with multiple myeloma
A. Sergey, V. Troyan, S. V. Kozyrev, O. A. Rukavitsyn*; Moscow/RU (sergey-alexeev@rambler.ru)*

Purpose: Using PET/CT with 18F-FDG, determine the volume of the metabolically active tumour (MAT) and TLG, and the change in the dynamics of these parameters.
Methods and materials: The results of 99 PET/CT were analysed in 15 patients. After each study, the volume of the MAT, TLG, was measured. The results of PET/CT were differentiated according to the status of the disease at the time of the study, where “1” - stringent complete response and complete response “2” - very good partial response and partial response; "3" – stable disease; "4" - progressive disease.
Results: The results were divided into four groups: “1” (n = 36); “2” (n = 19); "3" (n = 8); “4” (n = 33). In group “1”, lower values of the MAT and TLG were observed compared with other groups — the median of the MAT = 1 [0; 2.95]; median TLG = 2 [0; 11]. In group “3”, high values of the MAT and TLG were observed compared to other groups — the median of the MAT = 190 [65.5; 326]; median TLG = 2,298 [107; 671]. In the subsequent pairwise comparison of medians, significant differences (p> 0.01) in the measurement of the MAT and TLG were detected by the MAT in the groups “1” and “2”; “1” and “3”; “1” and “4”; “2” and “4”; by TLG in the groups “1” and “3”; “1” and “4”; "2" and "4".
Conclusion: Metabolically active tissue volume and TLG statistically significantly change at different disease statuses. This suggests that this method can be used as an independent criterion for assessing the status of the disease in patients with MM

Multi-parameter model-based on dual-energy CT predicts mediastinal lymph node metastasis in lung cancer patients
X. Hu, Q. Gu, K. Zhang, P. Li, H. Shen*; Changsha/CN (649291883@qq.com)*

Purpose: To develop a multi-parameter model based on dual-energy CT imaging to predict the mediastinal lymph node metastasis in lung cancer patients.
Methods and materials: Forty-two patients prospectively underwent dual-energy computed tomography (DECT) and a gemstone spectral imaging (GSI) before surgery due to lung cancer. The mediastinal lymph node short diameter, enhancement degree and enhancement mode were evaluated. The lymph nodes CT value at different energy levels (40keV～190keV, interval 10 keV) and spectrum slope, iodine density were obtained. Logistic regression analysis was performed to find out the factors associated with lymph node metastasis, and CT subjective imaging model, DECT model and multi-parameter combined model were established, respectively. The performance of these classifiers was evaluated by the receiver operating characteristic curve (ROC) and compared with Delong test.
Results: A total of 74 lymph nodes were obtained in 42 patients, including 33 lymph nodes metastasis positive and 41 lymph nodes metastasis negative. Logistic regression analysis showed that the CT value at 100Kev and the slope of the energy spectrum curve were correlated with lymph node metastasis (P<0.05). The DECT model achieved the best performance [AUC=0.904; 95% confidence interval (CI) 0.832 to 0.976] in predicting the mediastinal lymph node metastasis with sensitivity and specificity of 0.805 and 0.939, which was better than that of CT subjective imaging model(AUC=0.776, P=0.004). The multi-parameter combined model did not improve the predictive performance (AUC= 0.920,P = 0.123), with sensitivity and specificity of 0.780 and 0.970.
Conclusion: DECT model can significantly improve the accuracy of preoperative diagnosis of mediastinal lymph node metastasis in lung cancer patients.
Limitations: The sample size is small. The model needs to be tested with external test data.

Qualitative assessment in radiotherapy of lung cancer using gemstone spectral imaging
L. Weihua, Y. Wang, F. Lin, Y. Lei*; Shenzhen/CN (18804511716@163.com)*

Purpose: To evaluate tumour responses in patients treated with radiotherapy for medically inoperable non-small cell lung cancer (NSCLC) by assessing intratumoral changes and damage of nearby tissues using gemstone spectral imaging (GSI).
Methods and materials: 26 cases of early-stage, biopsy-proved, medically inoperable lung cancer (NSCLC) underwent gemstone spectral imaging before and 1-6 weeks after radiotherapy. The CT images before and after radiotherapy were obtained and iodine concentration, water concentration and spectrum energy curve and CT values at 40-50 keV were measured. All the data were post-processed by using GSI viewer software. Tumour response was evaluated

by comparing tumour dimensions, volumes and damage of nearby tissues before and after radiotherapy with standard PET/CT evaluation criteria. Those measurements between pre- and post-treatment and two methods were compared by using SPSS 17.0.
Results: Mean CT values of a tumour and iodine content of the tumour region of interest (ROI) in post-therapy were significantly lower than that in pre-therapy (50.13±7.50 vs 78.82±11.81 (HU), 0.91±0.32 vs 2.65±0.35 (g/L), P<0.05 respectively), while water concentrations were found no significant difference between them. The results also exhibited that the radiotherapy can be targeted more precisely with the help of GSI with reduced damage of nearby healthy tissues. Using response evaluation criteria for solid tumours (RECIST), 14 patients demonstrated complete responses, 8 partial responses and 4 stable diseases, which is consistent with previous qualitative evaluation by PET/CT.
Conclusion: Gemstone spectral CT imaging is a noninvasive, precise and rapid screening method. By spectral imaging and material separation technology, it could provide more qualitative and quantitative assessment in radiotherapy of lung cancer.
Limitations: The authors have declared that no competing interests exist.
Ethics committee approval: The ethics committee of Shenzhen Second People's Hospital has given ethical approval.

Exploring the implications of modified advanced lung cancer inflammation index on outcomes in patients with advanced non-small cell lung cancer

D. Goyal, A. Mahajan, K. Prabhash*; Mumbai/IN (devendragoyal4@gmail.com)*

Purpose: Sarcopenia and NLR are both predictive and prognostic marker in oncology. The objectives were to evaluate the prognostic value of modified ALI beyond original ALI and see the interaction between sarcopenia, SMD, NLR, ALI and mALI at baseline and post four cycles of chemotherapy and their effects on OS and PFS in patients with advanced NSCLC.
Methods and materials: This study consisted of a total of 285 advanced NSCLC patients. Morphometric parameters such as SMD, SMI and fat-free mass (FFM) were measured by CT at the L3 vertebra. ALI was defined as BMI x serum albumin/neutrophil-lymphocyte ratio (NLR) and mALI was defined as SMI x serum albumin/NLR.
Results: Based on the cut-off of <36.62 HU 185 (64.9 %) had poor muscle quality. Using the cut-offs described by Prado et al the prevalence of sarcopenia within the population was 162(56.8%). About 70% of patients were found to be suffering from sarcopenia across all the BMI categories and this was found to be significant. Patients having sarcopenia suffered from a higher incidence of chemotherapeutic drug toxicities 152 as compared to 121 amongst non-sarcopenics, but this was not found to be statistically significant. ROC curves were used to define poor ALI [<28.02] and mALI [<55.33]. Concordance was seen between ALI and mALI in the pre-treatment setting with 90% of patients with poor ALI having poor mALI and this was statistically significant.
Conclusion: Pre-and post-chemotherapy sarcopenia, SMD and mALI were statistically significant factors in predicting OS in both univariate and multivariate analysis. These biomarkers could potentially help triage patients for chemotherapy according to their tolerability and active nutritional intervention for better outcomes.
Limitations: Post-chemotherapy ALI could not be calculated.
Ethics committee approval: Approval was obtained.
Funding: No funding was received for this work.

Application of the new anaesthetic protocol N.O.R.A. (non-operating room anaesthesia) for osteoid osteoma percutaneous treatment

A. Paladini[1], A. Borzelli[2], F. Pane[2], M. Spinetta[1], D. Negroni[1], A. Galbiati[1], I. Percivale[1], Z. Falaschi[1], G. Mazzucca[1]; [1]*Novara/IT,* [2]*Naples/IT (andreapaladini1988@gmail.com)*

Purpose: The purpose of this study is to verify the effectiveness and complications occurrence of radiofrequency ablation (RFA) in the treatment of osteoid osteoma (OO) in non-operating room anaesthesia (N.O.R.A.).
Methods and materials: From 2016 to 2019, 61 patients affected by OO (40 men and 21 women) with an age of 20.7 years on average (range, 4-51 years; 12 patients aged 20 years or younger) underwent computed tomography-guided percutaneous radiofrequency ablation (RFA) in N.O.R.A. (non-operating room anaesthesia). Lesion sites treated were: femur (27), tibia (22), pelvis (2), talar bone (3), distal radius (1), and humerus (6). Mean follow-up time was 36 months. In each case, anaesthesiologic support followed a new protocol (N.O.R.A. protocol), approved by our institute. Primary success rate, complications, symptom-free intervals, and follow-up results were evaluated.
Results: Pain relief (evaluated with visual analogue scale – VAS) was significant in 97% of patients; it disappeared within 24 hours of the procedure in 44 patients, within 3 days in 10 patients, and within 7 days in 7 patients. After 6 months of observation time, 60 of 61 patients were successfully treated and had no more complaints. In 2 patients, two major complications were found: infection of the site treated, healed with antibiotics, and a nerve lesion, healed with steroid therapy. No other complications were observed.
Conclusion: RFA is a highly effective, efficient, minimally invasive and a safe method for the treatment of OO following N.O.R.A. protocol.
Limitations: No randomisation of patients and poor follow-up were identified as limitations.

LDCT the saviour? Low-dose CT chest as a cost-effective tool for lung cancer screening in developing countries

A. V. Alexander, A. Babu*; Thiruvalla/IN (ashwinalexander@gmail.com)*

Purpose: Lung cancer is the leading cause of death worldwide. In developed countries, morbidity and mortality due to lung cancer are decreasing due to screening and early detection. In a low income country, high-resolution CT (HRCT) of the lung is almost 15 times the average daily wage. Hence, HRCT is scarcely used as a screening tool, and clinicians mainly rely on chest x-rays for diagnostic purposes which often reveals only the tip of the iceberg. This study aims to create awareness about the effectiveness of low-dose CT (LDCT) as a screening tool.
Methods and materials: This is a descriptive, retrospective study of all patients who underwent LDCT chest in our institution from 1st January 2018 to 31st March 2019. Patients with a history of carcinoma lung/previously detected nodules/mass lesions were excluded. From LDCT images and reports demographic details, diagnosis, lymphadenopathy, mass lesions, nodules and calcification were collected. They were categorised based on ACR guidelines. All images and reports were viewed by the authors personally to remove any interpersonal bias.
Results: Total number of patients included in the study was 649. Findings were detected in 62.5% of the sample, which included 11.4% had miliary lesions, 8.4% had nodules and 0.1% had a mass lesion. Of the total nodules detected 78% were non-calcified. In miliary lesions, 59% were non-calcified.
Conclusion: LDCT is an effective tool for screening pulmonary cancers in countries and regions with limited economic resources. In our study, the positive screen was 6.8% in the general population. If LDCT is deployed for screening targeted populations like smokers, the detection rate would be higher.

Integrated PET/MRI for therapy response assessment of patients with Ewing sarcoma: preliminary results

J. Grueneisen[1], M. Chodyla[1], B. M. Schaarschmidt[2], O. Martin[2], M. Forsting[1], K. Herrmann[1], L. Umutlu[1]; [1]*Essen/DE,* [2]*Düsseldorf/DE (johannes.grueneisen@uk-essen.de)*

Purpose: To evaluate the clinical applicability of integrated PET/MRI for monitoring the effectiveness of primary systemic treatment of Ewing sarcoma patients.
Methods and materials: A total of 5 juvenile patients with the confirmation of an Ewing sarcoma and scheduled for the VIDE polychemotherapy regimen (6 cycles) underwent a PET/MR examination before the start (1st scan), after the second cycle (2nd scan) as well as after the end (3rd scan) of treatment. Two experienced physicians analysed the imaging datasets. They were instructed to

perform a whole-body tumour staging in each examination to identify all tumour lesions as well as to assess potential changes during treatment. Therapy response was defined according to the RECIST1.1 and PERCIST criteria. Histopathological analysis and follow-up imaging served as the reference standard.
Results: PET/MR examination of the primary tumours showed a slight decrease in size during treatment (mean size: 1st scan: 77.6mm; 2nd scan: 60.0mm (-22.9%); 3rd scan: 56.6mm (-27.2%), however revealed a significant reduction in metabolic activity (mean SUVmax: 1st scan: 5,9; 2nd scan: 2,3 (-61,0%); 3rd scan: 1,9 (-67.8%). Furthermore, in 4 cases distant metastases could be detected. One patient showed a metabolic complete response, while morphological analysis revealed stable disease. Three further patients revealed metabolic partial response, whereas, RECIST classified two patients as a partial responder and one patient as stable disease. One patient showed new FDG-avid metastases and was classified as a progressive disease.
Conclusion: Our preliminary results demonstrate a good diagnostic performance of integrated PET/MRI for staging and therapy monitoring juvenile patients with Ewing sarcomas, in combining morphological and metabolic information, accompanied with a reasonable radiation dose for the patient.
Limitations: This study was limited by patient cohort.
Ethics committee approval: The study was approved by the local ethics committee.

Multi-parametric MRI approach for post-TACE HCC
M. Elmansy, M. Elrakhawy, M. A. El-Adalany*; Mansoura/EG (sasamansy90@gmail.com)*

Purpose: To evaluate the role of dynamic-combined subtraction and diffusion magnetic resonance imaging (MRI) in the differentiation between residual and necrotic lesions after treatment by trans-arterial chemoembolization (TACE).
Methods and materials: This prospective study included 50 cases of hepatocellular carcinoma (HCC) patients underwent TACE based on ethical respect and eligibility of patients to do MRI on a 1.5-tesla machine. Diffusion-weighted images (DWI) were done before the dynamic study at different levels. Apparent diffusion coefficient (ADC) maps and subtraction dynamic series were created using a workstation and ADC value was calculated. MR images were interpreted by two different levels experienced observers taking the follow-up findings as regard imaging and arterial hypervascularity blush on repeated TACE as our reference standard. The diagnostic accuracy of dynamic, DWI, subtraction and ADC values for both observers were determined and considered statistically significant at p-value <0.050.
Results: Dynamic and subtraction studies were superior to DWI as regard their diagnostic accuracy and had the same values. Dynamic and subtraction specificity was 90.5 and 95 % for observer 1 and 2 respectively whereas DWI was 76 and 81 % for the same observers respectively. There was a statistically significant difference in ADC value between residue (n=29) and non-residue (n=21) groups with cut-off value for complete ablation >0.94 and >1.05 for both observer (1) and (2) respectively. The absolute agreement and consistency between the two observers Cohen K =0.9 for both dynamic and subtraction and 0.78 for DWI.
Conclusion: Each MRI modality has its merit and accuracy in evaluation of HCCs post-TACE.
Limitations: No pathology due to biopsy sample error post-TACE. No available CT for all patients for comparison.
Ethics committee approval: n/a

Multidisciplinary approach in the diagnosis of primary and secondary lung and pleura tumours in cases of synchronous and metachronous cancers
L. Petrychenko*; Dnipro/UA (petrychenkoliliana@gmail.com)*

Purpose: To increase preoperative diagnosis of lung and pleura tumours and to identify the belonging of metastases in the organs of the chest cavity in cases of multiple localisations of the oncological process with the help of CT-guided transthoracic trepan biopsy to obtain a histological material for verification and selection of a specific treatment.
Methods and materials: In the period from January to September 2019, we had made a transthoracic pulmonary biopsy of 27 patients with primary and secondary tumours and with lung and pleura nodes. 11 of them were patients with one localization of oncological process. There were 3 patients with primary non-verified tumours of the chest cavity. And 13 patients had multiple localisations of oncological process. The size of the nodes and tumours varied from 9mm to 11sm.
Results: Histological results were obtained from all investigated nodes and tumours of 27 patients. Biopsy gave a histological answer about the origin of the node or tumour, which made it possible to select the treatment for patients correctly and specifically. According to histological research, 3 patients had tumours and changes which were not related to the oncological disease. 6 patients were diagnosed lung cancer as the second localisation of oncological process. 18 patients had the continuation of the main process and we received the information about the genesis of metastases in cases of primary multiple localisation.
Conclusion: Obtainig a biopsy of tumour tissue makes it possible to get information about the genesis of metastases in cases of synchronous and metachronous cancers. CT guided transthoracic biopsy helps to get tumour tissue material, carry out molecular genetic studies and makes it possible to individualise approaches to the patient's treatment.

Assessment of body composition using magnetic resonance imaging and association with clinical outcomes in patients with colorectal and lung cancer
N. Sakai, A. Bhagwanani, J. Khalasthry, M. Hall-Craggs, S. A. Taylor*; London/UK*

Purpose: To examine the relationship between body composition, as measured by MRI, and the clinical outcome of patients with colorectal and lung cancer.
Methods and materials: Patients with colorectal or lung cancer were prospectively recruited to two multicentre studies examining the use of whole-body MRI in cancer staging (February 2013-September 2016). MR images (Philips mDixon) of patients from 9 sites were post-processed by 2 radiologists using a semi-automated in-house segmentation tool to derive total body fat mass (FM), fat-free mass (FFM), skeletal muscle (SM) mass and SM fat fraction (FF), corrected for height. Body composition parameters were compared between lung and colorectal cancer patients using the t-test, and with a length of hospital stay (LHS), metastatic status and mortality using linear regression and t-tests.
Results: 74 patients with colorectal (42M, 32F; mean age 62.9±12.1) and 53 patients with lung cancer (28M, 25F; mean age 66.9±10.5) were included. Patients with lung cancer had significantly greater mean SM FF than those with colorectal cancer (p=0.0124), and lower FFM (p=0.0071) and SM (p=0.0084) indices. LHS in lung cancer patients was significantly associated with SM FF (p=0.035). We found no relationship between body composition and metastatic status or 12-month mortality.
Conclusion: Patients with lung cancer have lower FFM and SM indices consistent with a reduction in muscle mass compared to colorectal cancer patients. In lung cancer patients, increasing SM FF (i.e. fatty infiltration) was associated with a greater LHS. These findings may reflect differences in the underlying disease pathogenesis and have implications for management in terms of optimising nutritional support.
Limitations: Specific reasons for hospital stay were not recorded so further analysis of the relationship between LHS and body composition was not possible.
Ethics committee approval: Ethical approval and written informed consent received.
Funding: No funding was received for this work.

A preliminary study of spectral imaging characteristic differences among tumour tissue, transition tissue and normal tissue of pancreatic cancer

W. Wu, Y. Xu; *Guangzhou/CN (zai.sa@163.com)*

Purpose: To investigate the clinical value of gemstone spectral imaging (GSI) parameters changes among tumour tissue, transition tissue and normal tissue of pancreatic cancer on wide detector spectral CT.
Methods and materials: 19 adult-patients diagnosed as pancreatic cancer and 12 adult-patients as control group were performed 4 phases spectral-enhanced examination on revolution CT. For the patients with pancreatic cancer, ROIs were drawn separately from tumour tissue, transition tissue to normal tissue. Iodine(water) density and water(iodine) density were measured in late-arterial phase and fat(iodine) density was measured in plain phase. The data of tumour tissue, transition tissue and normal tissue of pancreatic cancer were compared with each other, and their differences with those of control group were analysed.
Results: For the patients with pancreatic cancer, from the tumour, the transition zone to the normal tissue, the iodine(water) values, water(iodine) values and fat(iodine) values were gradually increased. The values of iodine(water) and water(iodine) among groups were found significant differences with each other ($p<0.05$); there were no significant differences between the fat(iodine) values between tumour and transition zone, transition zone and normal tissue ($p>0.05$), while there was significant difference between tumour and normal tissue ($p<0.05$). Compared with the control group, there were significant differences among tumour, transition zone and normal tissue in iodine(water) values respectively ($p<0.05$); there were significant differences between the control group and tumour, transition zone in water(iodine) values and fat(iodine) values ($p<0.05$), but no significant difference with normal tissue ($p>0.05$).
Conclusion: Using spectral imaging parameters, the changes of "the tumour side to the transition zone to normal tissue" in pancreatic cancer can be evaluated and differentiated with the normal pancreas.
Limitations: No golden standard.
Ethics committee approval: This study was approved by the ethics committee.
Funding: No funding was received for this work.

The role of diffusion-weighted magnetic resonance imaging in the assessment of response to treatment in cervical cancer patients after chemo-radiation therapy

G. Zanirato Rambaldi, M. Giannotta, A. Galuppi, E. Salizzoni; *Bologna/IT*

Purpose: To analyse the role of DW-MRI in early prediction of response to treatment in cervical cancer patients after chemo-radiation (RT).
Methods and materials: Between September 2017-August 2019, 68 women with histologically proven cervical cancer underwent DW-MRI in our centre before and after the completion of neoadjuvant RT. Two radiologists, with respectively 4-20 years of MR experience, measured tumour volume (TV) and ADC mean in consensus. Three regions of interest were drawn on a single DW image, avoiding areas of necrosis, and on the corresponding ADC map: the mean ADC was obtained. According to response evaluation criteria in solid tumours, treatment response was classified as complete (CR) partial (PR) response, stable disease (SD) or progression (PD). Comparisons were made with Mann-Whitney and Chi-square tests.
Results: 68 women aged between 31-85 years (average 55), affected by squamous cell carcinoma were analysed. The mean time from RT to the MRI was 23 days (range 2-55). CR was observed in 39 patients, PR in 17. No PD was observed. After RT, TV was higher in PR and SD than in CR ($p=0.001$). TV reduction was lower in PR than in CR ($p=0.01$). ADC was lower before RT than after, respectively 0.82 and 1.25 $*10^{-3}$ mm^2/s ($p<0.001$), and ΔADC was higher in CR than in SD ($p=0.035$); while no statistically significant differences were observed in ADC values in PR and SD, ADC in CR was higher than in PR, respectively 1.32 and 1.02 $*10^{-3}$ mm^2/s ($p<0.017$).
Conclusion: DW-MRI is useful for evaluating response to treatment after RT and for predicting CR.
Limitations: This study is a retrospective study and includes scarcer numerosity of population.

Correlation between diffusion-weighted MRI and the expression of PCNA and Ki-67 in cervical cancer cells

Z. Ma, X. Zhao; *Zhengzhou/CN (11430884@qq.com)*

Purpose: To investigate the changes of ADC and rADC values of DWI in patients with cervical cancer and their correlation with PCNA and Ki-67.
Methods and materials: Forty patients with cervical cancer were confirmed by pathology. All patients underwent magnetic resonance imaging and diffusion-weighted imaging before an operation. PCNA and Ki-67 immunohistochemical staining were performed during operation. The expression of PCNA and Ki-67 in cervical cancer patients with different differentiation degree was analysed by variance analysis. The correlation between PCNA, Ki-67, ADC and rADC was analysed by Pearson correlation analysis. SPSS 21.0 statistical software was used for statistical analysis of the data, $P < 0.05$ was statistically significant.
Results: The ADC value and rADC value of low differentiation group were lower than that of high differentiation group ($t = 2.118$, $P < 0.05$). There was no significant difference between the poorly differentiated group and the moderately differentiated group ($P > 0.05$). The expression of PCNA and Ki-67 increased with the decrease of differentiation. With the increase of PCNA and Ki-67 expression, the ADC value and r-ADC value decreased, and the difference was statistically significant ($P < 0.05$). After Pearson correlation test, ADC value was negatively correlated with Ki-67 and PCNA expression ($P < 0.05$).
Conclusion: The measurement of ADC and rADC values in DWI imaging of cervical cancer is helpful to evaluate and differentiate different pathological grades of cervical cancer and has potential as a non-invasive method for evaluating the degree of tumour proliferation.
Limitations: The pathological specimens obtained are not identical to the parts of the solid part of the tumours measured on ADC maps.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Does whole-body PET/MRI of abdominal cancers offer additional findings compared to contrast-enhanced CT?

S. G. Gür, B. Koyuncu Sökmen; *Istanbul/TR (bedriyekoyuncu@yahoo.com)*

Purpose: In this study, we aimed to compare the diagnostic value of contrast-enhanced CT and PET/MRI in patients with abdominal malignancy.
Methods and materials: Between January 2016 and May 2019, 77 patients with intraabdominal primary tumours with PET/MRI and contrast-enhanced CT examination were screened with retrospectively. PET/MRI and contrast-enhanced CT images of the patients were evaluated by two independent radiologists and the common consensus was obtained. Histopathological findings were taken as reference. Diagnostic value of two different modalities for the primary tumour, metastatic focus and lymphadenopathy were compared.
Results: PET/MRI and CT , respectively, regardless of the histology of the primary tumour, 100% of primary tumours (77 patients) and 98,7 % of primary tumours (76 patients); 100% of lymph node involvement(24 patients) and 91,6% of lymph node involvement (22 patients), 100% of distant metastases (36 patients) 97,2% of distant metastases (35 patients) has detected. There was no statistically significant difference between the PET/MRI and CT in terms of primary tumour ($p = 0.32$), lymph node metastasis ($p = 0.15$) and distant metastasis ($p = 0.32$). In addition, it provided additional information in 6,6% (1/15 patients) of patients in detecting multiple foci in hepatocellular carcinoma, regardless of our aim. In addition, PET/MRI detected undetectable brain and extremity metastases in 19.4% (7/36 patients) of patients compared with CT.
Conclusion: The biggest advantage of PET/MRI is the low ionising radiation. PET/MRI is superior to CT in lymph node and distant metastasis detection.
Limitations:
The main limitation of this study is low patient number.
Ethics committee approval:
The institutional review board approved the study; the requirement for informed consent was waived since the study was retrospective investigation.

Acoustic radiation force impulse elastography as a response evaluation tool for transarterial chemoembolisation in the treatment of hepatocellular carcinoma

J. Moideen, I. Subbanna, V. Bhargavi; *Bengaluru/IN (drjunise@gmail.com)*

Purpose: Trans-arterial chemoembolisation is chosen for patients with hepatocellular-carcinoma who falls into BCLC-stage B usually helps in the local control of the tumour burden. So it is necessary to monitor the results post TACE treatment for deciding further management. CECT/MRI abdomen is taken as the gold standard in considering the treatment response following treatment. In this study, we evaluated the role of ARFI-elastography to measure stiffness in deep tissues. As a response evaluation tool in HCC patients treated by TACE.
Methods and materials: A total of 95 lesions from 54 patients were evaluated with elastography before and after TACE procedure and findings were correlated with Triphasic CECT scans. The difference in enhancing areas in follow up CT scans were assessed and categorised and was compared with the difference in ARFI-Max values attained on ARFI-elastography on follow-up. It was also compared with the difference in stiffer areas within the lesion of follow-up. The lesions were categorised into lesions within a cirrhotic liver and lesions within a non-cirrhotic liver. Various parameters were compared using Kappa, weighted Kappa, Kruskal Wallis test and linear regression analysis.
Results: In our study, HCCs showed variable stiffness but predominantly the lesions were stiffer as compared to normal liver. Brighter areas on elastography represent the stiffer portions of the tumour which may represent the residual tumour post-treatment. There were 57 tumours in a cirrhotic background and 38 tumours in a non-cirrhotic background. We found that there is a statistically significant agreement on evaluation.
Conclusion: ARFI-elastography is a safe, non-invasive, rapid and novel technique which can be effectively used as a response evaluation tool after TACE in patients with hepatocellular-carcinoma especially when other imaging modalities are contraindicated.

Thermal effect of irreversible electroporation in pancreatic cancer

O. W. Kozak, S. Hac, T. Gorycki, B. Brzeska, K. Skrobisz, J. Pienkowska, M. Szymanski, M. Studniarek; *Gdansk/PL (oliwiak@gumed.edu.pl)*

Purpose: Irreversible electroporation (IRE) of the pancreas is an increasingly used method for unresectable pancreatic cancer that can be used in cytoreduction followed by surgical treatment and shows promising results in palliative care. It is claimed that IRE is not causing thermal effect comparing to radiofrequency and microwave ablation. Aim of the study is to assess the early post-IRE changes in signal intensities in the ablation zone with emphasis on thermal effect and vascularisation.
Methods and materials: We retrospectively analysed the MRI studies of 24 patients (10 F, 14M, aged 35-71) with unresectable pancreatic cancer during or shortly after chemotherapy. Standard IRE procedure was performed. MR images were performed on 1,5T and 3T scanners one day before IRE procedure and up to 7-days after. A standard protocol for pancreas was performed including T1W, TW2, DWI/ADC, DCE with subtraction series.
Results: Signal intensities in the ablated zone on T1-FatSat images after contrast media administration with subtraction was in the range 0-6,25. The ADC values after IRE were significantly higher compared to pre-IRE measurements. Signs of thermal effect were seen as gas bubbles close to the electrodes after CT-guided percutaneous procedures were performed. On MR images in 83,3% of patients, they were seen as small, hypointense zones in electrodes placement on T1-FatSat contrasted-enhanced images.
Conclusion: Low SI values in the ablated zones on T1-FatSat+CM images with subtraction proves that all vascular bed within the ablation zone was completely damaged. Growth of ADC values after IRE is the effect of cellular water displacement to intercellular space what is a sign of cytolysis. IRE can create thermal effect on exposed tissues.
Limitations: This study is limited by a small group of patients and that it is performed as a single centre study.
Ethics committee approval: All applied procedures were approved by a local ethical committee.
Funding: No funding was received for this work.

The prognostic value of neutrophils lymphocyte ratio (NLR) in patients treated with trans-arterial chemoembolisation with epirubicin particles for hepatocarcinoma

A. G. Chimenti[1], G. Zanirato Rambaldi[1], M. Giannotta[1], A. Rebonato[2]; *[1]Bologna/IT, [2]Pesaro/IT (achimenti2801@gmail.com)*

Purpose: To analyse the prognostic value of the neutrophils lymphocyte ratio (NLR) in patients treated with trans-arterial chemoembolisation with epirubic particles (TACE) for hepatocarcinoma (HCC).
Methods and materials: From the review of the chart, the following data were collected: the white blood cells count, the percentage of neutrophils, the percentage of lymphocytes, the value of albumin and total bilirubin, INR, the value of alpha-fetus protein pre-TACE, creatinine, the value of GFR, the value of ferritin pre-TACE, the CHILD-PUGH class. The lymphocyte neutrophils ratio (NLR) was calculated.
Results: Between January 2012 and April 2015, 83 patients affected by HCC underwent TACE at our centre: 52 of them (39 males) were included. Survival after the first procedure was 1.60 years (range 0.25-4.27). The average NLR value was 3.15 (range 0.61-19.02; median 1.96). Patients were divided into two groups according to the median NLR value, showing a significant poor survival among patients with NLR>1.96 (p 0.0087).
Conclusion: The lymphocyte neutrophils ratio is an important prognostic value for patients affected by hepatocarcinoma undergoing drug eluting beads-TACE.
Limitations: This study is retrospective.

Investigation of two FD stents' EMSA variation at a giant aneurysm neck by using virtual stent deployment

G. Guclu[1], T. Günaydın[1], C. Ünsal[1], A. B. Olcay[1], C. Bilgin[2], B. Hakyemez[2]; *[1]Istanbul/TR, [2]Türkiye/Bursa/TR (bahadir.olcay@yeditepe.edu.tr)*

Purpose: Flow diverter (FD) stents are typically used in the treatment of giant aneurysms. While these aneurysms may form and grow at the weak section of an artery wall, the use of FD restricts the blood flow going into aneurysm sac by diverting the blood flow through the parent artery when these stents are placed into the patients' aneurysm site.
Methods and materials: In the present study, a three-dimensional aneurysm site of a 41-year-old female patient was constructed using 220 digital subtraction angiography (DSA) images. The average hydraulic diameter of the left internal carotid artery (LICA) carrying aneurysm was calculated to be nearly 4.5 mm. Then, two FD stents, namely FRED 4518 and FRED 5014, were chosen for virtual stent deployment. It is noted that FRED 4518 has a 40% effective metal surface area (EMSA) and 18 mm working length while FRED 5014 has a 28% EMSA and 20 mm working length.
Results: Once the FD stents were placed into the artery separately using the virtual deployment method, the EMSA value of FRED 4518 decreased to 30.28% while FRED 5014's EMSA value became 21.67% at the patient's aneurysm neck due to the curly shape and non-uniform cross-sections of the parent artery.
Conclusion: This indicates that a decrease in FD's EMSA value can have an influence in haemodynamics inside an aneurysm sac by accelerating or decelerating the stagnation process.
Limitations: Radial forces in FD stents are not taken into account.
Ethics committee approval: Ethics committee approval obtained.

MRgFUS thalamotomy: the potential value of periprocedural parameters as a predictive tool for evaluating tremor treatment outcomes

M. Martino, A. Gagliardi, E. Tommasino, M. Allevi, F. Bruno, F. Arrigoni, A. Catalucci, P. Sucapane, C. Masciocchi*; L'Aquila/IT (aivlim@hotmail.it)*

Purpose: Therapeutic application for tremor treatment by transcranial high-intensity focused ultrasound (HIFU) demands a precise analysis of physical and control parameters to obtain optimal outcome. Our objective was to define the correlation between periprocedural parameters regarding HIFU procedures and treatment outcome.
Methods and materials: 57 patients with essential tremor (ET) and Parkinson disease (PD) tremor were treated using an MRgFUS brain system (ExAblate 4000, InSightec) in a 3T MR scanner (MR750, GE Healthcare). We retrospectively evaluated the intraprocedural MR-thermometry, measuring the accumulated thermal dose (ATD) size and temperature and the number of sonications and values of maximum energy delivered and temperatures reached. The periprocedural parameter profiles were correlated with the corresponding treatment outcome assessed using the Fahn-Tolosa-Marin scale after 1 day, 1 month, 3 months, and 6 months follow-up.
Results: Statistical analysis showed a mean ATD temperature significantly correlated with FTM scores after 1 day and 1 month follow up ($p<0.005$) We did not find any statistically significant correlation between ATD temperature and FTM in 3 and 6 months follow-up, or between clinical outcomes and other periprocedural parameters.
Conclusion: According to our preliminary results, intraprocedural ATD after the procedure may have a possible predictive value of treatment outcome after MRgFUS thalamotomy in patients with ET and PD tremor.
Limitations: The limited number of patients available could be a hindrance for statistical significativity.

The impact of balloon guide catheter usage in a mechanical thrombectomy on tissue integrity of the penumbra

M. T. Berndt, T. Boeckh-Behrens, J. Kaesmacher, C. Zimmer, B. Friedrich, F. Mück, S. Wirth, C. Maegerlein*; Munich/DE (maria.berndt@tum.de)*

Purpose: During mechanical recanalisation of large vessel occlusions (LVO), the use of proximal flow arrest with balloon guide catheters (BGC) was shown to be associated with better angiographic and clinical outcome. It is unclear if there is a benefit for the structural integrity of the penumbral brain tissue. The aim of the study was to analyse possible microstructural alterations in the salvaged penumbra dependent on BGC-usage.
Methods and materials: All patients who underwent mechanical recanalisation of LVO of the anterior circulation were reviewed within a prospective stroke registry of a single comprehensive stroke centre. 65 patients received an admission CT-perfusion together with post-interventional diffusion tensor imaging. Technical details such as BGC-usage were correlated with microstructural integrity changes of the salvaged grey matter through a MD (mean diffusivity)-index. Moderation analysis was performed to test the interaction of BGC on the correlation between angiographic and clinical outcome.
Results: For all patients with complete reperfusion (TICI 3), microstructural integrity changes with a lowered MD-index were found within the salvaged penumbra for cases of non-BGC-usage (mean=0.02) compared to cases with BGC-usage (0.01, p=0.04). The benefit of complete reperfusion on good clinical outcome is moderated by the BGC-group (effect 2.78, p=0.01 vs for non-BGC:0.3, p=0.71).
Conclusion: The lowered MD-index early after mechanical recanalisation without the use of BGC can be interpreted as microstructural ischaemic damage of the salvaged penumbra, possibly caused by microembolisation without using proximal flow arrest. It was shown that achieving complete reperfusion in a setting of BGC-usage minimises penumbral damage and improves the long-term outcome.
Limitations: Results should be confirmed in a multi-centric setting.
Ethics committee approval: Approval by the local ethics committee. The need for patient consent was waived.
Funding: No funding was received for this work.

Preliminary experience of endovascular embolisation of cerebral dural arteriovenous fistulas with SQUID 12

E. Lozupone, P. Trombatore, L. Milonia, F. D'argento, A. Alexandre, I. Valente, A. Pedicelli*; Rome/IT (PIETRO.TR@OUTLOOK.IT)*

Purpose: To show the effectiveness and safety of SQUID 12 in the embolisation of cerebral dural arteriovenous fistulas (cDAVF).
Methods and materials: From June 2017-January 2019, the authors retrospectively reviewed clinical, demographic, and embolisation data of 13 consecutive patients with cDAVF (3 IIb, 5 Cognard III, and 5 Cognard IV) who underwent embolisation using the SQUID 12. 4 patients were symptomatic for headache, 2 patients presented with vertigo and confusion, 2 patients with tinnitus, 1 patient with a bruit, and 1 patient with aphasia; 3 patients were asymptomatic. The number of arteries catheterised for embolisation, the total amount of embolic agent, the rate of occlusion, the time of the procedure, and

the rate of complication were recorded. Mid-term follow-up with MR and DSA was reviewed.
Results: In 11 patients, the cDAVF closure was accomplished at the end of the procedure; in one case, a double staged treatment was performed, while in another case, a small remnant was left. The average time of injection was 36 minutes and the average amount of SQUID 12 was 2.8 mL. One patient with a cDAVF of traverse sinus region (Cognard III) experienced a facial palsy which resolved after 2 weeks of corticosteroids; no other complications were recorded. Mid-term MR and angiographic follow-up confirmed complete occlusion of the cDAVFs in 12 patients; in 1 patient with an infratentorial fistula, a small relapse was detected.
Conclusion: The treatment of the DAVFs by using SQUID 12 seems to be effective and safe. The lower viscosity allow a distal migration of the agent, a lesser proximal reflux, and a deeper penetration in the cDAVF.
Limitations: A mall sample size and a retrospective study.

Radiation exposure of patients during interventional neuroradiology procedures

V. Opancina, R. Vojinovic*; Kragujevac/RS*

Purpose: To assess the doses received by patients during interventional neuroradiology procedures and to establish their dose range.
Methods and materials: Our study included all patients who underwent diagnostic and therapeutic interventional neuroradiology procedures from December 2017-June 2019 at our institution. The following variables were taken into account: dose area product, air kerma, and fluoroscopy exposure time. Peak skin dose was calculated from a published dose conversion formula for interventional procedures: PSD=249+5.2*DAP. We estimated an effective dose from DAP using a dose conversion factor, where DCC= ED/DAP, and calculated a brain dose using the ED and tissue weighing factor provided by ICRP-103.
Results: There were 224 cerebral angiographies, 55 aneurism embolisations, and 21 combined procedures. We calculated the total mean±SD and third quartiles for all dependent variables: DAP (93.95±50.48 Gy-cm^2; 116.23 Gy-cm^2), AK (595.23±382.07 Gy; 680.94 Gy), T (7.43±7.37 min; 9.26 min), ED (13.62±7.32 mSv; 16.85 mSv), and PSD (0.49±0.26 Gy; 0.60 Gy). Estimated brain doses for diagnostic, therapeutic, combined, and all procedures in total were 254.62 mGy, 227.84 mGy, 341.12 mGy, and 272.4 mGy. Post hoc analysis determined a Bonferroni correction of critical value which was significant for each test: DAP-procedure type (0.016), AK-procedure type (0.000), ED-procedure type (0.016), and PSD-procedure type (0.016).
Conclusion: Interventional neuroradiology procedures show significant variability in radiation dose due to patient constitution, radiologist expertise, and equipment factors. Knowing the doses can have a great benefit in terms of prevention of possible radiation effects.
Limitations: There is no standardised method for effective dose calculation.
Ethics committee approval: Approved by Institutional Ethics Committee.

RPS 909-6 09:00

Quantitative collateral vessel density associated with the prognosis of mechanical thrombectomy on intracranial large vessel occlusion: an initial study based on CT perfusion imaging

Z. Shi, M. Yang, H. Wang, J. Lu*; Shanghai/CN (shizhangmd@smmu.edu.cn)*

Purpose: This study on acute ischaemic stroke caused by intracranial large vessel occlusion (LAO) aims to further evaluate the high-risk factors of the prognosis of mechanical thrombectomy (MT) by collateral vessel density (CVD) using F-STROKE software.
Methods and materials: This study was retrospectively analysed on 92 patients with acute ischaemic stroke caused by LAO from January 2018-October 2018. All patients underwent CT perfusion (CTP) examination before MT. The patients were divided into two groups according to 90d-mRS (0-2 points: good prognosis; 3-6 points: poor prognosis). F-stroke software was used for CTP image analysis to quantitatively obtain core infarct volumes, ischaemic penumbra volumes, mismatch ratios, and CVD. A multivariate logistic regression model was used to calculate the odds ratio (OR) and 95% confidence interval (95%CI). P<0.05 was considered statistically significant.
Results: A total of 87 patients with LAO (51.2±8.4 years; 57 males and 30 females) were included. The univariate analysis showed that the core infarction volume (P=0.017), mismatch ratio (P=0.040), CVD (P=0.003), and symptom improvement (P<0.001) were associated with the prognosis after MT. As multivariate logistic regression analysis showed, CVD (P=0.008; OR=13.296; 95%CI, 1.948-90.736) and symptom improvement (P=0.003; OR=13.824; 95%CI, 2.476-77.196) were two independent high-risk factors for the prognosis of MT. According to ROC, the AUC value of CVD and symptom improvement were 0.819 and 0.760, respectively.
Conclusion: For patients with LAO who underwent MT, CVD was an independent quantitative predictor to the prognosis after MT surgery.
Limitations: The retrospective analysis of the acquired data. We only used CT scans performed on acute stroke patients.
Ethics committee approval: n/a
Funding: No funding was received for this work.

RPS 909-7 09:06

Automated contrast-uptake measurements on single-phase CT angiography for stroke triage

P. Reidler, D. Puhr-Westerheide, L. Rotkopf, D. Apel, F. Dorn, S. Tiedt, M. P. D. L. Kellert, M. P. Fabritius, W. G. Kunz*; Munich/DE*

Purpose: To determine the clinical value of software-based automated cerebral attenuation measurements at CT angiography (CTA) to classify eligibility for late time window thrombectomy as established by DEFUSE 3 criteria using CT perfusion (CTP) imaging.
Methods and materials: We enrolled stroke patients with large vessel occlusion and complete imaging datasets including non-contrast CT, CTA, and CTP. X-ray attenuation in Hounsfield Units (HU) was measured at non-contrast CT and CTA data in all Alberta stroke program early CT score (ASPECTS) regions using automated software. Contrast uptake (CU) was defined per ASPECTS region as the absolute difference of attenuation on CTA minus non-contrast CT. All regional values were merged into a composite CTA-CU score using a linear regression model. Extent of the ischaemic core and target mismatch were determined at CTP. Receiver-operating-characteristics analysis was performed to calculate area-under-the-curve (AUC) for the classification of DEFUSE 3 criteria (core<70 mL, target mismatch>1.8).
Results: We included 79 patients with ischaemic core sizes of 17 mL (IQR: 9-46 mL). Automatic CU measurements were technically successful in all patients. CU values over all ASPECTS regions were significantly lower in the ischaemic compared to the non-ischaemic hemisphere, with a median of 4.2HU (IQR: 2.7–5.8HU, p<0.001). The composite CTA-CU score enabled significant classification of DEFUSE 3 thrombectomy criteria (AUC: 0.85, p<0.001, sensitivity: 91%, specificity: 67%) while outperforming visual ASPECTS.
Conclusion: As an observer-independent and quantifiable imaging biomarker, the composite CTA-CU score was able to classify CTP imaging criteria for late time window thrombectomy criteria.
Limitations: Limitations include the use of only one CT vendor, the global variability of CTA protocols, and the rather small study sample.
Ethics committee approval: The study was appoved by the local IRB.
Funding: No funding was received for this work.

Prognostic value of semi-quantitative collateral assessment in the endovascular treatment of ischaemic stroke

M. V. M. Micelli, P. Palumbo, G. Bianchi, A. Izzo, F. Bruno, M. Varrassi, S. Carducci, A. V. Giordano, C. Masciocchi*; L'Aquila/IT (micelli.mvm@gmail.com)*

Purpose: To evaluate collateral circulation in patients with an acute ischaemic stroke (AIS) who underwent endovascular thrombectomy (ET) in order to investigate its value in the prediction of clinical outcome.
Methods and materials: We retrospectively investigated 120 patients with CTA-proven large vessel occlusion (LVO) treated with ET from January 2014-September 2019. Good collateral (GC), good recanalisation rate (RR), and clinical assessment (CA) were defined respectively by a collateral flow grading system (ASITN/SIR) score ≥2, a thrombolysis in cerebral infarction (TICI) score ≥2b, and the NIHSS scale before and 24 hours after ET.
Results: The patients were divided into two groups due to the presence of GC (63%) or not named worse collateral (WC) (37%). Each group was analysed in relation to onset time, TICI, and NIHSS using Spearman's rank correlation coefficient. Although analogue onset time of symptoms was considered, the 24h-NIHSS score was better in the GC-group than the WC-group ($p<0.001$). GC were also associated with a better RR ($p<0.05$).
Conclusion: In line with the recent randomised studies, the analysis of collateral and a better selection of patients have to be mandatory for a better clinical outcome.
Limitations: A small sample.
Ethics committee approval: n/a
Funding: No funding was received for this work.

6 to 24 hours endovascular thrombectomy for large intracranial vessel occlusion without perfusion CT patient selection: a single-centre experience

F. Giubbolini[1], A. Pedicelli[1], A. Alexandre[1], A. Bartolo[1], I. Valente[1], E. Lozupone[1], F. D'argento[2], C. Colosimo[1]; [1]*Rome/IT*, [2]*Taviano/IT*
(Francesca.giubbolini@gmail.com)

Purpose: The effect of endovascular thrombectomy performed more than 6 hours after the onset of ischaemic stroke has been shown by the DAWN and DEFUSE-3 trials. In these trials, strict criteria were employed for patient selection, including perfusion CT. We performed a retrospective single-centre evaluation of patient treated 6 to 24 hours after stroke onset without perfusion CT selection.
Methods and materials: On a total of 212 patients who received endovascular thrombectomy for major intracranial vessel occlusion, we identified 55 patients who were treated 6 to 24 hours after stroke onset. Patients were selected on the basis of clinical and radiological criteria. Co-primary endpoints were the rate of functional independence (0, 1, or 2 on the mRS) at 90 days and post-treatment symptomatic intracranial haemorrhage (ECASS II criteria). Secondary endpoints were an early therapeutic response and successful recanalisation.
Results: Out of 55 patient, 22 (40%) were functionally independent at 90 days (mRS 0-2). Of these, 11 were mRS 0, 7 were mRS 1, and 4 were mRS 2, while the rate of symptomatic intracranial haemorrhage was 4 out 55 (7%). Early therapeutic response was achieved in 22 out of 55 patients (40%). Successful recanalisation was achieved in 44 out of 55 patients (80%).
Conclusion: Our data confirms that endovascular thrombectomy for large intracranial vessel occlusion in a later time window is safe and effective, even without CT-perfusion patient selection. A larger population of patients can potentially benefit from endovascular thrombectomy even without applying strict selection criteria, compared to DWAN and DEFUSE-3 trials.
Limitations: A retrospective, monocentric study with a small sample size.

The clinical application of low-dose CT-guided craniocerebral puncture biopsy

Y. Lian, J. Dong, Z. Zhou, Z. Lu, Y. Pan; *Zhengzhou/CN*
(lybang0507@126.com)

Purpose: To investigate the clinical value and safety of CT-guided craniocerebral puncture biopsy.
Methods and materials: From March 2017-July 2019, 23 patients (14 males and 9 females, aged 17-80 years old with a mean age of 52.5 years old) with clinical neurological symptoms or signs underwent CT-guided craniocerebral puncture biopsy. Enhanced-MRI and MRS revealed that all patients had multi-intracranial space-occupying lesions. GE Lightspeed CT was used to perform the CT-guided craniocerebral puncture biopsy for pathological or bacteriological examinations. The number of scans, operation time, pathological type, and complications were counted and analysed.
Results: Of the 23 patients, a definite pathological diagnosis was made in 22 cases, with a high biopsy positive rate of 95.7% (22/23). Among them, an oncology-pathological diagnosis was obtained in 18 cases (18/22, 81.8%), including 8 cases of diffuse large B-cell lymphoma (8/18, 44.4%), 6 cases of astrocytoma (6/18, 33.3%), 3 cases of glioblastoma (3/18, 16.7%), and 1 case of metastatic composite small cell carcinoma (1/18, 5.6%). Inflammatory infectious disease was confirmed in 4 cases (4/22, 18.2%). One patient was diagnosed with cerebral gliosis hyperplasia but it was confirmed as a glioblastoma after surgery. The average operating time was 27 minutes and the mean DLP was 201.6 mGy*cm, with an average radiation dose of 0.42 mSv. 4 patients had a small amount of haemorrhage (about 0.5-1.5 ml) at the puncture site. No serious complications such as neurological damage, epilepsy, a large amount of intracranial haemorrhage, and intracranial infection occurred in all patients.
Conclusion: CT-guided craniocerebral puncture biopsy is minimally-invasive with fewer complications, low radiation dose, and a high pathological positive rate. It has great clinical value in the diagnosis of craniocerebral lesions.
Limitations: The radiation exposure.

Contrast-enhanced ultrasound-guided transoral core-needle biopsy: a novel, safe, and well-tolerated procedure for obtaining high-quality tissue in patients with oral cancer

M. Lu, T. Wei; *Chengdu/CN*

Purpose: To determine the tolerability, safety, and effectiveness of contrast-enhanced ultrasound (CEUS)-guided transoral core-needle biopsy (CNB) for oral lesions.
Methods and materials: A consecutive series of 44 patients who underwent CEUS-guided transoral CNB of oral lesions at our hospital were evaluated retrospectively. CEUS-guided transoral CNB was performed by using an endocavitary transducer and needle guide device attached to the transducer shaft. Tolerability questionnaires were completed prior to and following the sampling procedures. The CEUS characteristics, successful biopsy rate, diagnostic performance, tolerability, and complications were assessed and recorded.
Results: CEUS improved the conspicuity of target lesions and the detection rate of internal liquefied necrosis compared with transoral US ($p<0.05$). The successful biopsy rate was 100%. Based on the final diagnosis, 29 malignant lesions (23 squamous cell carcinomas, 3 adenoid cystic carcinomas, 2 mucoepidermoid carcinomas, and one melanoma) and 15 benign lesions (8 inflammatory lesions, 5 pleomorphic adenomas, one schwannoma, and one haematoma), the sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy of this technique were 96.7%, 100%, 100%, 93.8%, and 97.7%, respectively. No significant difference in pain and swelling of the biopsied site from before and after the procedure was observed. No serious complications were observed.
Conclusion: CEUS-guided transoral CNB can be considered as a safe, well-tolerated, and effective technique for patients with suspected oral cancer.
Limitations: This study design was retrospective. This was a single-centre study with a small sample of cases. Studies with sufficient samples should be performed further.
Ethics committee approval: This study was approved by the Institutional Review Board and Ethics Committee of Sichuan Cancer Hospital. Informed consent was obtained before the ultrasonography examination and biopsy.

Funding: No funding was received for this work.

High blood pressure levels after endovascular treatment for ischaemic stroke are associated with worse outcome: results from the MR CLEAN registry

N. Samuels[1], R. van de Graaf[1], C. van Den Berg[1], J. Hofmeijer[2], Y. Roos[3], B. Roozenbeek[1], H. Lingsma[1], D. W. J. Dippel[1], A. van der Lugt[1]; *[1]Rotterdam/NL, [2]Arnhem/NL, [3]Amsterdam/NL (n.samuels@erasmusmc.nl)*

Purpose: Optimal blood pressure (BP) management in the acute period of ischaemic stroke remains uncertain, specifically in patients undergoing endovascular treatment (EVT). We evaluated the association between BP levels post-EVT and outcome, according to recanalisation status.
Methods and materials: We included patients from the MR CLEAN registry who underwent EVT from March 2014-June 2016 in 7 centres registering post-EVT BP values. The primary outcome was the functional outcome (modified Rankin scale) at 90 days. Secondary outcomes were sICH and early neurological deficit (NIHSS at 24h). BP parameters were mean, maximum, and minimum systolic (SBP), and mean arterial pressure (MAP) during the first 6 hours post-EVT. We used multilevel regression analysis to account for the repeated measures per patient to evaluate the association between BP and outcomes, adjusted for centre and prognostic factors, and we tested for interaction between BP and recanalisation status.
Results: In total, 867 patients were included for analyses. Mean SBP and MAP were 140 ± 22 mmHg and 99 ± 18 mmHg, respectively. Maximum SBP and MAP were associated with worse functional outcome (adjusted common odds ratio per 10mmHg (acOR) 0.93, 95% CI 0.88 to 0.98 and acOR 0.42, 95% CI 0.21 to 0.86) and higher NIHSS scores (β 0.55, 95% CI 0.33-0.77 and β 5.5, 95% CI 2.7 to 8.4). Maximum SBP was associated with higher sICH rates (adjusted OR 1.28, 95% CI 1.14 to 1.49). There was no effect of mean or minimum BP on outcome and no interaction between BP and recanalisation status.
Conclusion: Higher maximum SBP and MAP levels in the first 6 hours after EVT are associated with worse functional and neurological outcomes and higher sICH rates.

Repetitive transarterial chemoperfusion in recurrent malignant head and neck neoplasms: local response rate and survival

T. J. Vogl, A. Tröger, T. Stöver, T. Gruber-Rouh*; Frankfurt am Main/DE (t.vogl@em.uni-frankfurt.de)*

Purpose: To evaluate the response and survival of malignant recurrent neoplasms located in the head and neck area post repetitive transarterial chemoperfusion (TACP) as a palliative treatment method.
Methods and materials: 47 patients (33 males, 14 females) were treated in 4-week intervals using TACP with mitomycin C 8.5 mg/m², gemcitabine 1000 mg/m², and cisplatin 35mg/m². Before treatment, a multiparametric MRI was performed in order to evaluate the size, location, and volume of the tumour prior to TACP. After TACP, a CT scan was performed for the exclusion of possible side-effects. Tumour response was evaluated according to the RECIST criteria.
Results: TACP was well-tolerated without significant side-effects. According to the RECIST criteria, 29.79% (n=14) of the patients presented with partial remission (PR), 68.09% (n=32) showed stable disease (SD), and 2.13% (n=1) had progressive disease (PD). The median survival rate of the patients from the start of TACP therapy was 14.7 months. Patients with PR after the first treatment session presented with significantly better survival (p=0.03) with a mean of 21.4 months, while patients with SD only presented with a survival of 11.3 months.
Conclusion: TACP seems to be an effective palliative treatment option in patients with head and neck tumours.
Limitations: A limited number of patients were included.
Ethics committee approval: Approval by the Institutional Review Board.
Funding: No funding was received for this work.

Mechanical thrombectomy using TIGER

L. Will, V. Maus, S. Fischer*; Bochum/DE (Lena.Will@kk-bochum.de)*

Purpose: To evaluate the safety and efficacy of mechanical thrombectomy with a manually adjustable stent retriever (Tigertriever) in acute stroke.
Methods and materials: The Tigertriever is a manually expandable mesh intended for the treatment of acute ischaemic stroke. The unique design enables the operator to manually adjust the radial force to the vessel wall during mechanical thrombectomy.
A total of 39 thrombectomy procedures carried out at a single neurovascular centre with Tigertriever were analysed in retrospect.
Results: Of the 39, 22 were successful with the Tigertriever alone resulting in a TICI score of >2b in 100% with a medium of 1 attempt. In 17 cases, the strategy was combined with another thrombectomy device resulting in a final TICI score of >2b in 80% of these cases.
10 of the cases were arterial occlusions located distally to the circle of Willis treated with Tigertriever 13, a device compatible with a 0.0013-inch microcatheter. Mechanical thrombectomy in these distal occlusions was successful in 9 cases.
Conclusion: The Tigertriever represents an efficient and safe addition to the existing concepts for mTE. The Tiger 13 expands the opportunities to perform mTE in distal locations, especially due to the compatibility with a 0.013-inch microcatheter.

One-stop management with perfusion for transfer patients with stroke due to a large-vessel occlusion: feasibility and effects on in-hospital times

A. Brehm[1], I. Tsogkas[1], I. Maier[2], H. J. Eisenberger[2], Y. Pengfei[3], J. M. Liu[3], J. Liman[2], M.-N. Psychogios[1]; *[1]Basel/CH, [2]Göttingen/DE, [3]Changhai/CN (alex.brehm@usb.ch)*

Purpose:
In-hospital time delays lead to a relevant deterioration of neurologic outcomes in patients with stroke with large-vessel occlusions. At the moment, CT perfusion is relevant in the triage of late-window patients with stroke. We conducted this study to determine whether one-stop management with perfusion is feasible and leads to a reduction of in-hospital times.
Methods and materials: In this observational study, we reported the first 15 consecutive transfer patients with stroke with externally confirmed large-vessel occlusions who underwent flat panel detector CT (FDCT) perfusion and thrombectomy in the same room. Preinterventional imaging consisted of non-contrast FDCT and FDCT perfusion, acquired with a biplane angiography system. The FDCT perfusion was used to reconstruct an FDCT angiography to confirm the large-vessel occlusions. After confirmation of the large-vessel occlusion, the patient underwent mechanical thrombectomy. We recorded time metrics and safety parameters prospectively and compared them with those of transfer patients who we treated before the introduction of one-stop management with perfusion.
Results: 15 transfer patients underwent FDCT perfusion and were treated with mechanical thrombectomy from June 2017-January 2019. The median time from symptom onset to admission was 241 minutes. The median door-to-groin time was 24 minutes. Compared with 23 transfer patients imaged with multidetector CT, it was reduced significantly (24 minutes; 95% CI, 19-37 minutes, versus 53

minutes; 95% CI, 44–66 minutes; P< 0.001). Safety parameters were comparable between groups.
Conclusion: In this small series, one-stop management with perfusion led to a significant reduction of in-hospital times compared with our previous workflow.
Limitations: The observational design and the small number of patients.
Ethics committee approval: Patients were taken from a prospective acquired board certifed database. (Ethik vote number: 13/7/15An Göttingen). Additional consent was waived.
Funding: No funding was received for this work.

Fully automatic femur length measurement in ultrasound images by a novel hybrid approach based on a convolutional network
M. Ghelich Oghli[1], R. Gerami[2], S. Moradi[1], N. Sirjani[1], A. Shabanzadeh[2], P. Ghaderi[2], I. Shiri[3]; *[1]Karaj/IR, [2]Tehran/IR, [3]Geneva/CH*
(m.g31.mesu@gmail.com)

Purpose: 2D fetal ultrasound biometrics have been extensively used to establish (or confirm) the gestational age of the foetus, estimate its size and weight, and identify growth patterns and abnormalities. Among various parameters, femur length (FL) measurement suffers from inter and intraobserver variability. In this paper, we proposed a deep learning-based approach to calculate FL automatically.
Methods and materials: Our prepared dataset contained 315 2D ultrasound images of the foetal femur in the standard plane. The dataset was gathered from two distinct centres: (i) Alvand Medical Imaging Center, Tehran, Iran, and (ii) Laleh Hospital, Tehran, Iran.
To segment the femur in the ultrasound image, we had a pre-processing step. We used the superpixel algorithm to remove darker parts of the image, as the femur is typically the brightest part of the US image. Then we applied an image saliency algorithm to represent the salient features of the image. Finally, a novel convolutional network was trained on these pre-processed images to segment the femur. The proposed network, namely MFP-Unet, was a combination of Unet and feature pyramid network (FPN). After the segmentation process, a skeletonisation algorithm achieved the femur length.
Results: We used the mean absolute difference (MAD) and root mean square error (RMSE) for the measurements' errors. The values of errors were 0.18 mm and 0.12 mm for FL. The correlation between automatic and manual measurements was evaluated by the correlation graph and the R-value was 0.97.
Conclusion: According to the results, we have proposed a robust and useful algorithm for automatic femur length measurement that can be extended to nuchal translucency (NT) measurement based on providing dataset.
Limitations: The images should be taken in the second trimester.

A ternary classification of chronic liver disease with a neural network using ultrasound B-Mode and shear-wave elastography examination parameters
P. Drazinos[1], I. Gatos[2], I. Theotokas[2], S. Yarmenitis[3], A. Soultatos[2], E. Panteleakou[2], P. Zoumpoulis[1]; *[1]Kifissia/GR, [2]Athens/GR, [3]Marousi/GR*
(p.drazinos@echomed.gr)

Purpose: Chronic liver disease (CLD) is one of the major causes of death and the major cause of hepatocellular carcinoma development. Accurate diagnosis regarding CLD progress is, therefore, very important. Our aim is to build and train a neural network (NN) classifier that will estimate the impact of parameters derived from an ultrasound (US) B-Mode and shear-wave elastography (SWE) examination in order to classify individuals into three main classes, F0-F1, F2-F3, and F4 fibrosis stages. Liver biopsy (LB) was considered as the 'gold standard'.
Methods and materials: Our dataset consisted of 315 individuals, 175 F0-F1, 52 F2-F3, and 88 F4 fibrosis stages. All individuals underwent a US examination performed by an experienced radiologist followed by an LB examination for individuals with fibrosis stage F1-F4. We randomly divided our dataset into 50% (training), 20% (testing), and validation (30%). For the training, 10-fold cross-validation (CV) was performed. The SWE measurements of the liver's right lobe (RL SWE), the existence of nodularity, and the known aetiology of each individual were used as inputs for the training and testing of a NN classifier.
Results: The NN classifier had a 10-fold CV accuracy of 88.78% and a 95% confidence interval (CI) of 88.52%-89.04%. The mean accuracy of the classifier on the test was 87.78% (95% CI 87.25%-88.31%). The mean area under the curve (AUC) for the test samples was 0.962 (95% CI 0.959-0.965). The validation accuracy was 84.63% (95% CI 84.27%-85.00%).
Conclusion: The NN classifier achieved good accuracy results in both training and testing and validation, and could be used to assist radiologists in CLD assessment in everyday clinical practice.

A preliminary study of parametric imaging with a contrast-enhanced ultrasound to predict luminal A breast cancer
L. Tang, J. Jiang, M. Chen; *Shanghai/CN*

Purpose: To explore the use of parametric imaging as an imaging ensemble method to analyse breast contrast ultrasound images to diagnose or predict luminal A breast cancer in the early stage.
Methods and materials: 189 patients with breast cancer who underwent a contrast-enhanced ultrasound and obtained pathological findings before surgery were enrolled in this retrospective analysis. After extracting the TIC curve of each pixel in the ROI region of images, the relevant parameters PI, AUC, MTT, WiR, WoR, TTP, and RT in the curve were used as independent parameters for two-dimensional imaging. Each parameter was unified between 0 and 255 grey-levels to generate a parametric image grey-scale image. By transforming the index map and the palette axis, the three fluxes were superimposed to generate a parametric imaging colour map.
Results: There were 46 luminal A breast cancers and a total of 644 parameter imaging features. After the dimension reduction was selected and the features of repetition or the same meaning were eliminated, 3 effective features were finally selected. After the SVM output the probability value, RT_E2 had an AUC of 0.677, a sensitivity of 83.9%, a specificity of 71.7%, and an accuracy of 81.0%. The AUC, sensitivity, specificity, and accuracy of RT_Hm2 were 0.650, 77.4%, 70.3%, and 71.4%, respectively. Those of RT_Et2 reached 0.665, 63.6%, 69.6%, and 65.1%, respectively.
Conclusion: Parametric imaging features, combined with time and distribution characteristics, provide more comprehensive diagnostic information and offer the possibility of predicting luminal A breast cancer.
Limitations: The design of this study has limitations. The sample was biased for the different incidence rates.
Ethics committee approval: All patients signed written informed consent.
Funding: No funding was received for this work.

Machine learning analysis in the prediction of placenta adhesion disorder in patients with placenta previa using ultrasound derived texture features
F. Verde, V. Romeo, R. Cuocolo, L. Sarno, S. Migliorini, A. Stanzione, M. D'armiento, A. Brunetti, M. P. S. Maurea*; Naples/IT (francescoverde87@gmail.com)*

Purpose: To predict the presence of placenta adhesion disorder (PAD) in patients with placenta previa using ultrasound (US) derived texture analysis (TA) features and a machine learning (ML) analysis.
Methods and materials: 53 patients (n=36 without PAS and n= 17 with PAS) with placenta previa who underwent endo-vaginal US examination for suspicion of PAD were retrospectively selected. 2D circle ROI was placed over homogeneous placental tissue. ROIs and corresponding images were then imported on a dedicated software (3D slicer, heterogeneity CAD) to extract first, second, and higher order TA features. ML analysis was subsequently run to identify the best performing method to correctly classify instances.
Results: A total of 688 TA features were extracted. 299 TA features showed an intraclass correlation coefficient values higher or equal to 0.75. No features showed low variance using a threshold of 0.0. Highly (r>0.8) correlated features were excluded, with 14 TA features further selected. Using these features with a bagged J48 algorithm, with each bag containing 70% of cases and 50 iterations, an accuracy of 82% was obtained.
Conclusion: ML analysis using TA featured extracted from US images may be useful to accurately identify PAS in patients with placenta previa.
Limitations: Limitations are related to a relatively small sample and a retrospective design.
Ethics committee approval: IRB approved, consent waived.
Funding: No funding was received for this work.

RPS 905-5 08:54
Transfer learning radiomics based on multimodal ultrasound imaging for staging liver fibrosis: a pilot study
H. Ding, L.-Y. Xue, Y.-L. Zhu, W.-P. Wang, J.-H. Yu*; Shanghai/CN (13651886013@163.com)*

Purpose: To propose a transfer learning (TL) radiomics model that efficiently combines the information from grey-scale and elastogram ultrasound images for accurate liver fibrosis grading.
Methods and materials: Totally, 466 patients undergoing partial hepatectomy were enrolled, including 401 with chronic hepatitis B and 65 without fibrosis pathologically. All patients received elastography and got liver stiffness measurement (LSM) 2-3 days before surgery. We proposed a deep convolutional neural network by TL to analyse images of grey-scale modality (GM) and elastogram modality (EM). The TL process was used for liver fibrosis classification by Inception-V3 network which pretrained on ImageNet. The diagnostic performance of TL and non-TL was compared. The value of single modalities, including GM and EM alone, and multimodalities, including GM+LSM and GM+EM, was evaluated and compared with that of LSM and serological indexes. Receiver operating characteristic curve analysis was performed to calculate the optimal area under the curve (AUC) for classifying fibrosis of S4, ≥S3, and ≥S2.
Results: TL in GM and EM demonstrated higher diagnostic accuracy than non-TL, with significantly higher AUCs (all P < .01). Single-modal GM and EM both performed better than LSM and serum indexes (all P < .001). Multimodal GM+EM was the most accurate prediction model (AUCs are 0.950, 0.932, and 0.930 for classifying S4, ≥S3, and ≥S2, respectively) compared with GM+LSM, GM and EM alone, LSM, and biomarkers (all P < .05).
Conclusion: Liver fibrosis can be staged by a transfer learning modal based on the combination of grey-scale and elastogram ultrasound images, with excellent performance.
Limitations: A single-centre study.
Ethics committee approval: n/a

Design and development of a convoluted neural network model for the detection and classification of ultrasound image-based thyroid nodules
B. Marconi Narvaez, F. Lubinus, Y. Arias, A. Ortiz*; Bucaramanga, Santander/CO (bmarconi1979@gmail.com)*

Purpose: To design a model based on convoluted neural networks capable of performing automatic detection of thyroid nodule (TN) on ultrasound (US) and classifying its risk of malignancy based on EU TIRADS 2017 criteria.
Also, to identify inter and intraobserver variability between a senior and junior radiologists for TN classification and compare levels of accuracy on classifying a TN between radiologists and a neural network model.
Methods and materials: The thyroid gland US image database (2,000 images) was acquired in grey-scale mode. Conversion from DICOM to JPG format was completed using PyDICOM library. Annotations and patient information from the image were deleted. Data augmentation methods were applied to increase the number of images (up to 6,000) for training the model. The convoluted neural network algorithm was designed by using TensorFlow 2.0 (Google). Two expert radiologists classified the US images based on EU TIRADS; only the matched images were selected for training the model. Training and validation of the model were completed by arranging different sets of neurons, convolution, and max-pooling layers. The CNN model and radiologist (1 senior and 1 junior) were tested by presenting 200 images choosen randomly from the database.
For the evaluation of interobserver variability, the Spearman correlation coefficient and Kruskall Gamma concordance were calculated. A secondary analysis was carried out using the criteria from the senior radiologist as a gold standard and the discriminatory capability (ROC curve) and the validity of the CNN model versus junior and senior radiologist were compared.
Results: Preliminary accuracy was 78% and a loss of 0.30%. Other statistical parameters are being calculated.
Conclusion: CNN models can be used as an assistance tool for the screening of thyroid nodes on US.
Limitations: Limited technical resources.
Ethics committee approval: Ethics committee approval was obtained.
Funding: No funding was received for this work.

No sonographer required: a feasibility study to investigate if midwives in resource-limited settings are able to acquire a prenatal ultrasound within two hours
T. L. A. van Den Heuvel, B. van Ginneken, C. L. de Korte*; Nijmegen/NL*

Purpose: Prenatal imaging is barely performed in resource-limited settings. This is mainly caused by a severe shortage of ultrasound devices and trained sonographers capable of acquiring and interpreting ultrasound images. We investigated if midwives in resource-limited settings are able to perform a predefined ultrasound acquisition protocol. This acquisition protocol consists of six predefined sweeps with the transducer over the abdomen of the pregnant woman. In previous research, we developed deep learning algorithms that can automatically interpret prenatal ultrasound images which were acquired using this protocol.
Methods and materials: A workshop was given to 5 midwives at St. Luke's Catholic Hospital in Wolisso, Ethiopia. The midwives had no prior knowledge of ultrasound. The workshop consisted of a presentation to introduce ultrasound imaging and the acquisition protocol. The midwives practised the acquisition protocol on each other to become familiar with the protocol. The midwives then went to the prenatal department to acquire the protocol from pregnant women.
Results: The midwives successfully acquired the protocol from all 72 pregnant women that visited the hospital. The protocol was acquired using the MicrUs EXT-1H (Telemed ultrasound medical systems, Vilnius, Lithuania). All midwives were able to perform the protocol within two hours of training.

Conclusion: The predefined ultrasound acquisition protocol can be taught within two hours to midwives without prior knowledge of ultrasound. Combining this protocol with algorithms that automatically interpret the ultrasound data has the potential to make implementation of prenatal screening in resource-limited settings much faster and easier, since it would avoid the need to train sonographers.
Limitations: This feasibility study only included five midwives from one city.
Ethics committee approval: This study was approved by the local ethics committee. Every woman in this study signed a written informed consent.
Funding: No funding was received for this work.

RPS 905-8 09:12
Automatic segmentation of the right ventricle from an ultrasound video using a novel deep learning approach
M. Ghelich Oghli[1], A. Alizadehasl[1], S. Moradi[2], N. Sirjani[2], A. Shabanzadeh[1], P. Ghaderi[1], I. Shiri[3]; [1]Tehran/IR, [2]Karaj/IR, [3]Geneva/SZ (m.g31.mesu@gmail.com)

Purpose: In contrast to more recent studies that disclosed the pivotal role of the right ventricle (RV) in pathological conditions, it has been considered a 'forgotten chamber' for decades. To quantify the RV function, fractional area change (FAC) is calculated through the apical 4-chamber view. As a prerequisite to estimate the RV area and FAC, the segmentation of the RV is necessary.
Methods and materials: We proposed an efficient approach for RV segmentation during the entire cardiac cycle. The presented architecture is based on an OSVOS network, which is a CNN architecture for semi-supervised video object segmentation. The network has three parts: the base, parent, and test networks. In the test phase, it gives the manual mask of one or more frames of the video. In summary, our contributions are:
1) The base network was trained on a CAMUS challenge dataset boosted by augmentation methods by a factor of 10.
2) The parent network was trained on our prepared dataset. It contained 142 apical 4-chamber videos with the annotation of RV endocardium.
3) The first frame of the cardiac cycle was segmented automatically using our previously presented method, MFP-Unet.
Results: The evaluation and comparison with the state-of-the-art approaches is performed using ROC curve, Dice coefficient (DC), Hausdorff distance (HD), and contour accuracy (CA). Our proposed network achieved 0.94 of AUC, 0.93 of DC, 0.57 cm of HD, 0.89 of CA, and these are the best results in comparison with PReMVOS, OSVOS-S, and ReConvNet.
Conclusion: The proposed architecture can capture the RV structure as well as manual expert tracing with an acceptable error range. The performance of the network could be improved by means of maintaining the training dataset and eliminating the augmentation procedure.
Limitations: There were no limitations.

The accuracy of a CAD system to classify breast masses on ultrasound according to BI-RADS lexicon 5th edition
E. F. C. Fleury; *Sao Paulo/BR (edufleury@hotmail.com)*

Purpose: To determine the accuracy of a CAD system to classify breast masses on ultrasound according to BI-RADS lexicon 5th edition
Methods and materials: 83 breast masses consecutively referred for biopsy (31 malignant) were included. A 15 years experienced radiologist classified the masses according to criteria proposed by the BI-RADS. For classification, the B-Mode findings associated with the strain elastography findings were considered. The radiologist final classification was compared to that obtained by a semi-automated CAD system adopting similar classification criteria as proposed by the BI-RADS lexicon. To perform the CAD system classification, the same observer manually delimited the masses at the B-Mode images. The CAD classification system consists of 3 steps: 1) Use of machine learning to classify masses in B-mode. 2) Quantitative classification of masses by strain elastography. 3) Integration of 1 and 2. We evaluated the diagnostic accuracy and the area under the ROC curve for the two classifications. It was also assessed the agreement between the visual classification with the CAD system. As a gold-standard reference, histological results of biopsies were adopted.
Results: The AUC for the radiologist was 0.714 and the CAD system was 0.807. The interobserver agreement according to the Kappa test was 0.8 if positive or negative results were considered. For all BI-RADS final category, including categories 2, 3, 4, and 5, the agreement was 0.58. The system impacts more at BI-RADS category 3 where a downgrade to category 2 was observed. Half of the lesions classified as BI-RADS were downgraded to 2.
Conclusion: A CAD system can be used to classify breast masses by ultrasound with similar accuracy to a radiologist.
Limitations: Experimental software in a small sample size.
Ethics committee approval: Approved by Institutional Ethical Committee and Brazilian Research Platform.

RPS 905-10 09:24
The classification of lymph node ultrasound images using texture analysis and machine learning
A. Bocoum[1], L. Chami[2], A. Giron[2], M. Lemahieu[3], O. Lucidarme[2], C. Nioche[1], I. Buvat[1], F. Frouin[1], C. Pellot-Barakat[1]; [1]Orsay/FR, [2]Paris/FR, [3]Gregy-sur-Yerre/FR (claire.barakat@inserm.fr)

Purpose: To differentiate malignant from benign ultrasound images of lymph nodes (LN) using texture analysis and machine learning models.
Methods and materials: The database consisted of 103 examinations of superficial LNs of patients (age: 54±18 years) who had undergone multi-parametric US imaging (B-mode, Doppler and shear-wave elastography) followed by a US-guided biopsy. Texture analysis was performed on all B-mode and elasticity images using the free LIFEx program (www.lifexsoft.org). Texture features relevant for LN discrimination were selected using univariate non-parametric comparisons of a means test ($p < 0.05$). Redundant correlated textural features (Pearson $R > 0.85$) were discarded. In addition, 20 conventional descriptive and quantitative clinical and imaging features (patient age, vascularisation degree, elasticity, etc.) were analysed. Using LN histology (benign/malignant) as classification outputs, various supervised machine learning algorithms implemented with SAS® Viya were trained (60% of the exams assigned to the training cohort) and subsequently tested on the remaining cohort.
Results: Of the 107 LNs, 35 (33%) were benign and 72 (67%) were malignant (20 carcinomas, 52 lymphomas). Of the 129 initial texture features, 38 were selected. Gradient boosting, logistic regression, and SVM achieved similar performances for the classification of LN in the test set (Youden-index: 0.80-0.81; misclassification rate: 9.5%-14.3%; AUC: 0.91-0.94). When using supervised classification without texture features, Youden was 0.56 only and the misclassification rate was 17%.
Conclusion: Textural analysis was found relevant to distinguish between malignant and benign LNs in our database, including a majority of lymphoma-related LN. Machine learning models involving textural features might facilitate LN diagnosis based on multi-parametric ultrasound imaging.
Limitations: The models must be evaluated on an external dataset.

Ultrasound-based radiomics technology for assessing foetal lung maturity during pregnancy complications
Y. Du; *Shanghai/CN (duyanran44@126.com)*

Purpose: To evaluate and compare the development of foetal lungs with pregnancy complications and normal pregnancy during different gestational weeks using ultrasound-based radiomics technology.
Methods and materials: A total of 548 foetal lung ultrasound images of 491 single pregnant women were obtained during routine ultrasound examinations between 28 and 41 weeks of gestation before birth. Ultrasound-based radiomics technology was used to extract foetal lung image features. A standard machine-learning model was composed of feature transformation and a regression model

was used to evaluate the relationship between texture features, pregnancy complications, and gestational age.
Results: Foetal lung ultrasound images were divided into four groups: GDM group, GDM + pre-eclampsia group, pre-eclampsia group, and normal group. The accuracy of foetal lung texture analysis in estimating complications of different pregnancies at different gestational weeks was 80.1%-92.9%. The accuracy of the gestational age prediction model established by foetal lung image texture analysis of the normal and complication groups was 61.5–82.1%.
Conclusion: Ultrasound-based radiomics technology is a noninvasive way to assess foetal lung development during different pregnancy complications. The foetal lung maturity prediction model will be of great help in the assessment of foetal lung development during different pregnancy complications, for monitoring the medication of disease, and the choice of termination time.
Limitations: By expanding the sample size, the stability and accuracy of the model will be improved. The GDM groups were not subdivided according to the severity of diabetes mellitus, further emphasising the need to test and verify the differences between examiners and machines.

Ultrasound-based radiomics approach: a potential method for the prediction of Ki-67 expression and differentiation grades in hepatocellular carcinoma

Y. Dong, Q. Zhang, Z. Yao, J. Yu, W. Wang*; Shanghai/CN (dr_mimi@163.com)*

Purpose: A radiomics approach can extract high-throughput image features, take full advantage of prognostic information from medical images, and provide prognosis information noninvasively. This study aimed to evaluate the correlation between liver ultrasound images based on a radiomics approach and Ki-67 expression differentiation grades of hepatocellular carcinoma (HCC).
Methods and materials: Clinical data and liver grey-scale ultrasound images of 93 operated-on and histopathologically proved HCC patients were retrospectively analysed. Two models were built to predict the Ki-67 expression and differentiation grades of HCC lesions based on grey-scale ultrasound images. Four radiomics approach steps were used: image segmentation, feature extraction, feature selection, and classification. Tumour regions from grey-scale ultrasound images were segmented to extract the wavelet, texture, and morphological features.
Results: By using a genetic algorithm with minimum-redundancy-maximum-relevance (mRMR), a Wisconsin Rank sum test, and sparse representation method, 452 grey-scale ultrasound image features were obtained and selected. The image features with the best discrimination performance were combined to establish our prediction models. With the same dataset, the area under the receiver operating characteristic curve (AUC) in the results reached 0.76 (Ki-67) and 0.87 (tumour differentiation grades).
Conclusion: A grey-scale ultrasound image based radiomics approach has potential application value in the clinical diagnosis and prognosis of Ki-67 expression and differentiation grades of HCC.
Limitations: The patient number is relatively limited. The stability evaluation of the radiomic analysis would be further improved by multicentre studies in the future.
Ethics committee approval: This study was approved by the institutional review board of our institution. Informed consent was waived before ultrasound examination. The procedure was in accordance with the declaration of Helsinki.
Funding: Supported by Shanghai Municipal Health and Family Planning Commission Research Project (Grant No. 201840215) and Shanghai Municipal Science and Technology Major Project (Grant No. 2017SHZDZX01).

Preoperative prediction of microvascular invasion in hepatocellular carcinoma: the application of a radiomic algorithm based on grey-scale ultrasound images

W. Wang[1], Y. Dong[1], L. Zhou[2], W. Xia[2], Q. Zhang[1], X. Gao[2]; *[1]Shanghai/CN, [2]Suzhou/CN (puguang61@126.com)*

Purpose: To establish a radiomic algorithm based on grey-scale ultrasound images and to make preoperative predictions of microvascular invasion (MVI) in hepatocellular carcinoma (HCC) patients.
Methods and materials: In this retrospective study, 322 cases of histopathologically confirmed HCC lesions were included. The classifications based on preoperative grey-scale ultrasound images were performed in two stages: (1) classifier #1, MVI-negative and MVI-positive cases, and (2) classifier #2, MVI-positive cases were further classified as M1 or M2 cases. The gross-tumoural region (GTR) and peri-tumoural region (PTR) signatures were combined to generate gross- and peri-tumoural region (GPTR) radiomic signatures. The optimal radiomic signatures were further incorporated with vital clinical information. Multivariable logistic regression was used to build radiomic models.
Results: 1,595 radiomic features were extracted from each HCC lesion. At the classifier #1 stage, the radiomic signatures based on features of GTR, PTR, and GPTR showed area under the curve (AUC) values of 0.708 (95 % CI, 0.603 - 0.812), 0.710 (95 % CI, 0.609 - 0.811), and 0.726 (95% CI, 0.625 - 0.827), respectively. Upon incorporation of vital clinical information, the AUC of the GPTR radiomic algorithm was 0.744 (95 % CI, 0.646 - 0.841). At the classifier #2 stage, the AUC of the GTR radiomic signature was 0.806 (95 % CI, 0.667 - 0.944).
Conclusion: Radiomic algorithm based on grey-scale ultrasound images has potential value to facilitate preoperative prediction of MVI in HCC patients. The GTR radiomic signature may be helpful for further discriminating among MVI-positive patients.
Limitations: The possibility of a selection bias due to retrospective study.
Ethics committee approval: This study was approved by the institutional review board of Zhongshan Hospital. Informed consent was waived before ultrasound examination.

A deep learning approach for multi-structure segmentation in echocardiography images

S. Moradi[1], A. Alizadehasl[1], M. Ghelich Oghli[1], N. Sirjani[2], A. Shabanzadeh[1], P. Ghaderi[1], I. Shiri[3]; *[1]Tehran/IR, [2]Karaj/IR, [3]Geneva/CH (shakiba.mrd71@gmail.com)*

Purpose: Most of the quantitative features in analysing echocardiography images are elicited from the cardiac chambers morphologies. Elevated atrial pressure or an increase in flow leads to atrial enlargement, and any changes on left ventricle morphology could be a sign of abnormality. Automatic segmentation makes the procedure more accurate and less operator-dependent, and these advantages leads to more precise prediction of the LV and left atrial (LA) volumes and ejection fraction. We proposed a deep learning (DL) approach for the segmentation of the LV endocardium, epicardium, and LA in apical 4-chamber view images.
Methods and materials: The dataset used is a publically available dataset of echocardiography images which is published in CAMUS challenge. The data contains 900 apical 4-chamber view images in end-systole (ES) and end-diastole (ED) frames. We used our DL architecture, which is recently introduced (MFP-Unet) for multi-structure segmentation. 720 ED and ES images (augmented by a power of 10) are used as the training dataset and 180 images are used for the testing procedure.
Results: The model achieved a Dice coefficient (DC) value of 95% for endocardium, 97% for epicardium, and 91% for LA segmentation at ED phase, and 92% DC, 95% DC, and 92% DC at ES phase. The Hausdorff distance was also used as a validation metric. It was 4.72 for epicardium, 4.83 for endocardium, and 5.11 for LA at ED phase, and 5.32, 5.5, and 5.18, respectively, at ES phase.
Conclusion: This study evaluated the power of our novel DL algorithm in echocardiographic image segmentation. It is shown that the proposed method is reliable and behaves similarly to clinical experts in calculating the clinical cardiac indices.

To explore the value of CT radiomics in evaluating the biological behaviour of pancreatic cancer
Q. Gu*; Changsha/CN (729570216@qq.com)*

Purpose: To investigate whether CT radiomics can be used to assess the biological behaviour of pancreatic cancer before surgery.
Methods and materials: 94 histopathological confirmed pancreatic cancer patients who underwent CT scans were retrospectively included. The volume of interest (VOI) of the tumour on CT images was manually delineated and radiomics features were extracted by MaZda software. After feature reduction, radiomics models reflecting tumour biological behaviour (differentiation, lymph node metastasis) were established and the radiomics score(Rad-score)of each patient was calculated. The performance of each model was assessed by the receiver operating characteristic curve (ROC).
Results: There were no significant differences in both the differentiation degree group and lymph node metastasis group based on age and gender (P>0.05). The tumour location was statistically significant between the lymph node metastasis positive group and negative group (P=0.02). The radiomics model established by 7 CT radiomics features can predict the differentiation degree of pancreatic cancer. The area under the ROC curve（AUC） is 0.78 and 0.76 in the training group and validation group, respectively. The radiomics model established by 6 CT radiomics features can predict the lymph node metastasis of pancreatic cancer. The AUC is 0.77 and 0.74 in the training group and validation group, respectively.
Conclusion: CT radiomics have a great prospect in the non-invasive evaluation of the biological behaviour of pancreatic cancer. It has certain reference significance for preoperative evaluation of the malignant degree and is helpful to clinical treatment decision in pancreatic cancer.
Limitations: The sample size is small, and the results need to be confirmed with large sample studies. The model built in this study was validated with internal data but not tested with external test data.

Automated estimations of body weight prior to CT examinations using a 3D camera
M. S. May[1], F. Geißler[1], A. Wimmer[2], M. Saake[1], M. Kopp[1], R. Heiß[1], M. Uder[1], W. Wuest[1]; *[1]Erlangen/DE, [2]Forchheim/DE (matthias.may@uk-erlangen.de)*

Purpose: The aim of this study was to automatically assess the body weight prior to CT examinations.
Methods and materials: Body weight of 100 consecutive adult patients with an indication for CT was visually estimated by a technologist and a radiologist prior to the examination. The patients were additionally asked for their current anamnestic values before the true values were weighed. A roof-mounted 3D camera was used after patient positioning on the scanner's table to fit in an individual avatar using machine learning algorithm that was taught by the 200 preceding patients. Body weight was mathematically derived from this information.
Results: Mean body weight of our collective was 80 kg (± 19kg). The vast majority was examined wearing street-wear (94%), only few patients were wearing medical gowns (6%). Shoes were worn in 60% of the cases. Anamnestic values had a very low error from the ground truth (± 2%). Automated calculations (± 3%) were comparably precise, but estimations by radiologists (± 8%) and technologist (± 9%) were significantly worse. All assessment techniques tended to slightly underestimate the true values.
Conclusion: Automated weight assessment is feasible in a clinical routine setting with a high precision using a 3D camera and machine learning algorithms. This information could be used for automated contrast agent adaptations in future CT generations.
Limitations: Different interfering circumstances like large clothes, covers, positioning and other medical devices may bias the assessment of body weight by a 3D camera. The accuracy of the algorithm could be improved especially in these patients by increasing the number of cases in future projects.
Ethics committee approval: The study was approved by the local review board, written informed consent was obtained from each patient.

A pilot study of radiomics signature-based on biparametric MRI for the preoperative prediction extrathyroidal extension in papillary thyroid carcinoma
S. Hu[1], X. Wang[2]; *[1]Wuxi/CN, [2]Zhenjiang/CN (hsd2001054@163.com)*

Purpose: To investigate the efficiency of radiomics signature to preoperatively predict aggressiveness histological feature extrathyroidal extension (ETE) in papillary thyroid carcinoma (PTC) with biparametric magnetic resonance imaging (bp-MRI) findings.
Methods and materials: For each patient, the images were manually segmented using ITK-SNAP software. 107 textural features were automatically calculated from the segmented region of interest (ROI). Random forest was used to do classification and the datasets were partitioned randomly 10 times to do training and testing with ratio 1:1. Furthermore, forward greedy feature selection based on feature importance was adopted to reduce overfitting. The classification accuracy was estimated on the test set using the area under the curve (AUC).
Results: After feature selection, the top 2 features of T2WI and the top 6 features of T2WI-FS achieve AUC 0.845 and 0.928, respectively. If the features in T2WI and T2WI-FS were combined, the performance of the model will decrease slightly (AUC 0.882 before and 0.913 after feature selection). Adding more radiomics feature filters on the T2WI-FS images to get more features does not improve the model performance (with AUC 0.891). Hyper parameters of the random forest model have negligible influence on the model performance with AUC mean 0.907 and std 0.006 for T2WI-FS images.
Conclusion: Radiomics features based on pre-contrast T2WI and T2WI-FS is helpful to predict aggressiveness histological feature ETE in PTC. And the T2WI-FS image features extracted without using any feature filters provide the best classification performance. The most important features are related to ROI size and the heterogeneity of the texture of ROI.
Limitations: The sample size of the study is small.
Ethics committee approval: The written informed consent was waived.
Funding: No funding was received for this work.

Ventriculoperitoneal shunt valve detection and identification using object detection with a faster RCNN
J. Haubold[1], A. Radbruch[2], M. Forsting[1], L. Umutlu[1], F. Nensa[1]; *[1]Essen/DE, [2]Heidelberg/DE (johannes.haubold@uk-essen.de)*

Purpose: Determining the pressure level of a ventriculoperitoneal (VP) shunt valve requires both the correct identification and finding the manufacturer's image for reading the pressure level. To reduce this effort, we have implemented a network for automated identification of the VP shunt valve and for an assignment of the manufacturer's image to read the pressure level.

Methods and materials: The collective (560 images of eight shunts) was split into 112 test images and 448 training images. For object detection, a Faster RCNN was trained. Subsequently, the detected label was used for a content-based image retrieval to assign the manufacturer's image for reading the pressure level. The mean average precision (mAP) at 0.5 intersections over union (IOU) was calculated to measure the precision.
Results: In the test set, a mAP of 0.77@0.5IOU was achieved for multiclass detection. In the next step, the fused images were demonstrated to a young resident in radiology. He was asked for each image whether the VP shunt was correctly identified. The assigned manufacturer's image for reading the pressure stage enabled the resident in radiology to correctly identify all misclassified VP shunt valves.
Conclusion: Using a Faster RCNN for an automated object detection it was possible to create a network with high performance for the identification of VP-shunts with a versatile mechanism to identify misclassifications.
Limitations: This study was performed in a single-centre because of the nature of machine learning more multi-centre data is needed for validation.
Ethics committee approval: This retrospective analysis was approved by the institutional review board of the University Hospital Essen. Informed consent was waived by the institutional review board, because of the retrospective character of the study.
Funding: No funding was received for this work.

Deep convolutional neural networks-based coronary computed tomography angiography for CAD classification
Z. Huang, X. Wang, J. Xiao, Z. Li, Y. Xie, Y. Hu*; Wuhan/CN (304527885@qq.com)*

Purpose: We aimed to assess the utility of an automatic post-processing and reporting system based on CAD-RADS™ in suspected coronary artery disease patients.
Methods and materials: The model was designed for CAD-RADS assessment categories with automatic coronary tree segmentation and stenosis detection algorithm based on convolutional neural networks with the training of consecutive 2000 CCTA examinations. The diagnostic value of CAD-RADS classification, one-vessel CAD, two-vessel CAD, left main CAD and three-vessel CAD were performed by the model compared to radiologists with commercially-available automated segmentation and manual post-processing and also compared to invasive coronary angiography (ICA).
Results: Of the 322 patients in the study, 15, 9, 48, 96, 99, 35, 20 were classified as CAD-RADS 0, 1, 2, 3, 4A, 4B and 5 based on the model. The consistency test showed that the Kappa value of the model and radiologists was 0.639 (P<0.05). The Kappa value for diagnosing one-vessel CAD, two-vessel CAD, left main CAD and three-vessel CAD between the model and radiologists with CCTA is 0.758, 0.747, 0.869 and 0.596, respectively. The Kappa value for diagnosing one-vessel CAD, two-vessel CAD, left main CAD and three-vessel CAD between the model and ICA is 0.581, 0.494, 0.758 and 350, respectively. However, there is a poor agreement for detecting plaque characteristics between the model and radiologists with CCTA (Kappa value 0.349).
Conclusion: The CNN-based CAD-RADS in CCTA images is good consistency with the radiologists. However, the poor agreement for detecting plaque characteristics is remarkable in the study.
Limitations: This study is limited by the select bias and the fact that it is a retrospective study.
Ethics committee approval: The present study was approved by the institutional review board of the Central Hospital of Wuhan.

Impact of an artificial intelligence-based noise reduction algorithm on image quality in low-dose coronary CT angiography of obese patients
P. Liu, Y. Wang, M. Yu, Z. Liu, M. Wang, Z. Jin*; Beijing/CN*

Purpose: This study aims to assess the impact of artificial intelligence (AI)-based noise reduction algorithm on image quality (IQ) in low-dose (LD) coronary CT angiography (CCTA) for obese patients.
Methods and materials: Forty consecutive patients with BMIs ≥ 25 kg/m^2 underwent clinically indicated CCTA examinations on a NeuViz 128 CT scanner using a step-and-shoot mode with 100 kV and automatic current modulation. Images were reconstructed with an iterative algorithm (group A) and an AI-based noise reduction algorithm (group B), respectively. Image noise, signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) were calculated on the aortic root (AO), left main artery (LM), left anterior descending artery (LAD), left circumflex artery (LCX), and right coronary artery (RCA) to evaluate IQ objectively. Subjective IQ scores were graded on a four-point scale (1: excellent, 4: poor).
Results: Compared to group A, group B yielded statistically significant reductions in image noise in the AO, LM, LAD, LCX and RCA of 63.97%, 38.63%, 21.29%, 24.38% and 29.99%, respectively. SNR and CNR both significantly increased in group B compared to group A (all P < 0.001). The subjective IQ scores in group B were superior to those in group A (1.57 ± 0.67 vs. 1.71 ± 0.67, P < 0.001). The effective dose was 2.3 ± 0.1mSv.
Conclusion: The AI-based noise reduction algorithm is an innovative and promising method that could effectively improve the IQ in LD CCTA for obese subjects.
Limitations: The diagnostic accuracy of coronary artery stenosis with AI-based noise reduction technology had not yet been evaluated using invasive coronary angiography as a standard examination.

Digitised patient history in computed tomography: data acquisition with mobile tablet computers
M. Kopp[1], F. Geißler[1], M. Wetzl[1], M. Wiesmüller[1], R. Heiss[1], T. Allmendinger[2], M. Uder[1], M. S. May[1]*; [1]Erlangen/DE, [2]Forchheim/DE*

Purpose: In contemporary healthcare systems, patient data is often unstructured and only available in hardcopy form. However, mobile tablet computers are a possibility to acquire digitized and structured patient data. Especially, for the indication of computed tomography (CT) consideration of critical patient history is mandatory. Also, high-quality reporting is supported by valid information about patient background. The aim of this study was to analyze the feasibility of structured, mobile tablet workflow for supporting informed consent discussion and reporting process. Secondly, the prevalence of critical patient history was evaluated.
Methods and materials: Mobile tablet computers were provided to consecutive patients, who answered independently a questionnaire (maximum 25 questions) concerning CT indication and general patient history. A specific software solution was used to provide structured access to all patient data for preparation of informed consent discussion and reporting process.
Results: In total 1159 patients answered the questionnaire with a mean age of 59.8 ± 15.3 years, 33% were female. Critical information on overall patient history was found for 54.9%. Evaluation of CT indication showed: 4.2% kidney disease, 3.4% diabetes medication, 3.1% claustrophobia, 1.6% allergic reactions to contrast agents and 1.4% thyroid hyperfunction. Furthermore, the patients indicated in 23.1% a pulmonary disease (most frequent: 4.5% asthma), in 12.1% a malignant disease and in 8.1% cardiovascular diseases.
Conclusion: Tablet-based acquisition of patient history is feasible and facilitates preparation of informed consent discussion and reporting process as critical patient history is frequent but easily accessible by using a specific software solution.
Limitations: Even higher patient numbers are necessary to obtain information about correlations between patient history, symptoms, CT related complications and the final radiology report.
Ethics committee approval: n/a

Whole-tumour texture analysis of apparent diffusion coefficient maps for distinguishing lateral ventricle central neurocytoma from ependymoma

W. Wang, J. Cheng; *Zhengzhou/CN (weijianwang520@163.com)*

Purpose: We explored the role of whole-tumour texture analysis of apparent diffusion coefficient (ADC) maps for discriminating lateral ventricle central neurocytoma from ependymoma.
Methods and materials: We retrospectively evaluated findings in 35 patients with lateral ventricle central neurocytoma and 20 patients with ependymoma who underwent diffusion-weighted imaging (b = 0,800 s/mm(2)) at 3T with the acquisition of corresponding ADC maps. We derived texture analysis data from regions of interest drawn on all slices of the ADC maps in which tumour was visualised, including areas of necrosis and haemorrhage in the tumour. We used the t-test to evaluate the capacity of texture analysis parameters (variance, kurtosis,1th,10th percentiles) to discriminate central neurocytoma from ependymoma and analysed the receiver operating characteristic (ROC) curve to determine the optimum threshold value for each parameter and its corresponding sensitivity and specificity.
Results: Lateral ventricle central neurocytoma demonstrated significantly lower variance, kurtosis, 1th, 10th percentiles than ependymoma (P < 0.05). ROC curve analysis of the variance yielded the best area under the ROC curve (AUC; 0.93), the sensitivity of 90%, and specificity of 92%, with a cut-off value of 2008.
Conclusion: A whole-tumour texture analysis of ADC maps might be helpful for discriminating lateral ventricle central neurocytoma from ependymoma.
Limitations: It is small-scale retrospective research in which the number of patients per tumour is unbalanced. The correlation between ADC texture analysis parameters and histopathological characteristics needs further study.
Ethics committee approval: No ethics committee approval was obtained.

Convolutional neural networks for automated fracture detection and localisation on ankle radiographs

Q. Xie, B. Yin, Y. Lu, X. Li, D. Geng; *Shanghai/CN (474278641@qq.com)*

Purpose: To identify the feasibility and performance of using a deep convolutional neural network (DCNN) for fracture detection and localisation on ankle radiographs.
Methods and materials: A total of 8957 ankle radiographic studies were extracted from our institution picture archiving and communication system (PACS). Radiologists annotated all tibia and fibula fractures with bounding boxes. The dataset was split into training (90%) and validation (10%) sets and used to train fracture localisation models for images of anteroposterior, lateral, and oblique view. ResNeXt101 + FPN was implemented as a proposal network, whose output of proposal regions are fed into EfficientNet to be elaborately classified. The accuracy, sensitivity, false-negative rate, and area under the receiver operating characteristic curve (AUC) were evaluated on an unseen test set of 600 consecutive emergency department ankle radiographic studies acquired during 2019, orthopedist and radiologist with more than 10 years of orthopaedic professional experience in consensus as to the reference standard. The results were compared with those of medical professional groups. The authors also used a segmentation branch (CNN decoder) to confirm the validity of the model.
Results: In a classification metric, the algorithm achieved an AUC of 0.932 for identifying ankle fractures. An accuracy of 86.8% is realised with a sensitivity of 97.6%, a false-negative rate of 13.2%. In object detection metric, we accomplish an average precision (AP) of 0.95. The network presented a similar diagnostic performance to that of the orthopaedists in terms of these variables.
Conclusion: The ability of a two-stage RCNN not only to detect ankle fractures on ankle radiographs with a low false-negative rate but also have high accuracy for localising fracture lesions was demonstrated.
Limitations: Automated classification of an ankle fracture is not done.

Machine learning-based analysis of nasopharyngeal carcinoma: MRI radiomics for prediction of recurrence or metastasis

D. Bao, D. Luo, S. Dai, Y. Geng; *Beijing/CN (baodanhb@126.com)*

Purpose: To use machine learning-based magnetic resonance imaging radiomics to predict recurrence or metastasis in patients with nasopharyngeal carcinoma.
Methods and materials: This study retrospectively analysed 142 patients with nasopharyngeal carcinoma, and randomly assigned to the training and validation group at a ratio of 8:2. Feature selection was performed in the radiomic feature sets extracted from images of T2-weighted fat suppression (T2WI/FS) and contrast-enhanced T1-weighted (CE-T1WI) sequence respectively, and the combining feature set incorporating two sequences with variance threshold, select K best and the LASSO methods gradually. Two machine learning algorithms (Random Forest[RF]; Logistic Regression [LR]) were utilised for predictive model constructing. The diagnostic performance of the models was evaluated by receiver operating characteristic curves with indicators of accuracy, sensitivity, specificity and area under the curve, and compared by DeLong test.
Results: 10, 28, and 17 optimal features were selected from 1409 T2WI/FS, 1409 CE-T1WI, and 2818 combining features, respectively. Four-group models were constructed using the 10 T2WI/FS features ($Model_{T2/FS}$), 28 CE-T1WI features ($Model_{CE\text{-}T1WI}$), the combined 38 features ($Model_{combined}$) and 17 optimal features selected from the 2818 features ($Model_{optimal}$) . The $Model_{optimal}$ using RF algorithm showed the best prediction performance with accuracy, sensitivity, specificity, and area under the curve of train/test: 0.96/0.79, 0.96/0.86, 0.97/0.63, and 0.99/0.80, respectively.
Conclusion: Radiomics models based on baseline nasopharyngeal carcinoma magnetic resonance imaging has a high potential for recurrence or metastasis prediction, especially the $Model_{optimal}$ using RF algorithm. Moreover, except for $Model_{optimal}$, the RF was not superior to the LR algorithm for model construction.
Limitations: This was a retrospective single centre study.
Ethics committee approval: This retrospective study was approved by the ethics committee of our institution, and the requirement for informed consent was waived.

Radiomics on ^{18}F-FDG PET and CT images can differentiate lymphomatous from metastatic lymphadenopathy

X. Ou[1], Z. Bo[1], J. Wang[2], F. Pang[1], J. Wu[1], Z. Zhao[1], P. Cao[1], X. Ma[1]; *[1]Chengdu/CN, [2]Nanjing/CN (drmaxuelei@gmail.com)*

Purpose: To assess the value of PET/CT radiomics combined with a large panel of machine-learning methods classifying lymphomatous and metastatic lymphadenopathy, and secondly to identify optimal machine-learning methods for radiomics-based malignant lymphadenopathy classification.
Methods and materials: PET and CT radiomic features from 492 lymph nodes were retrospectively analysed. Radiomic features were manually extracted using LIFEx software from PET and CT images within the same volume of interest (VOI). Five feature selection and nine classification methods were evaluated with independent training (n=394 lesions) and testing datasets (n=98 lesions). The performance of classification models was evaluated using the area under the curve (AUC), sensitivity and specificity.
Results: The ROC analysis revealed PET and CT radiomics with machine-learning methods possess a strong ability in differentiating malignant lymphadenopathy with the AUC up to 0.985. “Gradient Boosting Decision Tree (GBDT)” + “GBDT” achieved the highest classification AUC in the most differential assignments.
Conclusion: Radiomic features extracted from PET/CT images are efficient to differentiate between metastatic and lymphomatous lymphadenopathy using machine-learning methods. ”GBDT” + “GBDT” was found to be the optimal machine-learning method in our analysis.
Limitations: First, we didn’t compare the differences between malignant lymph nodes and inflammatory lymph nodes. Although the differential diagnosis of malignant and benign lymph nodes is not difficult and has been proven in the previous studies[13,22,25]. However, classifying of lymphadenopathy into metastatic, inflammatory and lymphomatous lymph nodes is frequently encountered in clinical practice. Second, although a large lymph nodes sample was included in this retrospective study, prospective studies are needed to verify our findings.
Ethics committee approval: This study was approved by the local ethics administration office. As this is a retrospective study, patients’ informed consent was waived.
Funding: No funding was received for this work.

Segmentation of heart from chest x-ray images using U-net
L. A. Klarov, A. Timofeev, D. Zakharova, S. Permyakov, E. Nikiforov, D. Egorov*; Yakutsk/RU*

Purpose: The purpose of the study is the accurate selection of heart shadow from x-rays.
Methods and materials: We collected a dataset of 1300 chest x-rays and applied masks to them. For analysis, all x-rays were converted to jpg, and the mask was created in png. To isolate the heart, we used a 9-layer U-net convolutional neural network. With startup parameters learning rate = 1e-5, Adam optimiser, batch = 5 (3, 5), epochs = 800. The network was launched with samples of 400, 800 and 1300 images. In each run, a generator of additional images was used (5 to 1 image every epoch).
Results: The direct relationship is determined: an increase in the quality of segmentation with an increase in the number of x-rays in the dataset on the training sample. The quality of the test data is also affected by significant parameters when selecting lr, batch size. The parameter of epochs=800 shows good convergence on the graphs and was chosen as the most optimal. Samples with 400 and 600 images contain mask artefacts in the inner contour of the heart shadow. When sampling 1300 images, there are artefacts of determination beyond the outer contour.
Conclusion: The accuracy of the contours (the pulmonary artery and the left atrial abalone) and the presence of artefacts depend on the volume of the dataset. The selection of optimal hyperparameters also affects the results of segmentation in more global moments, such as determining the main fixation zones.
Limitations: The lower border of the heart remains fuzzy, even with a large number of images.

Whole-tumour texture analysis of apparent diffusion coefficient maps obtained using 3.0T MRI for distinguishing uterine endometrial carcinoma from endometrial polyps
W. Wang, J. Cheng, Y. Zhang*; Zhengzhou/CN*

Purpose: We explored the role of whole-tumour texture analysis of apparent diffusion coefficient (ADC) maps for discriminating uterine endometrial carcinoma and endometrial polyps.
Methods and materials: We retrospectively evaluated findings in 40 patients with uterine endometrial polyps and 50 patients with endometrial carcinoma who underwent diffusion-weighted imaging (b = 0,800 s/mm(2)) at 3T with the acquisition of corresponding ADC maps. We derived texture analysis data from regions of interest drawn on all slices of the ADC maps in which tumour was visualised, including areas of necrosis and haemorrhage in the tumour. We used the Mann-Whitney test to evaluate the capacity of texture analysis parameters (mean, skewness, kurtosis,50th,90th percentiles) to discriminate uterine endometrial carcinoma from endometrial polyps and analysed the receiver operating characteristic (ROC) curve to determine the optimum threshold value for each parameter and its corresponding sensitivity and specificity.
Results: Uterine endometrial carcinoma demonstrated significantly higher mean vales of ADC, skewness, kurtosis,50th,90th percentiles than endometrial polyps ($P < 0.05$). ROC curve analysis of the 90th percentile yielded the best area under the ROC curve (AUC; 0.92), sensitivity of 90%, and specificity of 95%, with a cut-off value of 198.
Conclusion: Whole-tumour texture analysis of ADC maps might be helpful for discriminating uterine endometrial carcinoma from endometrial polyps.
Limitations: It is small-scale retrospective research in which the number of patients per tumour is unbalanced. The correlation between ADC texture analysis parameters and histopathological characteristics needs further study.
Ethics committee approval: No approval was obtained.

Radiomics analysis of 18F-FDG PET/MR datasets for the prediction of therapy response of isolated limb perfusion in patients with soft-tissue sarcomas
J. Grueneisen[1], M. Chodyla[1], A. Demircioglu[1], M. Forsting[1], K. Herrmann[1], O. Martin[2], L. Umutlu[1]; [1]*Essen/DE,* [2]*Düsseldorf/DE (johannes.grueneisen@uk-essen.de)*

Purpose: To investigate the potential of radiomic analysis based on PET/MR-derived imaging parameters for the prediction of therapy response of isolated limb perfusion with melphalan and alpha-TNF (TM-ILP) in patients with soft-tissue sarcomas (STS).
Methods and materials: A total of 47 patients with the verification of a STS manifestation were prospectively enrolled for an integrated 18F-FDG PET/MR examination prior to neoadjuvant TM-ILP. The study protocol comprised the acquisition of several 18F-FDG PET- and MR-derived morphological After tumour segmentation, 17748 quantitative imaging features were extracted and tested for significance by a χ^2-test. Statistical modelling was performed using Random Forests and evaluated by repeated 5-fold cross-validation. Histopathological results after subsequent tumour resection served as reference standard and patients were categorized as responders/non-responders based on the grading scale by Salzer-Kuntschik.
Results: Histopathological analysis categorised 28 patients as therapy responders (Grade I-III) and 19 patients as non-responders (Grade IV-VI). For the differentiation between histopathological therapy response and non-response to TM-ILP, receiver operating characteristic analysis revealed an area under the curve (AUC) of 0.71. Furthermore, statistical analysis showed a positive predictive value of 76% to identify therapy responders in our patient cohort and a specificity of 74% to correctly define patients as non-responders.
Conclusion: Our preliminary results demonstrate the potential to predict therapy response of soft-tissue sarcomas under TM-ILP with a non-invasive imaging procedure, which has a high impact on further treatment and patients' prognosis. Accordingly, besides primary tumour staging, PET/MRI may have the potential to enhance the comprehensive pre-therapeutic evaluation of STS and improve patient therapy management.
Limitations: This study was limited by patient cohort.
Ethics committee approval: The study was approved by the local ethics committee. Written informed consent was obtained from all patients before each examination.

Deep learning-based evaluation of normal bone marrow activity in ^{18}F-NaF PET/CT in patients with prostate cancer
S. Lindgren Belal[1], O. Enqvist[1], J. Ulén[1], L. Edenbrandt[2], E. Trägårdh[1]; [1]*Malmö/SE,* [2]*Gothenburg/SE (sarah.lindgren_belal@med.lu.se)*

Purpose: Bone marrow is the primary site of skeletal metastases in prostate cancer. ^{18}F-sodium fluoride (NaF) can detect activity due to malignancy, but also identifies irrelevant degenerative cortical uptake. Normal radiotracer activity in solely the marrow has yet to be described and could be the first step towards automated tumour burden calculation. We aimed to investigate the normal activity of ^{18}F-NaF in whole bone and bone marrow in patients with localised prostate cancer.
Methods and materials: ^{18}F-NaF PET/CT scans from 87 patients with high-risk prostate cancer from two centres were retrospectively analysed. All patients had a recent negative or inconclusive bone scan. In the first centre, a PET scan was acquired 1-1.5 hours after i.v. injection of 4 MBq/kg ^{18}F-NaF on an integrated PET/CT system (Gemini TF, Philips Medical Systems) (53/87). In the second centre, scanning was performed 1 hour after i.v. injection of 3 MBq/kg ^{18}F-NaF

on an integrated PET/CT system (Discovery ST, GE Healthcare) (34/87). CT scans were obtained in immediate connection to the PET scan. Automated segmentation of vertebrae, pelvis, femora, humeri and sternum were performed in the CT scans using a deep learning-based method. Bone <7 mm from skeletal surfaces was removed to isolate the marrow. SUV was measured within the remaining area in the PET scan.
Results: SUV_{max} and SUV_{mean} in the whole bone and bone marrow of the different regions were presented.
Conclusion: We present a deep-learning approach for evaluation of normal radiotracer activity. Knowledge about radiotracer uptake in normal bone prior to cancerous involvement is a necessary first step for subsequent tumour assessment and could be of value when implementing future tracers.

Machine learning and radiomics analysis of breast MRI for prediction of grading, hormone receptor status and lymph node metastases in patients with breast cancer
M. Chodyla[1], J. Grueneisen[1], O. Martin[2], J. Haubold[1], M. Forsting[1], F. Nensa[1], L. Umutlu[1]; *[1]Essen/DE, [2]Düsseldorf/DE (Michal-Kamil.Chodyla@uk-essen.de)*

Purpose: To investigate the potential of MR-derived parameters for the prediction of grading, the hormone receptor status and lymph node metastases in patients with breast cancer.
Methods and materials: A total of 81 patients with BI-RADS 5 and 6 lesions were prospectively enrolled for a dedicated breast MRI examination prior to resection. The study protocol comprised diffusion-weighted imaging, T2-weighted imaging and dynamic contrast-enhanced T1-weighted imaging as well as consecutive subtraction imaging. After tumour segmentation, 13145 quantitative imaging features were extracted and tested for importance by the following feature selection methods: χ^2-test, t-test, Fisher-score, randomised logistic regression. Statistical modelling was performed using logistic regression, Random Forests or SVMs and evaluated by 5-fold cross-validation with 25 repeats. Histopathological results after subsequent tumour resection served as a reference standard.
Results: Prediction of the N-stage, as well as Elston-Ellis Grading, was moderately high with AUCs of 0.75 and 0.78, respectively. AUCs of prediction of the ER-status was moderate (0.68), while the prediction of Ki67 and HER2 status was weak (AUC = 0.61 and 0.56).
Conclusion: Our preliminary results demonstrate the potential for MR imaging-based tumour decoding and phenotyping of breast cancer with a prediction of N-stage and grading showing promising results. Prediction of the hormonal status was insufficient.
Limitations: The study was limited by small sample size and lack of control.
Ethics committee approval: This study was approved by the local ethics committee. Written informed consent was obtained from all patients before each examination.
Funding: No funding was received for this work.

Clinical value of MRI texture analysis for differentiating solitary fibrous tumours/hemangiopericytoma from angiomatous meningioma based on ADC and enhanced T1WI images
S. Zhang, J. Cheng*; Zhengzhou/CN*

Purpose: To explore the clinical value of preoperative texture analysis based on ADC and T1CE images in distinguishing solitary fibrous tumours/hemangiopericytoma and angiomatous meningioma.
Methods and materials: The clinical data and preoperative magnetic resonance imaging data of 24 patients with SFT/HPC and 20 patients with AM were retrospectively analysed. The histogram and GLCM parameters were analysed with Image J software to compare the difference between SFT/HPC and AM, and establish logistic regression model and plot the ROC curve for statistically significant parameters and joint parameters to confirm their efficacy in predicting SFT/HPC and AM.
Results: The Max, Min, Mean, Med of T1CE and ADC sequences of SFT/HPC are lower than AM (P<0.05, except MaxADC). The SD of T1CE sequences of SFT/HPC is larger than AM (P=0.031). The Kurt and Ske of T1CE and ADC sequences of SFT/HPC are larger than AM (P=0.003, p=0.001). ASM of ADC sequence of SFT/HPC is lower than AM (p=0.013); Con of T1CE sequence of SFT/HPC is lower than AM (p=0.027); Ent of ADC sequence of SFT/HPC was higher than AM (p=0.003); Among them, the AUC of Max, Min, Mean, Med, SD, Kurt of T1CE sequence and Min, Mean, Med, ASM, IDM, Ent of ADC sequence were greater than 0.7, and the AUC of MinT1CE, MedT1CE, and MeanT1CE were 0.970,0.964 and 0.960;multi-parameter joint analysis AUC and diagnostic efficacy (sensitivity, specificity, accuracy) were significantly improved.
Conclusion: This study shows that the analysis of tumour region texture of ADC and T1CE sequences has important clinical value for preoperative identification of SFT/HPC and AM.
Limitations: SFT/HPC and AM are rare, and the sample size is small.

DoseGuard: a fully automated and fast Monte Carlo-based dose calculation system for interventional radiology
N. J. Staut, G. Paiva Fonseca, C. Jeukens, A. Vaniqui, M. Podesta, S. van Hoof, F. Verhaegen*; Maastricht/NL (nick.staut@smartscientific.nl)*

Purpose: Legislation regarding radiation dose registration creates the need for more accurate dose information. In interventional radiology, the patient dose and especially skin dose is of particular interest. Current calculation methods are based solely on the radiation dose structured report (RDSR) data or indirect dose metrics resulting in high inaccuracies. In this work, a more accurate and fully automated system is developed allowing for accurate calculations giving almost real-time feedback to the physician.
Methods and materials: An automated dose calculation system based on Monte Carlo simulations and computer vision were developed using three RGB-D cameras (Microsoft Kinect). The calibrated camera system determined the geometric relationship between the patient and x-ray source and combines this information with the RDSR data to create a fast Monte Carlo model and calculate the patient's skin dose. The patient is modelled using a family of mathematical (XCAT) phantoms. The system was tested on a clinical machine using an anthropomorphic RANDO-phantom and GafChromic film.
Results: Fully automated skin dose calculations can be performed under 10 seconds within a 10% uncertainty for all field sizes, and uncertainties below 5% for field sizes smaller than 15 cm x 15 cm. Initial tests show differences between film and simulations smaller than 5%. Organ doses can be calculated offline.
Conclusion: The built prototype shows that the combination of Monte Carlo simulation and computer vision has the potential to improve the accuracy of dose calculations in radiology. Even providing near the real-time skin dose feedback during interventional procedures allowing for the prevention of radiation-induced skin lesions. The system can also calculate organ doses to estimate the long term radiation effect.
Limitations: Only phantom measurements were performed.

A combination of eight cortical morphologic neuroimaging biomarkers could effectively differentiate tinnitus patients from healthy subjects: evidence from the application of machine learning
H. Lv, Z. Wang, P. Zhao, Y. Liu*; Beijing/CN (chrislvhan@126.com)*

Purpose: A large number of neuroanatomical alterations in patients with tinnitus were detected in many previous studies. However, the most probable cortical morphologic neuroimaging biomarkers that characterise tinnitus should only enrol a limited number of features.
Methods and materials: To test this hypothesis, we would apply the machine learning method to develop a feature selection method in order to differentiate tinnitus patients from healthy subjects. The brain regions with anatomical alterations in tinnitus patients were further validated. We firstly summarised 61

brain regions with significant morphologic alterations reported by previous studies and defined them as the features. From this feature pool, a hybrid feature selection algorithms combined with F-score and sequential forward floating selection (SFFS) was performed to select relevant features. The support vector machine (SVM) model was applied to analyse their performance and created a classifier. On a database of 46 tinnitus patients and 56 healthy controls, 5-fold cross-validation was used in this study to evaluate the accuracy of this classifier.
Results: A combination of eight brain regions was featured by the highest accuracy of classification in differentiating tinnitus patients from healthy controls effectively. Those brain regions including bilateral hypothalamus, left superior frontal gyrus (SFG), right rostal middle frontal gyrus, right insula, right inferior parietal lobule (IPL), and two neighbored nodes in left superior temporal gyrus (STG).
Conclusion: Our study elucidated the most characteristic anatomical changes in patients with tinnitus by applying SVM classifier, providing validated cortical morphologic neuroimaging biomarkers to differentiate tinnitus patients from normal controls.
Limitations: Results of cortical thickness and cortical surface area were not included. Larger datasets for training and testing will be more helpful.
Ethics committee approval: This study was approved by the medical research ethics committees and institutional review board of our institution.

The correlation of artificial intelligence-based CAD-RADs by coronary computed tomography angiography with breast arterial calcification on mammography
X. Wang, Z. Huang, J. Xiao, Z. Li, Y. Hu*; Wuhan/CN*
(wangxiangwhch1971@163.com)

Purpose: This study sought to evaluate the association of breast arterial calcification (BAC) on breast screening mammography with coronary artery disease-reporting and data system (CAD-RADS™) based on artificial intelligence-coronary computed tomography angiography (CCTA).
Methods and materials: This prospective single-institution study included asymptomatic women over 40 who underwent CCTA and breast cancer screening mammography between 2018 were recorded. CAD-RADS™ was scored based on artificial intelligence. Mammograms were assessed visually for the presence and severity of BAC.
Results: 560 eligible women underwent a CCTA. Of these 214 patients also underwent mammography. In comparison to the low CAD-RADS (CAD-RADS< 3) group, the high CAD-RADS (CAD-RADS≥3) group, they more often had a history of hypertension (p=0.032), diabetes (p=0.011), hypercholesterolemia (p=0.024). They also had a statistically higher level of LDL-C (p=0.037), where HDL-C was lower than the low CAD-RADS group with (p=0.029). BAC was significantly higher in the high CAD-RADS group (p=0.008). A multivariate analysis, BAC (odd ratio [OR] 6.24, 95% confidence interval [CI]:3.39-15.45), diabetes (odd ratio [OR] 3.77, 95% confidence interval [CI]:2.16-7.98) and LDL-C (odd ratio [OR] 1.28, 95% confidence interval [CI]:1.04-4.71) were independent predictive factors for patients with high CAD-RADS patients.
Conclusion: There was a significant correlation between the severities of CAD detected by artificial intelligence and BAC. BAC, diabetes and LDL-C may be used as an additional diagnostic tool to predict the severity of CAD.
Limitations: This was a retrospective analysis. BAC was showed absence or present in the present study, more precise BAC quantification or semi-quantitative scale would be useful.
Ethics committee approval: The present study was approved by the institutional review board of the Central Hospital of Wuhan.
Funding: No funding was received for this work.

Variations of standard quality control for clinical PET/MRI systems: a European perspective
A. Valladares[1], T. Beyer[1], R. Boellaard[2], Z. Chalampalakis[3], C. Comtat[3], L. Dal Toso[4], A. E. Hansen[5], J. Nuyts[6], I. Rausch[1]; *[1]Vienna/AT, [2]Amsterdam/NL, [3]Orsay/FR, [4]London/UK, [5]Copenhagen/DK, [6]Leuven/BE*
(alejandra.valladares@meduniwien.ac.at)

Purpose: Hybrid imaging systems play an important role in non-invasive disease characterisation. Therefore, stringent quality control (QC) procedures are required to ensure proper functionality of the systems and to gain accurate quantitative results. Here, we evaluate existing QC procedures for combined PET/MRI systems in clinical routine.
Methods and materials: Eight highly-experienced European imaging sites were surveyed about locally implemented PET/MRI QC procedures. The survey was based on existing recommendations on QC for stand-alone PET and MRI systems. In addition, relevant vendor-specific information on QC measures was collected.
Results: In total, five Siemens, two GE, and one Philips PET/MRI systems were reported. For all the systems, the centres reported performing the PET daily QC as implemented by the vendor. However, moderate to high variations were found across other tests and testing frequencies for the PET and MRI components of the systems. Based on the observed variability in QC procedures across sites and vendors, a consensus on QC procedures was reached. This consensus includes for the PET component: a daily QC as suggested by the local vendor, a quarterly cross-calibration measurement including the assessment of uniformity, and a yearly image quality test. For the MRI component, monthly coil checks and a quarterly MR IQ test including the assessment of signal-to-noise ratios and artefacts that could affect clinical scans and image quality.
Conclusion: Significant variations in daily QC procedures were observed across PET/MR imaging sites. A consensus on minimum QC procedures for clinical routine was proposed. This consensus can help assure high-quality examinations across sites.
Limitations: Specific applications will require additional tests.

GLINT GlucoCEST in neoplastic tumours at 3T: the first clinical results of GlucoCEST in brain tumours
T. Lindig[1], B. Bender[1], K. Herz[1], A. Deshmane[1], J. Schittenhelm[1], X. Golay[2], K. Scheffler[1], U. Ernemann[1], M. Zaiss[1]; *[1]Tübingen/DE, [2]London/UK*
(tobias.lindig@med.uni-tuebingen.de)

Purpose: Dynamic glucose enhanced (DGE) CEST imaging has almost only been shown at ultra-high field (UHF) due to the low effect size. The first results of 10 glioma patients of a DGE CEST method with fast 3D imaging developed for clinical field strength are shown herein.
Methods and materials: CEST saturated images at different frequency offsets were acquired at 160 time points before, during, and after glucose injection (0.3mg/kg) with 6.3s temporal resolution to detect accumulation in the brain. The total scan time was 16:45 min. 7 glioma patients with blood-brain barrier (BBB) leakage (6 WHO°4, IDH wild-type (WT) and 1 WHO°2, IDH positive), 3 glioma patients without BBB leakage (WHO°2, IDH positive; WHO°3, WT and WHO°4, WT), and 3 healthy controls were scanned with a clinical 3T system. After motion

and field inhomogeneity correction, the DGE images were analysed by subtracting each image from a pre-injection baseline image: $\Delta DGE(t)=DGE_{baseline}-DGE(t)$.
Results: In the high-grade gliomas with BBB leak, glucose uptake could be detected in the gadolinium-enhancing region and in tumour necrosis approximately 4 minutes after injection with a maximum increase of ΔDGE around 0.4% after approximately 9 minutes, whereas unaffected white matter ROIs did not show any significant DGE increase in accordance with previous UHF studies. Healthy controls and all 3 glioma patients without gadolinium enhancement showed no significant detectable DGE effect.
Conclusion: We demonstrated that stable DGE imaging can be accomplished at clinical field strength using optimised saturation and readout parameters. The first results are promising and indicate that glucoCEST corresponds more to the disruptions of the blood-brain barrier with gadolinium uptake than to the molecular tumour profile or tumour grading.

T2-FLAIR mismatch in grade II and III gliomas: fifty shades of mismatch?
A. Desagneaux, S. Grand, M. D. C. Pasteris, M. D. J. Boutonnat, S. Charara, C. Berthet, A. Krainik, A. Kastler*; Grenoble/FR (desagneaux.andrea@gmail.com)*

Purpose: The identification of imaging criteria predictive of a specific molecular subtype has become a priority to enable accurate glioma subtypes diagnosis with imaging. We aimed to assess possible variants of the typical T2-FLAIR mismatch in grade II and III glioma tumours with correlation to both histologic and molecular findings.
Methods and materials: A single-centre retrospective study including WHO grade II and III gliomas with complete IDH and 1p19q status was conducted. Two types of mismatch were defined. Typical, as previously described, and atypical T2-FLAIR mismatch, defined as the presence of one or more of the following characteristics: very low signal in flair, thick T2-FLAIR rim hyperintensity, irregular shaped T2-FLAIR mismatch, incomplete rim, or peri T2-FLAIR mismatch tumoural spread.
Results: Among 39 included patients, 20 had IDH–mutant astrocytomas, 14 had IDH–mutant oligodendromas, and 5 had IDH-wild type. The T2-FLAIR mismatch was found in 16/20 astrocytoma IDH-mutant cases (80%), with an excellent inter-reader agreement (k of 0.89 (95% CI 0.76-1.01, p<0.001) and high PPV (100%), specificity 100%, NPV 82.6%, and sensibility 80%). The T2-FLAIR mismatch sign among IDH–mutant astrocytoma was present with a typical presentation in 6/20 (30%) cases and atypical presentation was present in 10/20 (50%) cases.
Conclusion: This study confirmed the usefulness of the T2-FLAIR mismatch to help to diagnose IDH-mutant astrocytoma. Atypical T2-FLAIR mismatch should also be considered, as this study has shown that broadening the definition of the already well-described T2-FLAIR mismatch may improve the MRI prediction accuracy of molecular subtypes in grade II and III gliomas.
Limitations: A retrospective study with a small sample.
Ethics committee approval: Study ethics approval (CECIC Rhône-Alpes-Auvergne, Clermont-Ferrand, IRB 5891).

MRI diffusion kurtosis imaging and a location-specific analysis for paediatric glioma grading
I. P. Voicu[1], A. Napolitano[1], M. Vinci[1], E. Miele[1], A. Carai[1], A. Carboni[1], A. Mastronuzzi[1], M. Caulo[2], G. S. Colafati[1]; *[1]Rome/IT, [2]Chieti/IT (paul.voicu@hotmail.it)*

Purpose: To investigate whether diffusion kurtosis imaging (DKI) can help differentiate low- and high-grade gliomas in paediatric patients.
Methods and materials: We retrospectively analysed preoperative MRIs including DKI in 69 children (8.3±4.3 years, 32 females) with gliomas, divided into a testing (n=58) and validation (n=11) cohort. Mean, axial, radial, and fractional anisotropy kurtosis values (MK, AK, RK, and kFA, respectively) were extracted from semiautomatically-segmented solid tumour volumes. For each metric we analysed: 1) conventional accuracy, 2) accuracy for location-specific subgroup analyses, hypothesising an opposite pattern in infratentorial midline gliomas compared to other locations, 3) location-specific overall accuracy and comparison with the conventional analysis model, and 4) model validation. Statistical analyses included t-test, ROC, and correlation analyses.
Results: 1) Conventional AUCs were 0.699, 0.658, 0.649, and 0.672 for MK, AK, RK, and kFA .
2) T-tests on 15 infratentorial midline gliomas (9 pHGG) and 43 other-location gliomas (10 pHGG) confirmed our hypotheses, yielding P<0.05 for all metrics except kFA. ROC analyses yielded AUCs of 0.925, 0.907, and 0.870 for MK, AK, and RK, respectively, in the infratentorial midline subgroup, and 0.906, 0.875, and 0.821 for MK, AK0 and RK0 respectively0 in other locations.
3) Whole-cohort location-specific estimates yielded AUCs of 0.900, 0.879, and 0.837 for MK, AK0 and RK0 respectively. Model comparisons yielded superiority for location-specific AUCs (P=0.01, P=0.01, and P=0.06 for MK, AK, and RK, respectively).
4) Validation on 11 patients yielded higher Matthews' correlation coefficient for location-specific metrics (0.82, 0.69, and 1 versus 0.31, 0.44, and 0.62 for MK, AK, and RK).
Conclusion: DKI accurately grades paediatric gliomas with a location-specific analysis.
Limitations: Further validation on more ample cohorts is needed.

Tumour microvascular normalisation enhancing CAR-T immunotherapy to glioblastoma via MRI
X. Chen, T. Xie*; Chongqing/CN (xiaochen229@foxmail.com)*

Purpose: To investigate whether tumour microvascular normalisation based on anti-angiogenesis could enhance CAR-T immunotherapy to solid tumours guided by MRI.
Methods and materials: Based on our previous studies on IL13R2α-CAR-T therapy in glioblastomas, we evaluated the effects of treatment with lower-dose bevacizumab on a NOD-SCID mice orthotopic glioblastoma model by 7.0T MRI to obtain the imaging biomarkers of tumour microvascular normalisation to determine the right time to transplant CAR-T cells. We used the USPIO-labelled cell tracking technique with MRI to evaluate the penetration and persistence of CAR-T cells in the tumour and functional MRI to assess the therapeutic effect.
Results: Tumour vascular normalisation appeared on day 3 and gradually faded away on day 7 after lower-dose bevacizumab treatment. The DCE-MRI and IVIM-MRI parameters show great potential in the non-invasive assessment of the normalisation window induced by bevacizumab. The K^{trans} value showed a significant decrease and the ADC value marked an increase in the combination therapy group 3 days after treatment compared to the monotherapy or the control groups, which were verified by immunohistochemical staining.
Conclusion: We established a combinational regimen that synchronises CAR-T therapy with tumour vascular normalisation. Moreover, we established an imaging platform and evaluation system for in vivo tracking of tumour vascular normalisation enhancing CAR-T immunotherapy to glioblastomas. These findings offer hope for developing new approaches that could enhance CAR-T therapy in solid tumours.
Limitations: n/a

Ethics committee approval: Human peripheral blood was obtained from healthy donors under an institutional review board-approved protocol. The use of laboratory animals was in compliance with the guideline of the National Institute of Health. Cerebral blood volume measurement at tumour-microvascularity derived from local image variance of susceptibility-weighted imaging in glioblastomas: correlation with IDH mutational status

H. Wu[1], X. Zhou[2], W. Zhang[1]; [1]*Chongqing/CN,* [2]*Shanghai/CN (cefradine1005@gmail.com)*

Purpose: To assess the clinical practice of rCBV value of tumour-microvascularity derived from local image variance (LIV) of susceptibility-weighted imaging (SWI) for IDH genotype prediction in glioblastomas (GBM).
Methods and materials: Preoperative MRI examinations of 78 GBM patients with a known IDH genotype were recruited. rCBVs derived from DSC-MRI was computed and normalised against the contralateral unaffected white matter value. rCBV and SWI images were coregistered to the MNI space. SWI-LIV were calculated according to the steiner translation theorem. The LIV regions were then extracted as ROI for rCBV measurement. The hot-spot ROI-based rCBV analysis was also conducted for confrontation. The discriminating potential for assessing IDH mutation status prediction was assessed by ROC curves.
Results: ROC analysis revealed that the rCBVs in SWI-LIV regions had a great ability to predict the IDH genotype with a sensitivity of 82.05% and a specificity of 97.06% (AUC=0.955). The SWI-LIV-based rCBV analysis has a superior diagnostic performance for IDH genotype prediction compared to the hot-spot ROI method (the difference between areas=0.077, z-score=1.697, and p=0.09).
Conclusion: Our study has proven that rCBVs in SWI-LIV regions has high prediction capabilities for the IDH mutation status in GBM patients. As SWI hypointensity is highly correlated with tumour microvascularity, the SWI-LIV-based ROI method is reliable to evaluate the haemodynamic change compared to the hot-spot based method.
Limitations: Lacking the microvascular-related biopsy data or pathologic sampling to comfirm the rCBV change in SWI-LIV regions.
Ethics committee approval: This study was approved by the institutional review board of the Army Medical University and was conducted in accordance with Health Insurance Portability and Accountability Act regulations.
Funding: The National Key R&D Program of China (2018YFC0115004) and grants from the Natural Science Foundation of China (81871421 and 81571660).

Remodelling tumour microenvironments through inhibiting the glycolytic activator PFKFB3 to synergise with antiangiogenic therapy in glioblastoma: insights from multiparametric MRI and proteome profiling

J. Zhang, W. Zhang*; Chongqing/CN (ilovetqm@qq.com)*

Purpose: To investigate whether targeting tumour glycolysis by PFKFB3 blockade is a novel potential strategy to enhance antiangiogenic therapy in glioblastomas (GBM) and to evaluate treatment-related molecular characterisation and clinically translatable MR imaging biomarkers of tumour response.
Methods and materials: Patient-derived orthotopic GBM xenografts in mice were established and imaged before (baseline) and at different time points after treatment with bevacizumab (BEV), 3PO (PFKFB3 inhibitor), BEV and 3PO, and saline. The tumour volume, cellularity, neovascularisation, and metabolites were monitored by T_2WI, IVIM, DCE-MRI, and ^{1}H-MRS, respectively. Pathology and proteome microarray were analysed to correlate with imaging parameters and evaluate post-treatment molecular profiling.
Results: BEV treatment induced remarkable PFKFB3 expression compared with the control ($P<0.05$). 3PO enhanced BEV therapeutic efficacy by sustained vascular normalisation, improved oxygenate status, and reduced the expression of matrix metalloprotein-9. K^{trans} and f were positively correlated with microvascular density (r=0.8776; r=0.9177), hypoxia (r=0.5566; r=0.5681), and negatively vascular maturation (r=-0.4898; r=-0.5884). Only co-treatment improved vascular perfusion corresponding to increased D*. BEV activated glycolysis with a rising trend of Lac/Cr and lactate dehydrogenase-A level. Co-treatment inhibited multiple proangiogenic factors by downregulating VEGF-independent pathways.
Conclusion: Targeting PFKFB3 has much potential to abate BEV-induced glycolytic adaption resistance by remodelling tumour microenvironments and could be monitored through multiparametric MRI thoroughly. IVIM is a promising alternative to DCE-MRI to characterise tumour response.
Limitations: The patient-derived GBM xenografts were modelled from one patient specimen only. Taking the tumour inherent heterogeneity into account, large-scale studies based on xenografts obtained from different GBM patients are needed to recapitulate diversity tumour habits and draw a definite conclusion.
Ethics committee approval: This preclinical study was approved by the Animal Use Subcommittee of Daping Hospital, Army Medical University.
Funding: The National Natural Science Foundation of China (No.81511660 and 81871421).

RPS 916-7 09:16

^{18}F-FET or ^{18}F-FCH PET/CT in the primary diagnosis of low-grade glioma: a pilot study

M. Hodolic[1], A. M. Krpan[2], A. T. Golubic[2], J. Nemir[2], G. Mrak[2], M. Zuvic[2], D. Huic[2]; [1]*Olomouc/CZ,* [2]*Zagreb/HR (marina.hodolic@gmail.com)*

Purpose: Gliomas are associated with varied survival, in part linked with their histological subtype. The diagnosis of low-grade glioma (LGG) is challenging, as conventional imaging modalities can often give inconclusive or equivocal results. Function imaging modalities can provide additional metabolic information. O- (2-[18F]-fluoroethyl) -L-tyrosine (^{18}F-FET) is radiopharmaceutical approved for the characterisation of glioma-suggestive brain lesions. ^{18}F-FET displays a high tumour-to-background ratio and no accumulation in inflammatory lesions. Because of low uptake in normal brain parenchyma, some centres use fluoromethyl-(18F)-dimethyl-2-hydroxyethyl-ammonium chloride (^{18}F-FCH) PET for the characterisation of glioma-suggestive brain lesions.
The aim of this study was to determine the diagnostic accuracy of ^{18}F-FET and ^{18}F-FCH PET/CT in patients with primary LGG.
Methods and materials: 11 patients aged 21-80 years with MRI-suspected LGG were involved. Patients underwent ^{18}F-FET and ^{18}F-FCH PET/CT within one week. Surgery and pathohistological diagnoses were performed in the next two weeks.
Results: 11/11 patients with suspected LGG underwent MRI, ^{18}F-FET and ^{18}F-FCH PET/CT. 9/11 patients underwent surgery and pathohistological diagnosis.
6 patients positive on ^{18}F-FET (SUVmax values ranging from 1.3-3.1) and negative on ^{18}F-FCH PET had a pathohistological diagnosis of LGG (2 ganglioma and 4 diffuse astrocytomas).
2 patients with ^{18}F-FET and ^{18}F-FCH PET avid lesion had a final diagnosis of glioblastoma multiforme.
1 patient negative on ^{18}F-FET and negative on ^{18}F-FCH PET had a diagnosis of focal cortical dysplasia.
2/11 patients are still waiting for surgery.
Conclusion: Appropriate radiopharmaceutical should be chosen before performing PET/CT in patients with newly diagnosed LGG. ^{18}F-FET seems to be more accurate than ^{18}F-FCH in the primary diagnosis of LGG.
Limitations: The small number of patients.
Ethics committee approval: The University Hospital Centre Zagreb, Croatia, approved this study.
Funding: 18F-FET was received for free.

The use of contrast clearance analysis for the post-therapeutic follow-up of brain tumours and metastases treated with radiotherapy

S. Mahmoudi, A. Toutaoui, T. Baroudi, R. Louelh*; Tizi Ouzou/DZ (abdelkader.toutaoui@gmail.com)*

Purpose: Contrast clearance analysis calculated from delayed-contrast-MRI is a novel methodology that enables the reliable differentiation between tumour and non-tumoural tissues in brain tumour patients. Analysis maps are calculated by subtracting 3D-T1-MRIs acquired 5 min post-contrast injection from those acquired 60-105 min later. We studied applications of this methodology for the post-therapeutic follow-up of patients in conventional/stereotactic radiotherapy.
Methods and materials: 10 patient treated in our department were included in this study. 5 patients with glioblastoma, 2 patients with germinoma, and 3 with brain metastases were scanned following the protocol. The first scan was

performed 4 months after the end of treatment. For 3 patients, 3 additional scans were performed every 3 months. 2 other patients had 2 more scans.
Results: 24 contrast clearance analysis maps were calculated for 10 patients. Detailed examples demonstrating the potential application of this method for the management of brain tumours are presented in this study. The potential application of the method for assessing the existence/absence of residual tumours after radiotherapy is demonstrated in the case of all patients with the first scan. The use of this technique for differentiating progression from treatment effects is demonstrated in the case of patients with 4 and 3 scan maps. In the case of 4 patients, a significant increase in the red volume in the maps was indicative of necrosis. For 1 patient, the map favoured pseudoprogression over progression. These evaluations are supported by clinical signs and tumour markers.
Conclusion: The contrast clearance analysis presents a novel model-independent approach providing efficient separation between tumour/non-tumour tissues. The presented results provide histological validation of analysis maps and demonstrate their potential contribution to the management of brain tumour patients.

RPS 916-9 09:28

Early post-treatment assessment of multi-parametric MRI after stereotactic radiosurgery: can it predict the long-term response of brain metastases?

P. P. Arcuri, S. Roccia, A. Quattrone, G. Fodero, V. Aiello, C. Bertucci, E. Mazzei, D. Laganà*; Catanzaro/IT (arppaolo@alice.it)*

Purpose: Imaging criteria to evaluate the response of brain metastases to stereotactic radiosurgery (SRS) in the early post-treatment period remains an important need not yet resolved. The aim of this study is to correlate early (within 12 weeks) post-treatment multi-parametric MRI changes with long-term outcomes after treatment of brain metastases with SRS.
Methods and materials: We evaluated 24 patients with multi-parametric MRI techniques, including spectroscopy, diffusion, and perfusion imaging in the pre- and post-treatment early period for the differentiation of radiation-related changes and tumour recurrence after SRS in intracranial metastases. Patients were followed longitudinally until death, progression, or intervention. All patients presented with enlargement of the treated lesion, an increase in perilesional brain oedema, and aggravation of neurological signs and symptoms from 7-29 weeks after primary treatment. Kruskal–Wallis' non-parametric test was performed. Sensitivity, specificity, and accuracy were assessed. Fisher's exact test was used to evaluate statistical significance. Histology or radiological follow-up was the gold standard.
Results: A low apparent diffusion coefficient (ADC) $<1\times10^{-3}$ mm^2/s, a high relative cerebral blood volume (rCBV) ratio >2.3, and a high choline/creatine (Cho/Cr) ratio >1.9 suggested tumour recurrence. A high ADC $>1\times10^{-3}$ mm^2/s, a low rCBV ratio <2.3, and a Cho/Cr ratio <1.9 suggested SRS-induced radiation changes. Sensitivity, specificity, and diagnostic accuracy were, respectively: rCBV=82%, 79%, and 81%, ADC= 75%, 73%, and 79%, and Cho/Cr ratio=76%, 80%, and 82%.
Conclusion: Early post-treatment rCBV and, to a lesser extent, ADC values and Cho/Cr ratios may be used as imaging biomarkers to help predict the long-term response of brain metastases to SRS. This can help identify patients who will ultimately fail SRS and allow for timelier adjustments in the treatment approach.
Limitations: The different primitive neoplasms.

The efficacy prediction of enzatiinib in brain metastases of crizotinib-resistant ALK-positive non-small-cell lung cancer (NSCLC) based on radiomics of brain MRI

D. H. Hou, S. J. Zhao, N. Wu*; Beijing/CN (1661874241@qq.com)*

Purpose: To investigate the feasibility of efficacy prediction of enzatiinib in brain metastases of crizotinib-resistant ALK-positive NSCLC based on radiomics of brain MRI.
Methods and materials: We enrolled ALK-positive NSCLC patients with brain metastases who progressed on crizotinib from 27 centres across China and acquired their clinical information and MRI images. The efficacy of patients was grouped according to progression-free survival (PFS=69 weeks). Radiomic features of T1-weighted contrast material-enhanced images on baseline were extracted using software A. K. and analysed in IPMs. Clinical characteristics analyses were performed using the statistical package R.
Results: By the latest evaluation date, this multicentre analysis included 69 brain metastases (mean size: 1.13 cm (0.46-3.25 cm); lesion location: 29 in frontal lobes, 6 in parietal lobes, 8 in occipital lobes, 10 in temporal lobes, 9 in cerebellums, and 7 in other parts) in 18 patients (10 women, 8 men; mean age: 51 years (36-66 years). Clinical characteristics (gender, age, lesion size, and location) were independent of the efficacy (P>0.05). Statistically significant differences were found in 2 radiomic features in multivariate analysis (p<0.05). Multivariate logistic regression models reconstructed with these radiomic features had predictive power for efficacy (AUC: 0.745, sensitivity: 0.714, and specificity: 0.714).
Conclusion: Radiomics provides prognostic value for PFS in patients receiving enzatiinib treatment.
Limitations: The study only included a small number of patients. We designed the study using a lesion-based approach reflecting the prognosis condition of patients, which may leaded to overfitting. We only analysed brain metastases but not meningeal metastasis.
Ethics committee approval: Approved by the local ethics review board. Patients provided written informed consent.

MRI radiomics: tumour marker at the pretreatment prediction of response to neoadjuvant chemotherapy of nasopharyngeal carcinoma

J. Sun[1], S. Chen[2], J. Ding[2], F. Shan[1], C. Huang[2];
[1]Shaoguan/CN, [2]Stony Brook/CN
(sunjunqi1233668@sina.com)

Purpose: To develop and validate a non-invasive radiomic model to predict the response to cisplatin-based neoadjuvant chemotherapy in NPC patients using pretreatment contrast-enhanced T1WI MRI (CE-MRI) and T2WI.
Methods and materials: Currently, we have response data from 105 NPC patients who received the cisplatin-based neoadjuvant chemotherapy. 63 patients showed a response to neoadjuvant chemotherapy (by RECIST). Their pretreatment CE-MRI images were used for radiomic analysis. Regions-of-interest covering the whole tumour were manually delineated by a radiologist and a total of 850 radiomic features were extracted for each patient, including shape, texture, wavelet, and Laws features. The dataset was split into a training cohort (n=70) and a temporal validation cohort (n=35). Features with strong discriminative power were selected by pre-selection (Mann Whitney U-test p<0.05, Spearman correlation |r|<0.7) followed by a least absolute shrinkage and selection operator (LASSO) with 10-fold cross-validation in the training cohort. The prediction performance was evaluated in the temporal validation set. The receiver operating characteristic (ROC) analysis was performed with the optimal threshold determined by maximising the Youden index in the training set.
Results: In the training cohort, 4 radiomic features were selected for the prediction model, with an area under the ROC curve (AUC)=0.89, sensitivity=0.82, and specificity=0.90. The corresponding temporal validation results were 0.89, 0.67, and 0.86, respectively.
Conclusion: This study demonstrates the potential of using routine pretreatment CE-MRI to predict NPC patients' response to cisplatin-based neoadjuvant chemotherapy.
Limitations: The relatively small number of patients.

Dual-energy 4D-CT of parathyroid adenomas not clearly localised by sestamibi scintigraphy and ultrasonography: a retrospective study

M. Woisetschlager[1], O. Gimm[1], K. Johansson[2], G. Wallin[3], I. Garcia[1], A. Spångeus[1]; [1]Linköping/SE, [2]Västervik/SE, [3]Örebro/SE

Purpose: To evaluate if four-dimensional dual-energy computed tomography (4D-DECT) and quantitative information can improve the localisation of PAs and better distinguish between PAs, lymph nodes (LNs), and the thyroid gland (Thy).
Methods and materials: 15 patients (mean age: 57±18.9 years; range: 22-82 years) with persistent or recurrent primary hyperparathyroidism underwent 4D-DECT in 3 different phases: no-contrast, arterial, and venous. Quantitative data was also determined, including Hounsfield unit (HU) values, dual-energy information (electron density [Rho], atomic number [Z], and dual-energy index [DEI]), and spectral information (keV).
Results: With regards to spectral information, lower energies showed greater HU differences between the 3 tissues than higher energies. In the venous phase, there were significant differences between all 3 tissues up to 100keV ($p<0.05$). For all energies, PA was significantly lower in HU than Thy in non-contrast images and higher than LN in the arterial phase ($p<0.05$). All 3 tissues differed significantly from each other in terms of HU in the venous phase at 90kV, 150kV, and mixed 0.8 images. Thy was significantly higher than PA and LN in non-contrast images for 90kV, 150kV, mixed 0.8, and Rho ($p<0.05$). LN was significantly lower than PA and Thy in the arterial phase for 90kV, 150kV, mixed 0.8, Rho, Z, and DEI ($p<0.05$).
Conclusion: There were significant differences between PA, LN, and Thy at different energies and contrast phases, as well as in their spectral information, which might enhance diagnostic accuracy and location. Dual-energy information from real non-contrast scans might be helpful in equivocal cases.
Limitations: The small number of participants and retrospective design.
Ethics committee approval: D/N: 2017/241-31.

Computer-assisted diagnosis of hip dysplasia and femoroacetabular impingement FAI using automatic reconstruction of MRI-based 3D models of the hip joint: a deep learning-based study

T. Lerch, G. Zeng, F. Schmaranzer, N. Gerber, K. Siebenrock, M. Tannast; Berne/CH (till.lerch@insel.ch)

Purpose: Hip dysplasia and FAI are complex three-dimensional hip pathologies that can cause hip pain in young and active patients of child-bearing age. Imaging is static and based on 2D pelvic radiographs. Computer-assisted CT-based diagnosis of hip dysplasia and FAI was introduced for patient-specific planning of surgical treatment but MRI-based 3D models would offer a radiation-free alternative.
This study explores the difference between automatic and manual MRI-based 3D-models and if diagnostic parameters correlate between automatic and manual MR-based 3D-models.
Methods and materials: We performed an IRB-approved comparative, retrospective study of 31 hips of 26 symptomatic patients with FAI and hip dysplasia. We compared CT-and MR-based osseous 3D models of the hip joint of the same patients. A 3D-CT scan (isovoxel: 1 mm^3) of the entire pelvis and the distal femoral condyles were obtained. Preoperative MR arthrograms of the hip were obtained including axial-oblique T1 3D-VIBE sequence (0.8 mm^3 isovoxel) and two axial anisotropic (1.2 x1.2 x 1 mm) 3D-T1 VIBE DIXON sequences of the entire pelvis and the distal femoral condyles. Automatic reconstruction of MRI-based 3D models was performed using machine-learning (deep learning). Threshold-based manual reconstruction of CT- and MR-based 3D-models was performed using commercial software (AMIRA).
Results: The difference between MRI-based 3D-models was below 1 mm. The median difference was 0.2±0.1 mm for the proximal femur and 0.2±0.5 mm for the acetabulum. The Dice coefficient was 97% for the acetabulum and 98% for the femur. The correlation for 6 diagnostic parameters was excellent and significant ($r=0.99$, $p<0.001$) between automatic and manual MR-based 3D-models. The absolute difference was below 2°.
Conclusion: Automatic MRI-based 3D models can replace CT-based 3D-models for patients of childbearing age with hip dysplasia and FAI.
Limitations: A retrospective study.
Ethics committee approval: IRB approval was obtained.

To test the ability of artificial intelligence to differentiate between benign and malignant soft tissue masses in ultrasonography

L. Perronne[1], B. Wang[2], R. S. Adler[2]; [1]Paris/FR, [2]New York/US

Purpose: Ultrasound evaluation of superficial soft tissue masses is increasingly utilised in routine clinical practice. However, differentiating benign from malignant aetiologies may be challenging. Deep convolutional neural networks (CNNs) have shown the potential to classify images with good accuracy. We propose to test the ability of this methodology to differentiate between benign and malignant superficial soft tissue masses.
Methods and materials: A total of 760 ultrasound images from focused ultrasounds of superficial soft tissue masses were selected to train a CNN classifier. The dataset consisted of 523 images of benign soft tissue masses and 237 images of malignant masses, all confirmed by pathologic diagnosis. We selected the pre-trained VGG-16 architecture implemented on Keras. We performed a binary classification (benign and malignant). Then, we tried to differentiate between 3 subgroups of benign masses: lipomas, benign nerve sheath tumours, and vascular malformations.
Results: The test accuracy of the model to determine if the mass was benign or malignant mass was 0.75. The CNN outperformed two experienced musculoskeletal radiologists on a test sample dataset. The accuracy of the model to differentiate between the 3 benign subgroups test dataset was 0.66.
Conclusion: As an initial step, artificial intelligence (AI) shows promise in the differentiation of benign from malignant soft masses, outperforming two musculoskeletal radiologists. The addition of a larger variety and number of soft tissue masses will be necessary to establish the utility of AI as a useful tool going forward.
Limitations: The limited size of our dataset restricted the number of subgroups that could be investigated. We tested the accuracy of only two radiologists, which does not necessarily reflect the accuracy of radiologists with varying experience.
Ethics committee approval: This study has institutional board review approval.
Funding: No funding was received for this work.

Tumour margin infiltration in soft tissue sarcomas: prediction with 3T MR texture analysis

M. Kim[1], W.-H. Jee[1], Y. Lee[1], J. H. Hong[2], Y.-G. Chung[2], W.-J. Bahk[1]; [1]Gyeonggi/KR, [2]Seoul/KR

Purpose: To determine the value of MR texture analysis to assess tumour margin infiltration in soft tissue sarcomas at 3T MRI including IVIM DWI.
Methods and materials: 31 patients with pathologically confirmed soft tissue sarcomas after surgery who underwent 3T MRI including IVIM DWI were included in this study. Margin infiltration on pathology was used as a golden standard. Texture analysis was performed by drawing ROIs on axial T1- and T2-weighted images, contrast-enhanced (CE) T1-weighted images, high b value DWI, and ADC maps using software (TexRad). Mean, SD, entropy, MPP, skewness, and kurtosis were compared between sarcomas with an infiltrative margin and sarcomas with a circumscribed margin. A Mann-Whitney U test was performed. The ROC curve with AUC was obtained.
Results: Among 31 patients with sarcomas, 22 sarcomas had tumour margin infiltration at pathology. T1 kurtosis was significantly higher in sarcomas with an infiltrative margin than a circumscribed margin: 1.959 vs 0.12 ($p=0.017$). CE T1 kurtosis was significantly lower in sarcomas with an infiltrative margin than a

circumscribed margin: 0.563 vs 1.413 (p=0.020). The mean and MPP on DWI were higher in sarcomas with an infiltrative margin than a circumscribed margin: 404.4 vs 269.4 (p=0.082). AUCs of T1 kurtosis and skewness were 0.792 (95% CI, 0.628-955) and 0.601 (95% CI, 0.371-830), respectively. On DWI, AUC of mean and MPP was 0.702 (95% CI, 0.520-0.884). AUC of CE T1 mean and MPP was 0.630 (95% CI, 0.383-877). With a cutoff of 0.545 in T1 kurtosis, sensitivity and specificity for predicting tumour margin infiltration were 71% and 88%, respectively.
Conclusion: MR texture analysis may be reliable to predict the tumour margin infiltration in soft tissue sarcomas, particularly using T1 kurtosis at 3T.
Limitations: A retrospective study with potential selection bias and a small study population.
Ethics committee approval: Approved by IRB and informed consent was waived.
Funding: No funding was received for this work.

Paediatric radiographic detection of the acute distal tibial fracture using trained AI-networks
Z. A. Starosolski, J. H. Kan, A. Annapragada*; Houston, TX/US (zastaros@texaschildrens.org)*

Purpose: Tibial fracture detection is a routine task in paediatric radiology. Its precision depends on knowledge of anatomy and experience-based training. Until recently, there were no computer-aided detection tools due to anatomical complexity, a variety of 2d projections, additional objects in the image, the presentation of pathology, the age of patients, and gender.
Methods and materials: We presented a CNN-based system that can automatise radiographic distal tibia fracture detection. The system used two connected CNNs. The first CNN was trained to localise the distal tibia using 500 normal and 500 pathological studies, including displaced and nondisplaced fractures. The images were manually annotated with a box containing the distal tibia. This CNN had a 98% accuracy with zero false-positives. The second CNN was chosen from previously developed CNNs trained on a different, broader set of manually segmented distal tibia images and had undergone the 10 fold cross-validation. The best CNN, which formerly achieved an accuracy of 95.9%, was selected for validation in this study.
Results: The whole system combined two models into the pipeline. An x-ray image was read and the distal tibia localised as an ROI. The ROI was transferred to the fracture detection algorithm. If the distal tibia was not localised, then it was not processed by the second model. The whole system achieved an area under the receiver-operating curve (AUC-ROC) of 0.89.
Conclusion: This method could become a computer-aided diagnosis (CAD) tool, accelerating the workflow in paediatric radiology departments.
Limitations: This study was limited to images acquired and read at a single institution.
Ethics committee approval: This work was conducted under a protocol approved by the Institutional Review Board.
Funding: No funding was received for this work.

Quantitative ultrashort echo time MRI (UTE-MRI) for the diagnosis of early cartilage degeneration: a comparison with T2 mapping
J. Yang[1], H. Shao[1], L. Wan[2], J. Du[2], G. Tang[1]*; [1]Shanghai/CN, [2]San Diego/US (yangjiaweitj@126.com)*

Purpose: To investigate the feasibility of using a quantitative ultrashort echo time MRI (UTE-MRI) technique to diagnose early cartilage degeneration and to compare the technique's diagnostic efficacy with T2 mapping.
Methods and materials: 20 patients with a total knee arthroplasty were obtained and underwent an MR scan on a clinical 3.0T scanner. 72 regions of interest were manually drawn on specimens for UTE-adiabaticT1ρ, UTE-T2*, and T2 measurement, and the corresponding cartilage-bone regions were further divided into normal (n=11, Mankin scores 0-1), mild (n=28, Mankin scores 2-5), moderate(n=21, Mankin scores 6-9), and severe (n=12, Mankin scores 10-14) degeneration groups based on histological measures of degeneration (Mankin scores) as a reference standard. Statistical analysis was performed to compare the differences among the groups.
Results: The UTE-adiabaticT1ρ in the normal group was significantly different from the mild group moderate group and severe group. The adiabaticT1ρ, UTE-T2*, and T2 values correlated significantly with Mankin scores, with UTE-adiabaticT1ρ and UTE-T2* markedly correlated with Mankin scores, and with T2 values weakly correlated with Mankin scores. The diagnostic efficacy of UTE-adiabatic T1ρ was better than UTE T2* mapping and T2 mapping for the diagnosis of early cartilage degeneration.
Conclusion: UTE-adiabaticT1ρ may provide a more promising imaging biomarker with potential application in more comprehensive diagnoses and the monitoring of cartilage degeneration compared to UTE-T2* and T2.
Limitations: The sample size was small. The study was performed ex vivo and the measurement condition was different from the real physiological environment. Additionally, this study could not utilise quantitative biochemical measurements for PG and the collagen of cartilage.
Ethics committee approval: The study was approved by Ethics Committee at our Hospital (Ethics Committee approval number: shsy-iec-ky-3964).

Dixon or DWI: quantitative discrimination between malignant and acute osteoporotic vertebral fractures
R. Donners, M. M. Obmann, D. Boll, D. Harder*; Basel/CH (ricardo.donners@usb.ch)*

Purpose: To compare Dixon MRI derived fat-fraction (FF) and ADC to discriminate between malignant and acute osteoporotic vertebral fractures.
Methods and materials: 1.5T MRI of 42 malignant and 27 acute osteoporotic vertebral fractures were retrospectively reviewed. Fractured vertebrae showed extensive hyperintensity on fluid-sensitive fat-suppressed sequences. FF was derived from axial T1 VIBE two-point Dixon images with dedicated in and opposed echo timing by dividing the fat-only sequence through the sum of the fat-plus water-only sequence. ADC maps were calculated from axial b50 and b900 images. ROI-based measurements of mean FF and ADC were performed for each fractured vertebra in the axial plane. A blinded MSK-radiologist classified fractures as malignant or osteoporotic based only on morphologic features, also noting diagnostic confidence. Diagnostic performance was compared by ROC curve analyses and discriminating cut-off values were derived. P<0.05 was deemed significant.
Results: FF and ADC were significantly smaller in malignant fractures (p<0.01). AUC was significantly larger for FF than for ADC (p=0.03). The FF AUC (0.92), sensitivity (86%), and specificity (85%) were not significantly inferior compared to the radiologist's interpretations (0.93, 98%, and 89%; each p>0.05). ADC AUC (0.78) and sensitivity (62%) were significantly smaller compared to the radiologist (each p<0.01). Low-reader confidence was reported in 11% of fractures. In this subgroup, the specificity of FF and ADC (83% each) exceeded the radiologist's specificity (50%).
Conclusion: Quantitative FF and ADC can distinguish malignant from acute osteoporotic fractures. FF showed superior diagnostic accuracy over ADC and was non-inferior to an MSK-radiologist's evaluation.
Limitations: The study size, retrospective design, lack of histopathology, and recall bias.
Ethics committee approval: This study follows the regulations of the local ethics committee. Patient consent was waived.
Funding: No funding was received for this work.

RPS 1010a-8 11:51
Shape-based machine learning for three-dimensional phenotyping of the lumbosacral spine and dural sac: a prediction of Fibrillin-1 gene mutations pathogenic for Marfan syndrome
F. Rengier, O. Naas, T. Norajitra, C. Lückerath, M. Karck, K. Maier-Hein, H.-U. Kauczor*; Heidelberg/DE (fabian.rengier@web.de)*

Purpose: To test our hypothesis that three-dimensional phenotyping of the lumbosacral spine and dural sac using shape-based machine learning enables the prediction of Fibrillin-1 gene mutations pathogenic for Marfan syndrome.
Methods and materials: 184 patients being evaluated for Marfan syndrome, 01/2012-12/2016, underwent 1.5T-MRI with 3D T2-weighted TSE-sequence of the lumbosacral spine with 1x1x1 mm³ spatial resolution. 110 patients (32.4±11.6 years, 50 female) agreed to genetic testing; 38 had a Fibrillin-1 gene

mutation pathogenic for Marfan syndrome (FBN1+) and 72 were tested negative (FBN1-). Shape-based machine learning allowed three-dimensional segmentation and quantification of volumes and volume ratios of vertebral bodies L3-L5 and dural sac segments L3-S1.
Results: Dural sac volumes were significantly enlarged in FBN1+ vs FBN1- patients (in mL): segment L3 12.5±3.0 vs 10.3±2.3, L4 11.8±3.5 vs 9.0±2.5, L5 11.7±4.4 vs 7.9±3.1, and S1 13.5±8.7 vs 5.3±3.1 (all p<0.001). Vertebral body volumes did not significantly differ between FBN1+ vs FBN1- patients. ROC analysis for the identification of FBN1+ patients showed AUCs of 0.797 for total lumbosacral dural sac volume, 0.660 for L3 volume ratio, 0.694 for L4 volume ratio, 0.766 for L5 volume ratio, 0.786 for S1 dural sac volume, and 0.753 for S1 to L4 dural sac volume ratio. Combined sensitivity, specificity, and positive and negative predictive values for identification of FBN1+ patients were 69%, 93%, 84%, and 85%.
Conclusion: Fibrillin-1 gene mutations were associated with a significantly altered three-dimensional phenotype of the lumbosacral spine and dural sac. Shape-based machine learning allowed identification of patients with Fibrillin-1 gene mutations with a high specificity and moderate sensitivity.
Limitations: Potential sources of bias are the retrospective study design and secondary exclusion of those patients without genetic testing.
Ethics committee approval: An ethics committee approved the study and waived written informed consent.
Funding: No funding was received for this work.

Radiology improving the diagnosis and management of patients suffering with Ehlers-Danlos syndrome. An upright biomechanical MRI study
F. W. Smith; *London/UK (franciswsmith@hotmail.com)*

Purpose: The incidence of the hypermobile Ehlers-Danlos syndrome (hEDS) is larger than is generally understood, with many patients being misdiagnosed as suffering from ME or fibromyalgia. It is important to make the correct diagnosis to enable appropriate treatment.
Methods and materials: 112 consecutive patients with hEDS had MRI scans of the cervical spine and craniocervical junction performed in an upright MRI scanner, where the cervical spine angle was measured with the neck in neutral flexion and extension, and compared with an age-sex matched control group. MRI of the atlantoaxial joint was performed looking forwards, to the right, and to the left to assess for evidence of laxity of the craniocervical ligamentous complex. The cerebellar tonsillar station was also recorded.
Results: Patients with hEDS showed a decrease in their cervical spine angle in neutral 20% less than the control group (16º vs 20º), a 50% larger ability to flex the neck (-20º vs -11º), and a 45% greater angle in extension (55º vs 32º). 72% showed ligamentous laxity/instability of the cervical spine. 80% showed evidence of atlantoaxial instability.
43.5% demonstrated hindbrain herniation of greater than 5 mm, with no evidence of syringomyelia in a pattern distinctly different from the Chiari malformation.
Conclusion: It is important to be able to make accurate measurements of increased mobility and laxity of both the cervical spine and atlantoaxial joints in patients suffering from hEDS to allow for referral for the appropriate treatment, including surgery where indicated. It is also important for the reassurance of these patients, who have a physical disability, that they do have hEDS and are not psychologically disturbed or suffering from ME or fibromyalgia.

Can sacrum height predict body height, age, and sex? A large population-based MRI study
F. Yahya[1], D. Cantré[2], K. Thierfelder[1], M.-A. Weber[1], S. Langner[1];
[1]Rostock/DE, [2]Roggentin/DE (Fathi.yahya@med.uni-rostock.de)

Purpose: Post-mortem identification of unknown deceased persons and age estimation in the living are central tasks of forensic scientists. Body height is traditionally derived from measurements of long bones. The sacrum is a centrally located bone that is relatively unsusceptible to environmental factors. The aim of the study was to investigate if sacrum height can be used to estimate body height, weight, age, and sex using datasets from a population-based magnetic resonance imaging (MRI) study.
Methods and materials: A total of 2,499 whole-body MRIs were evaluated. Sacrum height was measured in the median plane of sagittal T2-weighted images of the spine and associations with age, sex, and body height were analysed. Linear regression was used to derive formulas for body height estimation.
Results: Male participants had significantly (p<0.001) greater sacrum height (11.4 cm, standard deviation 1.1 cm, range: 7.9-14.6 cm) compared to female participants (10.9 cm, standard deviation 1.0 cm, range: 7.3-14.5 cm). The Pearson-correlation was r=0.44 for body height. The mean absolute difference (MAD) between calculated and measured body height was 4.9 cm for females and 4.8 cm for males. ROC cut-off to classify sex had a 60% sensitivity and 57.3% specificity.
Conclusion: Contrary to previous reports, sacrum height alone cannot be recommended to predict body height, age, or sex. It is not as reliable as predictions based on large bones.
Limitations: A population-based MR-study from a specific region of Germany. Not all participants in the study were included in the final analysis. There was no correlation with established techniques for age, sex, and height determination based on the analysis of long bones.
Ethics committee approval: Approved by the local ethics committee and all participants gave their written informed consent.
Funding: No funding was received for this work.

The use of whole-body MRI in chronic recurrent multifocal osteomyelitis in children: our experience in 29 patients
M. Gónzalez[1], L. Rodríguez Díez[2], E. Ladera González[2], I. Barber Martinez[3], E. Iglesias[2], E. J. J. Inarejos Clemente[3]; *[1]Montevideo/UY, [2]Barcelona/ES, [3]Esplugues de Llobregat/ES*
(made.gonzalez@gmail.com)

Purpose: To describe the most common locations of involvement in chronic recurrent multifocal osteomyelitis (CRMO) in children using whole-body magnetic resonance imaging (WB-MRI).
Methods and materials: We retrospectively reviewed 29 patients (12 girls, 17 boys) with a diagnosis of CRMO from 2014-May 2019. All patients underwent WB-MRI using STIR sequences in axial and coronal planes, and sagittal planes to evaluate the spine. Imaging data was evaluated by a paediatric radiologist with more than 10 years of experience and a radiology fellow with 3 years of experience.
Results: The mean age at diagnosis was 11 years (3-16 years), but the mean age of clinical presentation was 10 years.
A total of 175 lesions were investigated. The lesions were multifocal in 28/29 cases (96.5%) and the number of lesions encountered per patient ranged from 1-28 lesions.
The most common sites of involvement were the pelvis and femur (21%), followed by tibia (19.3%), and the spine and humerus (7.4%). Other less frequent locations included clavicles (4.5%), tarsus (4%), foot (3.4%), radius and cuboid (2.8%), fibula (2.3%), and the sternum (1.7%). The involvement of the patella, ribs, carpus, and scapula was exceedingly rare, accounting for 0.6%.
The metaphysis of long bones was most frequently involved (56.4%), followed by epiphysis (13.6%). Bilateral lesions were 42.9%.
Conclusion: WB-MRI is the diagnostic modality of choice in patients with a clinical diagnosis of CRMO. Bilateral involvement of metaphysis and epiphysis of long bones, and the pelvis, are the most frequent areas of involvement.

Clinical validation of a deep learning-based bone age software: a feasibility study
W. W.-I. Lea, S.-J. Hong, H.-K. Nam, H. S. Yong, Z. Yang, J. Jeong, J. Kim; *Seoul/KR (lwooin17@gmail.com)*

Purpose: To evaluate the clinical performance of deep learning (DL)-based software for bone age assessment in a paediatric endocrinology clinic in South Korea.
Methods and materials: We compared the bone age estimated from commercial DL-based software (BoneAge, Vuno, Seoul, Korea) with the bone ages independently estimated by 3 physicians (1 musculoskeletal radiologist, 1 paediatric endocrinologist, and 1 radiology resident) using a Greulich-Pyle atlas. In total, 109 children (8 boys, 101 girls) aged between 4 and 17 years who visited the paediatric endocrinology clinic from December 2018 were enrolled. Fisher's exact test (two sides), Pearson's correlation coefficient, and root mean squared error (RMSE) were used to compare the bone ages of DL software and those of the 3 physicians. An intraclass correlation coefficient (ICC) evaluated inter-rater variation.
Results: Fisher's exact test showed significant differences between DL bone age and all 3 physicians' bone age ($p<0.025$). There were good correlations ($r=0.93$, 0.92, and 0.9, $p<0.05$), however, the RMSE values were 9.7, 13.1, and 9.9 months between the bone age of DL software and those of the musculoskeletal radiologist, paediatric endocrinologist, and radiology resident, respectively. RMSE values between the 3 physicians were 12.3, 18, and 14.8 months, with relatively good correlation with each other ($r=0.88$, 0.89, and 0.88, $p<0.05$). ICC values between the 3 physicians were 0.93, 0.84, and 0.87 each, with an overall ICC value of 0.92.
Conclusion: Bone age estimated by DL-based software showed good correlation with the bone ages estimated using a traditional Greulich-Pyle atlas by 3 physicians but showed statistically different values.
Limitations: A retrospective, single-centre study with a small number of patients

A longitudinal glioblastoma analysis of multi-parametric brain MRI using deep learning
M. Perkuhn[1], R. Shahzad[1], F. Thiele[2], P. Stavrinou[1], M. Schlamann[3], C. Kabbasch[1], J. Borggrefe[1]; *[1]Cologne/DE, [2]Aachen/DE, [3]Essen/DE (rahilshahzad@gmail.com)*

Purpose: Cytoreductive surgery, radiation, and chemotherapy are the cornerstones of glioblastoma (GB) therapy. Currently, response to therapy is assessed by MRI based on two-dimensional tumour measurements, which have inherent limitations around the tumour-cavity. Manual segmentation of the lesions is time-consuming and suffers from high inter-rater-variability. To overcome these limitations and allow for a user-independent volume assessment, this study aimed to train and evaluate a state-of-the-art deep learning model (DLM) for fully-automatic GB segmentation of contrast-enhancing tumours (CET), oedema (ED), and tumour cavities (TC) on clinical routine follow-up data.
Methods and materials: 94 subjects undergoing primary GB resection were included. T1, T2, FLAIR, and contrast-enhancing (CE) T1 sequences were obtained during the course of treatment follow-up. Ground truth segmentations for the tumour compartments were obtained by consensus reading. Data was split into a training set (80 subjects) and test set (14 subjects). A multi-parametric, multi-label DLM for GB segmentation was trained on postoperative scans of the training set. A transfer learning approach was also used by including a preoperative model trained on an additional 220 GB subjects.
Results: The DLM was tested on 85 longitudinal follow-up scans from the test set. Volume correlations (R) of DLM to manual segmentations were 0.89 (CET), 0.95 (ED), and 0.96 (TC). Automatic segmentation achieved Dice coefficients (±SD) of 0.35±0.33 (CET), 0.64±0.22 (ED), and 0.57±0.30 (TC). For CET>2 ml, the median Dice was 0.61.
Conclusion: The proposed fully-automatic approach is robust in detecting the different tumour compartments on routine follow-up data. A DLM which is sensitive to small CET's (<2 ml) is currently being developed. DLM's show a strong potential to provide automated deep-learning-based GB segmentation in longitudinal GB analysis that may facilitate RANO assessment and improve the radiologist's workflow.

MRI characterisation of peri-operative brain haemodynamic alterations after awake surgery in diffuse low-grade gliomas
A. Coget, J. Deverdun, E. Le Bars, L. van Dokkum, F. Molino, N. Menjot de Champfleur; *Montpellier/FR (arthur.coget@gmail.com)*

Purpose: No data is currently available on postoperative haemodynamic variations after neurosurgery, while these presumed variations could have imaging, clinical, and physiopathological implications. Here, we aim to characterise perioperative brain perfusion modifications after awake surgery in a cohort of patients with diffuse low-grade gliomas using MRI.
Methods and materials: 53 patients with diffuse low-grade gliomas who underwent awake surgery were included in this study. MRI acquisitions on a 3.0T magnet including perfusion-weighted imaging GE-EPI with contrast agent were performed before, within 36 h, and three months after surgery. Mean perfusion parameter values, as well as their asymmetry index, have been estimated for each hemisphere and each ROI and then compared between the three time-points. ROIs were extracted from the AAL atlas.
Results: We observed haemodynamic alterations ipsilateral to the tumour resection, marked by a stronger asymmetry index between hemispheres and on all perfusion parameters. Regional differences in the evolution of the haemodynamic variations were found, including both transient postoperative modifications (e.g. in the putamen) and persistent postoperative alterations (e.g. in the precuneus). Finally, permanent haemodynamic impairments at 3 months post-surgery existed not only in specific regions but also translated to a general ipsilateral hemispheric impairment.
Conclusion: The observed post-operative regional differences and persisting modifications of the cerebral vascular autoregulatory processes ask for caution in the analysis and interpretation of perfusion and BOLD-based imaging immediately and long-term after brain surgery.
Limitations: A main limitation concerns the impact of post-operative brainshift that could induce misalignement between AAL maps and perfusion volumes between MRI sessions.
Ethics committee approval: The study was approved by the local ethical committee. Participants gave informed consent before inclusion.

MRI evaluation of targeted adoptive immunotherapy for gliomas using biotinylated adoptive T lymphocytes

H. Zhang[1], S. Wu[2]; [1]Qingdao/CN, [2]Shanghai/CN (smwu19@fudan.edu.cn)

Purpose: To explore the biotinylation of adoptive T lymphocytes and its feasibility of targeted adoptive T cells immunotherapy (ACT) for gliomas based on biotin receptors.
Methods and materials: Adoptive CD8+ T lymphocytes were co-cultured with Sulfo-NHS-Biotin to form biotinylated adoptive T lymphocytes in vitro, and Alexa Four 647-labelled streptavidin was further co-cultured with biotinylated adoptive T lymphocytes. The proportion of glioma cells apoptosis and death were further analysed by FCM. Glioma cells recruiting biotinylated adoptive T cells were observed by CLSM and enhanced MRI to observe the size changes of in situ gliomas at different time points after targeted ACT. Using transferase-mediated deoxyuridine triphosphate-biotin nick end labelling (TUNEL), apoptosis was detected in tumour tissues and the proportion of glioma recruiting biotinylated adoptive T lymphocytes was analysed by FCM.
Results: FCM showed that the overall biotinylation efficiency of adoptive T lymphocytes reached 96.3%. The apoptosis proportion of glioma cells induced by biotinylated adoptive T lymphocytes (34.14%) was significantly increased. FCM showed that the proportion of biotinylated CD8+ T lymphocytes in the targeted glioma area was 4.77% and the total proportion of CD8+ T lymphocytes (8.89%) was more obvious than the control group (1.81%). Enhanced MRI found that only 20% of the individuals in the targeting group had a reduced tumour volume, but the mean value was not significantly different from the control group ($p>0.05$). In addition, the TUNEL apoptosis assay found that level of tumour cell apoptosis in the targeting group was only slightly better than the non-targeting group.
Conclusion: Biotinylation of adoptive T lymphocytes increases the proportion of gliomas recruited, enhancing the killing of glioma cells.

An unsupervised learning method for IDH mutation prediction in glioblastomas based on cumulative probability distribution curves in vascular habitats

H. Wu[1], W. Jiang[2], X. Zhou[3], W. Zhang[1]; [1]Chongqing/CN, [2]Hangzhou/CN, [3]Shanghai/CN (cefradine1005@gmail.com)

Purpose: To evaluate the clinical practice for an unsupervised learning method in IDH genotype prediction in malignant glioblastomas (GBM).
Methods and materials: Preoperative MRI examinations of 25 GBM patients with known IDH genotype were recruited into this study. Perfusion parameters were used to automatically draw the reproducible habitats related to vascular heterogeneity (i.e. high-angiogenic enhancing tumour habitats (HAT) and low-angiogenic enhancing tumour habitats (LAT)). We extracted the voxel matrix of each habitat to build cumulative probability distribution functions (CDF) and obtain the cohort-specific CDF via the function coefficient average. The Fréchet distance between the individual CDF and cohort-specific CDF and for the LOOCV was evaluated. In addition, the rCBV values at 25%, 50%, and 75% of peak height were used for the ROC analysis and KM survival analysis.
Results: Our model achieved 84% accuracy for IDH prediction in the training cohort and 80.0% in the validation cohort at the HAT habitat, in addition to 84% in the training cohort the validation cohort at the LAT habitat. Significant results were obtained for $rCBV_{C25}$ and $rCBV_{C50}$ in the HAT habitat (hazard ratios(HR), 3.29 [p=0.02] and 3.86 [p<0.00], respectively).
Conclusion: Our classifiers can provide natural boundaries for efficient discrimination of the IDH-wildtype and mutation cohort and is concise and robust in inter-institutional comparison for natural features and cohort-specific classifier.
Limitations: One primary limitation is the small sample size (n=25) in the analyses due to the single-institution, retrospectively collected data.
Ethics committee approval: This study was approved by the institutional review board of the Army Medical University and was conducted in accordance with Health Insurance Portability and Accountability Act regulations.
Funding: Natural Science Foundation of China (81571660 and 81871421).

RPS 1011a-5 11:49

A non-invasive in-vivo evaluation of IDH mutation status using 3T MR edited spectroscopy in brain glioma patients

D. Juskanic[1], J. Polakova Mistinova[2], M. Marjanska[3], S. Holly[1], L. Patrovic[1], M. Halaj[1], M. Sekeresova[1], K. Kolejak[1], M. Kavec[2]; [1]Nitra/SK, [2]Bratislava/SK, [3]Minneapolis/US

Purpose: The presence of isocitrate dehydrogenase (IDH) mutation is a major diagnostic and prognostic marker in gliomas. The proteomic footprint of IDH mutation is the intracellular presence of oncometabolite 2-hydroxy-glutarate (2HG), which is detectable by MR spectroscopy (MRS). The primary aim of the study was to evaluate the diagnostic performance of in-vivo MRS to determine IDH status. Spectral quality subanalysis was also performed.
Methods and materials: 39 spectra were acquired and reported prospectively in 36 consecutive patients with MR imaging appearance of CNS glioma from February 2018-June 2019 at a tertiary referral hospital with a neurosurgery department. Single voxel MRS data was acquired at a 3T system (Magnetom Skyra, Siemens) with a Mescher–Garwood point-resolved spectroscopy (MEGA-PRESS) sequence. Standard voxel size was 8 ml; adjustment to the tumour volume was an option. Postprocessing and an evaluation of the spectra were performed with LCModel. Positive finding was defined as detectability of 2HG peak with a CRLB value less than 60%. Immunohistochemistry or genetic test results were available to compare to the 18 spectra.
Results: Single voxel MEGA-PRESS MR spectroscopy provided 80% sensitivity (CI 95%, 0.44-0.96) and 75% specificity (CI 95%, 0.36-0.95) in the detection of 2HG. Spectral quality subanalysis revealed that the greatest limitation of the method is lower SNR, which resulted in an intermediate quality of 44% and a non-diagnostic test in 13% of all acquired spectra.
Conclusion: 2HG MR spectroscopy has a competing diagnostic accuracy considering its non-invasive, non-contrast, and radiation-free nature. It may be an integral part of advanced MR tumour protocol, aiding prognostic assessment and multidisciplinary treatment planning for glioma patients.
Limitations: SNR decreases after spectral subtraction, especially in smaller and subcortically located tumours.
Ethics committee approval: Ethics commitee approval. Written informed consent.

Topographical mapping of 436 newly diagnosed IDH wildtype glioblastomas with versus without MGMT promoter methylation

F. Incekara, S. R. van der Voort, S. Klein, M. J. van Den Bent, M. Smits; Rotterdam/NL

Purpose: O^6-methylguanine-methyltransferase (MGMT) promoter methylation status is an important prognostic factor for patients with glioblastomas (GBM). There are conflicting reports about the topographical distribution of GBM with versus without MGMT promotor methylation, possibly caused by molecular heterogeneity in GBM populations. We initiated this study to re-evaluate the topographical distribution of GBM with versus without MGMT promoter methylation.
Methods and materials: Preoperative T2-weighted/FLAIR and post-contrast T1-weighted MRI scans of patients aged 18 years or older with IDH wildtype GBM were collected. Tumours were semi-automatically segmented and the topographical distribution between GBM with versus without MGMT promoter methylation presented using frequency heatmaps. Voxel-wise differences were analysed using permutation testing with threshold-free cluster enhancement.
Results: 436 IDH wildtype GBM patients were included, 211 with and 225 without MGMT promoter methylation. Visual examination suggested that when compared with MGMT unmethylated GBM, MGMT methylated GBM were more frequently located near the bifrontal and left occipital periventricular area and less frequently near the right occipital periventricular area. Statistical analyses, however, showed no significant difference in topographical distribution between MGMT methylated versus MGMT unmethylated GBM.
Conclusion: This study re-evaluated the topographical distribution of MGMT promoter methylation in 436 newly diagnosed IDH wildtype GBM, which is the largest homogenous IDH wildtype GBM population to date, in light of the updated WHO 2016 classification. There was no statistically significant difference in anatomical localisation between MGMT methylated versus unmethylated IDH wildtype GBM.

Limitations: The retrospective design, potential selection and confounding biases.
Ethics committee approval: The study design was approved by the Medical Ethical Committee of Erasmus MC and HMC. (IRB: no informed consent needed due to retrospective nature of study).
Funding: The Dutch Cancer Society (KWF project number EMCR 2015-7859).

Discriminative validity of DSC perfusion MRI and DWI for IDH mutation status
E. Cindil, N. Erdoğan, N. Dağ, M. N. Cerit, H. N. N. Şendur, A. Y. Öner, E. T. Tali*; Ankara/TR*

Purpose: Isocitrate dehydrogenase (IDH) mutation has a predictive prognostic value in high grade gliomas (HGG). The aim of this study was to investigate if dynamic susceptibility contrast perfusion (DSC) MRI is able to differentiate IDH mutationstatus in HGGs.
Methods and materials: 60 patients with HGG (21 glioblastomas, 17 anaplasticastrositomas; 14 IDH-mutant, 24 IDH-wild) who underwent 3T conventional MRI and DSC-MRI prior to a biopsy or surgery were included retrospectively. Perfusion (rCBV, PSR) and diffusion metrics (mean ADC, minimum ADC) in the tumour core and peritumoral non-enhancing area were measured. A Mann Whitney U test was used to detect statistically significant differences in metrics between IDH-mutant and IDH-wild type tumours. P>0.05 was considered significant.
Results: rCBV in the tumour core was the only parameter which showed statistically significant differences between IDH-mutant (meanrCBV=3.14) and IDH-wild tumour types (meanrCBV=5.29, p<0.001). The AUC value of rCBV was 0.86 with a sensitivity of 0.83 and a specificity of 0.79 at the best cut-off point of 3.26. There were no significant differences for other metrics for both the tumour core and peritumoural area between IDH-mutant and IDH-wild tumours.
Conclusion: rCBV's measurement of the tumour core may help to differentiate IDH mutation status in HGGs but it is not possible to differentiate by using other DSC perfusion metrics and DWI metrics of the tumour core and peritumoural non-enhancing area.
Limitations: The inadequate number of cases.
Ethics committee approval: The local institutional review board approved this retrospective study.
Funding: No funding was received for this work.

Whole-brain apparent diffusion coefficient measurements correlate with survival in glioblastoma patients
A. Rulseh, J. Vymazal*; Prague/CZ (aarulseh@gmail.com)*

Purpose: Glioblastomas (GBM) are the most common malignant primary brain tumour and methods to improve early detection and evaluate the treatment response are highly desirable. We explored changes in whole-brain apparent diffusion coefficient (ADC) values with respect to survival (progression-free [PFS], overall [OS]) in a cohort of GBM patients followed at regular intervals until disease progression.
Methods and materials: A total of 43 subjects met the inclusion criteria and were analysed retrospectively. Histogram data was extracted from whole-brain ADC maps including skewness, kurtosis, entropy, median, mode, and 15th percentile (p15) and 85th percentile (p85) values, and linear regression slopes (versus time) were fitted. Regression slope directionality (positive/negative) was subjected to univariate Cox regression. The final model was determined by a LASSO on metrics above the threshold.
Results: Skewness, kurtosis, median, p15, and p85 were all below the threshold for both PFS and OS and were analysed further. The median regression slope directionality best modelled PFS (p=0.001; HR 3.3; 95% CI 1.6-6.7), while p85 was selected for OS (p=0.002; HR 0.29; 95% CI 0.13-0.64).
Conclusion: Our data showed tantalising potential in the use of whole-brain ADC measurements in following GBM patients, specifically serial median ADC values which correlated with PFS, and p85 values which correlated with OS. Whole-brain ADC measurements are fast and easy to perform and free of ROI-placement bias.
Limitations: Due to the retrospective design, detailed clinical information was not available and the assessment of potential prognostic benefit at individual time points was not possible.
Ethics committee approval: The study was approved by the institutional review boards or ethics committees of all participating centres, and all patients provided written informed consent.
Funding: Supported by MH CZ-DRO (NHH, 00023884). IG174301 and AZV MZ CR NV18-04-00457.

Correlation of dynamic contrast-enhanced perfusion MRI with glioblastoma wild-type and brain metastases
P. M. M. Latorre Brajovic[1], L. Hernandez Martinez[2], C. Casado Pérez[2], J. Alonso Sánchez[2], A. Hilario Barrio[2], L. Koren Fernandez[2], P. Martin[2], A. C. Martinez de Aragon[2], A. Ramos Gonzalez[2]*; [1]Santiago/CL, [2]Madrid/ES, (pmlatorre@gmail.com)*

Purpose: Glioblastomas and metastatic brain tumours are the most common malignant brain tumours. It is often difficult to differentiate between these two neoplasms on conventional MR imaging. Our goal is to evaluate the role of the T1-weighted dynamic contrast-enhanced (DCE) MRI perfusion technique to differentiate between glioblastomas and metastatic lesions.
Methods and materials: DCE-MRI was retrospectively analysed in 19 patients with unique metastatic brain lesions and 22 patients with glioblastoma wild-type prior to any therapeutic intervention. DCE perfusion parameters calculated for the region of maximal tumoural enhancement were volume transfer constant (K^{trans}), efflux rate constant (K^{ep}), fractional volume of extravascular extracellular space (V_e), initial area under the gadolinium contrast agent concentration-time curve (IAUGC), contrast enhancement ratio (CER), and maximum slope of increase (Max Slope). Mann-Whitney U-tests were applied to these parameters.
Results: CER was significantly higher in metastasis (0.94) than in glioblastoma (0.67) (P=0.032). V_e was marginally higher in metastasis (0.37) than in glioblastoma (0.25) (P=0.055). The remaining perfusion parameters did not show statistically significant differences.
Conclusion: DCE-MRI showed that it has a limited potential to differentiate glioblastoma wild-type and metastases brain tumours. V_e and CER were the best parameters to discriminate between glioblastomas and metastases.
Limitations: It is a retrospective study with a small series of cases.

The predictive power of MRI in identifying the pathological grading of meningiomas
F. Ballati[1], P. Lomoro[1], S. Sacco[1], C. Paganelli[2], G. Buizza[2], L. M. Farina[1], A. M. Bacila Turcanu[1], A. Iannalfi[1], L. Preda[1]*; [1]Pavia/IT, [2]Milan/IT (france.balla@hotmail.it)*

Purpose: To assess whether magnetic resonance imaging (MRI) can predict the histological WHO grading of meningiomas and if it is able to differentiate WHOI from WHOII and WHOIII.
Methods and materials: 76 patients with 77 histologically proven meningiomas were enrolled (43 WHOI, 27 WHOII, and 7 WHOIII). Data was derived from multiparametric MRI sequences: pre- and post-contrast T1, T2, FLAIR, and diffusion (DWI). T1 post-contrast was used to obtain lesion volume, which was rigidly registered on the ADC map obtained from DWI in order to derive multi-parametric imaging features based on conventional ADC and an intra-voxel-incoherent-motion (IVIM) model (i.e. ADC, D, D*, and f) within the whole tumour volume. Qualitative features from morphological images were also evaluated: tumour localisation, T1- and T2- signal intensity relative to grey matter, shape, tumour-brain interface, peritumoural oedema, capsular enhancement, and tumour enhancement (homogeneous vs inhomogeneous).

Results: Regarding DWI parameters, median values of ADC, D, and D* were higher for WHOI than WHOII and WHOIII meningiomas (p<0.05) in univariate analysis. Statistically significant differences (p<0.05) were also found in univariate analysis among qualitative features such as tumour localisation, T1- and T2- signal intensity relative to grey matter, tumour shape, peritumoural oedema, capsular enhancement, and tumour enhancement. Combining DWI and qualitative parameters, the median ADC and tumour enhancement resulted statistically different in multivariate analysis between the two groups (p<0.05), with an AUC of 0.98, a specificity of 0.93, and sensitivity of 0.97.
Conclusion: Both DWI and qualitative features could be potential predictors of meningiomas histological grade. Lower ADC and inhomogeneous tumour enhancement suggest a high-grade meningioma. In future, these features may be useful to characterise lesions with no histological diagnosis and for the application in tailored therapy treatments.

T1-weighted dynamic contrast-enhanced MRI perfusion of chordoma: a biomarker and innovative follow-up imaging tool for assessing tumour response after proton therapy
A. Rajendran, N. Chidambaranathan, F. Abubacker Sulaiman*; Chennai/IN (adhithyan40@gmail.com)*

Purpose: We hypothesised that T1-weighted dynamic contrast-enhanced (DCE) MR imaging parameters and time-intensity curves can be used to characterise tumour response to proton therapy, detecting subsequent changes in chordoma vasculature, which may later predict parallel changes in tumour volume as detected by conventional MR imaging.
Methods and materials: We retrospectively analysed MRIs from patients with a pathology-proved chordoma of the sacrum, spine, or clivus. 15 patients with DCE-MR perfusion imaging (3T philips Ignenia Elition) before and after proton-therapy were enrolled. DCE-MR imaging was acquired on completion of routine MR imaging. Kinetic enhancement of tissues before and after contrast injection was obtained by using a 3D T1-weighted fast-spoiled gradient-echo sequence.
ROIs were drawn to encompass the entirety of the chordoma by 2 attending neuroradiologists. The area under the curve (AUC), wash-in and wash-out rates, and relative enhancement were the parameters analysed.
Dynamic concentration-time curves illustrate changes in MR imaging signal intensity as a function of time. Two curves for before and after RT were obtained for each patient.
Results: Chordoma lesions did not exhibit significant changes in tumour volume in response to therapy and limited the utility of conventional MR imaging in evaluating treatment efficacy and subsequent patient prognosis.
However, quantitative DCE parameters such as AUC and wash-in significantly decreased post-treatment. This change reflected the extent of vascular damage induced by proton therapy.
Characteristic dynamic MR signal intensity–time curves shifted to the left side post proton therapy and served as a biomarker in our study.
Conclusion: DCE-MR imaging presents a novel alternative to conventional MR imaging for tumour monitoring in patients with chordoma, providing insight into the physiologic and haemodynamic processes within a particular lesion.
Limitations: A retrospective study.

Automated MR phenotyping improves the prediction of survival in primary invasive breast cancer
M. Dietzel[1], R. Schulz-Wendtland[1], P. Clauser[2], M. Hammon[1], S. Ellmann[1], E. Wenkel[1], R. Zoubi[3], M. Uder[1], P. A. T. Baltzer[2]; *[1]Erlangen/DE, [2]Vienna/AT, [3]Ibbenbüren/DE*

Purpose: To investigate whether automated MRI-phenotyping improves the prediction of survival in PBC.
Methods and materials: Within this retrospective study, 314 consecutive patients with PBC received standard clinical-staging MRI examinations before the initiation of treatment.
Diagnostic work-up, treatment, and follow-up were done at 1 tertiary-care, academic breast-centre (disease-specific-survival/DSS=279; death from breast-cancer=35). The Nottingham prognostic index (NPI) was used as the reference method with which to predict the survival of breast cancer.
Automated MRI analysis was accomplished by commercially available, FDA-cleared software. Based on this analysis, MRI-phenotypes that provided a specificity >99% for DSS were identified by machine-learning algorithms (classification-and-regression trees). Results were 10-fold cross-validated.
The prediction of survival based on MRI-phenotypes, according to the NPI, and MRI-phenotypes plus the NPI in combination were investigated (Cox-regression and Kaplan-Meier statistics).
Results: Predictive accuracies for NPI and MRI-phenotypes alone were similar (P=0.5). MRI-phenotypes showed a high prevalence of 42.7% (134/314), practically ruling out the occurrence of death in these patients. 21.6% of these patients (29/134) would have been falsely predicted by NPI as at-risk for disease-specific death. Inclusion of MRI-phenotypes into the NPI significantly improved its prediction of survival by 31.5% (29/92), giving a hazard ratio (HR) of 8.5 compared to the standard NPI (HR_{NPI}=5.4; P=0.03). The potential improvement of survival prediction by MR-phenotypes was verified for molecular subtypes.
Conclusion: Automated MRI-phenotyping improved the prediction of survival in PBC. MRI-phenotyping based on standard breast MRI examinations might support the indication for more complex diagnostic procedures (genetic profiling, etc.). They could support the decision as to whether a more aggressive cytotoxic therapy is warranted or not.
Limitations: Multicentric validation of our initial results with a special focus on potential oncological implementation is pending.

The assessment of uterine cervical cancer with intravoxel incoherent motion imaging (IVIM) and diffusion kurtosis imaging (DKI) at 3T

Y. Qi, Y. He, C. Lin, H. Zhou, X. Wang, H. Xue, Z. Jin*; Beijing/CN*

Purpose: To explore the application of intravoxel incoherent motion imaging (IVIM) and diffusion kurtosis imaging (DKI) in the diagnosis of cervical cancer and to analyse the correlations between IVIM-DKI with the pathology result.
Methods and materials: 64 patients with cervical cancer and 25 patients with normal uterine cervixes were enrolled. The pathological type and differentiation degree of cervical cancer were collected. The patients underwent female pelvis MR on a 3T MR scanner for diffusion imaging with b-values at 0, 10, 50, 100, 200, 800, 1,200, and 2,000 s/mm^2. IVIM results (D-IVIM, D*, and f) and DKI results (D-kurtosis and K) were derived from images with b=0~800 s/mm^2 and 0, 800~2,000s/mm^2 respectively. ROC analysis was used to identify cervical cancer. Spearman's non-parametric correlation was used to analyse the correlation between the pathological data and image results. ICC was calculated to assess the inter-class repeatability.
Results: D-IVIM were significantly lower in the cervical cancer group (0.92±0.20) than in the normal group (1.37±0.25) (p=0.000), with a sensitivity of 88.2% and specificity of 92.2% at 1.145. D-kurtosis were significantly lower in the cervical cancer group (1.19±0.24) than in the normal group (1.82±0.27) (p=0.000), with a sensitivity of 95.2% and 92.2% at 1.47. F values were lower in the cancer group (0.11±0.05) than in the normal group (0.20±0.09) (p=0.000). K-values were higher in the cancer group (1.05±0.24) than in the normal group (0.89±0.18)(p=0.003). The lower tumour differentiation degree, the lower D-kurtosis, and the higher K value (r=0.33, 0.47, all p<0.05). ICC ranged from 0.897-0.991.
Conclusion: IVIM and DKI have been applied for cervical cancer diagnosis, showing good diagnostic efficacy. IVIM-DKI results correlated with the tumour differentiation degree.
Limitations: Some patients did not undergo surgery and only biopsy pathology was available.
Ethics committee approval: This study was approved by ethics committee and written informed consent was obtained.
Funding: No funding was received for this work.

The effects of 8th edition TNM AJCC staging in breast cancers detected with a screening programme

A. Pittaro[1], G. Gennaro[1], V. Pasqualino[1], G. Romanucci[2], S. A. Montemezzi[3], F. Caumo[1]; *[1]Padua/IT, [2]Verona, loc. Marzana/IT, [3]Verona/IT*
(pittaroalice@gmail.com)

Purpose: In 2017, the American Joint Committee on Cancer (AJCC) updated the Cancer Staging Manual to the 8th edition, including a definition of a prognostic staging that incorporates TNM classification and tumour biomarkers. The purpose of this study is to compare the staging of screen-detected breast cancers using the 7th and 8th AJCC Cancer Staging Manual editions.
Methods and materials: The characteristics of 423 breast cancers detected in a screening programme from 2013-2016 were retrospectively reviewed. For each cancer, the anatomical stage based on the 7th TNM edition and the prognostic stage based on the 8th edition were calculated and differences analysed.
Results: The median age at diagnosis was 61 years (range 50-75 years). The anatomical stage was 0 in 13.9% of cases, IA in 63.1%, IB in 6.1%, IIA in 9.9%, IIB in 5.2%, IIIA in 0.7%, and IV in 0.9%, respectively. The application of TNM 8th edition changed the stage group in 18.2% of women with an upstage in 4.8% and a downstage in 13.2%. Among the upstaged group, 23.8% of cancers were luminal-A, 23.8% luminal-B, and 52.4% triple-negative. 4.8% were grade 1, 38.1% grade 2, and 57.1% grade 3. Among the downstaged group, 76.8% of women were luminal-A and 23.2% luminal-B. 23.2% were grade 1, 69.6% grade 2, and 7.1% grade 3. Major staging changes were observed in stage IA (3.3%), IIA (8.7%), and IIB (3.3%).
Conclusion: The adjunct of biomarkers to anatomical characteristics (TNM) can change the staging of breast cancers found in a screening programme, resulting most often in a downstage. The application of prognostic staging is important to better define the prognosis and the therapeutic approach, which should be oriented by cancer subtypes.
Limitations: The cancers that were screen-detected rarely include advanced stages.

The impact of ^{18}F-FDG PET/MR on therapeutic management in breast cancer patients: a prospective evaluation of staging algorithms

J. Kirchner[1], O. Martin[1], L. Umutlu[2], K. Herrmann[2], L. M. Sawicki[1], G. Antoch[1], C. Buchbender[1]; *[1]Düsseldorf/DE, [2]Essen/DE*
(Julian.Kirchner@med.uni-duesseldorf.de)

Purpose: To investigate whether the potential differences in staging between a traditional staging imaging algorithm and ^{18}F-FDG PET/MR leads to a change in patient management in breast carcinoma and to compare the diagnostic accuracy between the traditional staging algorithm and ^{18}F-FDG PET/MR for the TNM classification.
Methods and materials: In this prospective, multicentre cohort study, 56 women with newly diagnosed, therapy-naive breast cancer were included. All patients were examined by a traditional staging imaging algorithm and whole-body ^{18}F-FDG PET/MR including dedicated ^{18}F-FDG PET/MR breast examinations. Each patient was discussed twice in a separate tumour board session to determine a total of 3 therapy recommendations based on a traditional algorithm only, a traditional algorithm and ^{18}F-FDG PET/MR as well as histopathology, and ^{18}F-FDG PET/MR alone. The major changes in therapy recommendations and the differences between the traditional staging algorithm and ^{18}F-FDG PET/MR for the TNM classification were evaluated.
Results: Differences with major changes in therapy recommendations among the 3 tumour boards were seen in 23% patients, whereas in 14%, the recommendation based on the ^{18}F-FDG PET/MR was consistent with the recommendations from the tumour board with all available information. Therapy changes included therapy of the breast (3.5%), locoregional nodes (12.5%), and systemic therapy (9.0%).
Conclusion: Current guidelines should consider systemic staging with ^{18}F-FDG-PET/MRI as optional in breast cancer patients with an elevated pre-test probability for distant metastases at the time of initial diagnosis. Further scientific assessment of ^{18}F-FDG-PET/MR in this setting is necessary.
Limitations: Patient survival has not been assessed.
Ethics committee approval: The ethics committee of the Medical Faculties of the Universities of Duisburg-Essen and Düsseldorf approved the study.
Funding: Deutsche Forschungsgemeinschaft (DFG), the German Research Foundation (BU3075/2-1).

Pretreatment identification of non-responders to neoadjuvant chemotherapy in breast cancer patients

L. Vanovcanova, I. Waczulikova, B. Vertakova-Krakovska, V. Lehotska*; Bratislava/SK (lucia.vanovcanova@ousa.sk)*

Purpose: To estimate the diagnostic performance of multiparametric breast MRI in the pretreatment identification of non-responders to neoadjuvant chemotherapy (NAC).
Methods and materials: 85 patients (median 44y) with locally advanced invasive breast carcinoma were enrolled in this retrospective study. All underwent a core-cut biopsy with histopathological analysis of ER, HER2, and Ki67. Baseline breast MRI was performed before NAC with an evaluation of T2, ADC coefficient, enhancement pattern, and necrosis. Based on these parameters, patients were designated as responders or non-responders. Levels of response to NAC were based on postoperative histology results: pathological complete response (pCR) as responding, pathological residual disease (pRD) as non-responding. An MRI-based predictive model supplemented by selected histopathological characteristics of breast carcinoma was constructed using logistic regression analysis. Agreement analysis and diagnostic performance measures (Cohen's kappa, sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV)) were calculated. The AUC curve served as an overall measure of discriminative performance.

Results: Non-responders on initial MRI were non.significantly associated with 1.2 times higher odds for having pRD after NAC in comparison with responders. None of individual MRI features were significantly associated with pRD. Combining an MRI response prediction with histopathological characteristics significantly improved the model performance (for cut-off probability=0.5, sensitivity 89.1%, specificity 36.7%, correct classifications 70.6%, and AUC=72.4% (model deviance Chi-square test: p=0.044; ER+: OR=3.15, 95% CI 1.09-9.15, p=0.035), HER 2 (HER2+: OR=3.15, 95% CI 1.02–9.69, p=0.046), ki67 (ki67>30%: OR=2.26, p=0.125)).
Conclusion: Pretreatment identification of non-responders to NAC is crucial for the further complex management of patients with breast cancer. Multiparametric MRI supported by histopathological parameters of tumours is sufficiently predictive of non-responders to NAC.

Relaxation-compensated CEST (chemical exchange saturation transfer) MRI at 7T aids breast cancer diagnostics

D. Paech, L. Loi, F. Zimmermann, P. Bachert, M. Ladd, S. Bickelhaupt, S. Goerke, S. Schott, H.-P. Schlemmer*; Heidelberg/DE (d.paech@dkfz.de)*

Purpose: To investigate fat-corrected, relaxation-compensated amide proton transfer (APT) CEST MRI at 7 Tesla (7T) in patients with newly-diagnosed breast cancer.
Methods and materials: 10 patients with newly-diagnosed breast cancer and 7 healthy volunteers were included. APT CEST MRI was performed on a 7T whole-body scanner. APT signal intensities were quantified using a multi-Lorentzian fit analysis in the tumour area and in healthy fibroglandular breast tissue after correction of B_0/B_1-field inhomogeneities, fat signal contribution, and T_1- and T_2 -relaxation. Signal intensity differences between normal-appearing and tumour breast tissue were compared using the Mann–Whitney U test. Furthermore, Pearson's correlation analysis between tumour APT signal intensities and the Ki-67 proliferation index was performed.
Results: APT signals in breast cancer tissue (6.70±1.38%Hz) were significantly increased compared to normal-appearing fibroglandular breast tissue (p=0.001). Between patients with normal-appearing breast tissue (3.56±0.54%Hz) and the fibroglandular breast tissue of healthy volunteers (3.70±0.68%Hz), no differences were observed (p=0.88). A moderate positive correlation was found between the APT signal and the proliferation index Ki-67 (r=0.61, p<0.01).
Conclusion: Relaxation-compensated APT CEST MRI at 7T allowed a non-invasive differentiation of breast cancer lesions and normal-appearing breast tissue by quantifying increased protein-specific signal intensities in malignant tumours. Thus, APT CEST MRI represents a contrast agent-free method that may help to increase diagnostic accuracy in MR mammography.
Limitations: The relatively small sample size (n = 17) prevents generalisation of the results. However, statistically meaningful results were obtained. 7T MRI devices are not widely available, which limits an immediate clinical translation of the presented approach.
Ethics committee approval: This prospective, monocentric study was approved by the local ethics committee. Written informed consent was obtained.
Funding: No funding was received for this work.

The predictive role of body composition parameters (BCP) assessed by computed tomography in operable breast cancer treated with neoadjuvant chemotherapy: a retrospective observational cohort study

S. Draisci, A. Pecchi, R. Bonacini, C. Omarini, P. Torricelli*; Modena/IT (stefanodraisci@gmail.com)*

Purpose: To establish the prognostic value of clinical and radiological body compositions parameters (BCP) on the tumour response to neoadjuvant chemotherapy (NC) in patients with operable breast cancer (BC).
Methods and materials: From 2005-2017, we retrospectively evaluated patients who underwent a CT examination before treatment and whose weight, height, age, and menopausal status information were available. BMI, liver-to-spleen ratio, subcutaneous fat area (SFA, cm^2), visceral fat area (VFA, cm^2) at L4 level, and skeletal muscle index (LSMI, cm^2/m^2) at L3 level were carried out combining clinical and radiologic findings. Tumour characteristics (stage, grade, and subtypes) were collected. This data was related to pathological complete response (pCR), overall survival (OS), and relapse free survival (RFS) by calculating odds and hazard ratios and their 95% confidence intervals through univariate logistic regression and univariate and multivariate Cox models, considering BMI subgroups, BCPs, and pCR.
Results: 407 patients were included, 55% with BMI <25 and 45% with BMI >25. 137 patients underwent CT examination. Hormonal receptor-positive BC was more frequent in overweight patients (p<0.05). Post-menopausal women had higher VFA, fatty liver disease, and obesity compared to premenopausal patients. High VFA and liver steatosis were negative predictive factors for pCR (pCR rate: 36% normal VFA vs 20% high VFA, p=0.048; no steatosis 32% vs steatosis 13%, p=0.056). No association between BMI classes and tumour response was detected. Neither BMI classes nor BCPs significantly influenced OS and RFS.
Conclusion: Visceral adiposity and hepatosteatosis were involved in chemosensitivity in BC patients treated with NC, and both can be reliably assessed by native CT scans.

Whole-body diffusion-weighted magnetic resonance imaging (WB-DWIBS/MRI) in peritoneal carcinomatosis from ovarian cancer: a diagnostic performance

F. J. Garcia Prado, E. Utrera, L. Reguera Berenguer, R. Saiz Martinez, E. Martin Illana, J. Blazquez Sanchez, T. Castellanos, R. Marquez, E. Grande Pulido*; Madrid/ES (javiergarciaprado@yahoo.es)*

Purpose: To assess the diagnostic performance (DP) and tumour burden correlation of whole-body DWI with background suppression MRI (WB-DWIBS/MRI) in peritoneal carcinomatosis (PC) of suspected OC using the peritoneal cancer index (PCI) referring to cytoreduction surgery.
Methods and materials: 39/217 patients with disseminated OC underwent cytoreduction and WB-DWIBS/MRI. The PCI scored tumour burden (0-3) in 13 anatomical regions (global range of 0-39). Two radiologists (Rad1/Rad2) assessed the PCI preoperatively and with surgical findings.
We evaluated regional and global DP, the interobserver agreement, statistical differences (McNemar test), and correlation (Pearson's test).
Results: Global evaluation: The overall positive scoring (PCI>0) for Rad1, Rad2, and surgery were 34.52%, 27.22%, and 31.76%, with a global average PCI 7.82, 8, and 8.44, respectively. The tumour burden correlation with surgery was 0.762 (p<0.001) for Rad1 and 0.642 (p<0.001) for Rad2. The sensibility, specificity, and accuracy were 0.84, 0.88, and 0.87. The global Kappa was 0.53. Regional evaluation: Kappa was moderate to substantial in 6/13 regions. The pelvis followed by the central region presented the highest number of positives and sensitivity. The bowel loops showed the lowest detection rate. Accuracy was over 0.86 in all regions for Rad1.
Conclusion: WB-DWIBS/MRI is a reliable imaging technique that is useful in preoperatively quantifying and depicting PC in OC to achieve complete cytoreductive surgery.
Limitations: A single institutional study. Occult selection bias as patients selected were also candidates for cytoreduction. Areas that may contraindicate resectability might be underevaluated. More than half were postoperative patients. DP may be affected. No direct comparison with other imaging techniques such as CT or PET/CT.

Ethics committee approval: Institutional review board approval and all patients signed written informed consent.
Funding: No funding was received for this work.

Using IVIM and DCE-MRI to monitor the focal perfusion status of uterine fibroids after high-intensity focused ultrasound
X. Lu, Y. Ban, H. Du, X. Wang, X. Ding*; Urumqi/CN (305844324@qq.com)*

Purpose: To assess the value of IVIM and DCE-MRI in monitoring microcirculation information after HIFU ablation of uterine fibroids.
Methods and materials: All 58 patients underwent IVIM and DCE-MRI scans before and 48h after therapy, and 27 patients underwent a third scan 3-6M after therapy. The apparent diffusion coefficient (ADC), diffusion coefficient (D), pseudo diffusion coefficient (D*), perfusion fraction (f), maximum slope of increase (MSI), and signal enhancement ratio (SER) of the uterine fibroid were compared.
Results: Compared to pretreatment, the f and MSI values of 48h after therapy were significantly higher, while the D* and SER values were lower. Compared to pretreatment, the f, D*, and MSI values of 3-6 months after therapy were significantly lower, while the SER values were higher. Compared to 48h after therapy, the f and MSI values of 3-6 months after therapy were significantly higher, while the D* and SER values were lower. When referred to the Pearson correlation result, SER was negatively correlated with f and positively correlated with D*.
Conclusion: Along with the MSI and SER values, the D* and f values of IVIM can also monitor microcirculation perfusion changes of uterine fibroids after HIFU. As IVIM-DWI is non-invasive and contrast agent-free, it may be an alternate choice in the evaluation of HIFU ablation.
Limitations: A larger patient population is needed for further validation. Its application in other types of tumours should be further evaluated.
Ethics committee approval: All procedures performed in studies involving human participants were in accordance with the ethical standards of the institution and with the 1965 Helsinki declaration and its later amendments or comparable ethical standards. Written informed consent was obtained.
Funding: National Natural Science Foundation of Xinjiang Uygur Autonomous Region, China (2018D01C298).

The application quantitative parameters of multiple models of multi-b value DWI-MRI in different pathological type, grade, and clinical stage of cervical cancer
J. Sun[1], F. Shan[1], C. Huang[2]; *[1]Shaoguan/CN, [2]Stony Brook/US (sunjunqi1233668@sina.com)*

Purpose: To investigate the application of quantitative parameters of a mono-exponential model, bi-exponential model, and stretching exponential model of multi-b value DWI-MRI in different pathological types, grades, and clinical stages of cervical cancer.
Methods and materials: 142 patients confirmed with cervical cancer cases were subjected to MRI routine sequence and multi-b value DWI-MRI sequence imaging. A mono-exponential model parameter (ADC), bi-exponential model parameters (D, D*, f), and stretching-exponential model parameters (DDC, α) were obtained by FUNCTOOL post-processing software. The multiple quantitative parameters of the 3 models were used to distinguish the pathological type, grade, and clinical stage of cervical cancer. ROC analysis was performed to identify meaningful parameters.
Results: 142 cases of cervical cancer were enrolled. ADC, f, and DDC values were statistically different in clinically high and low stages of cervical cancer ($P < 0.05$). ADC, f, DDC, and alpha values were statistically different in the cervical squamous cell carcinoma and adenocarcinoma group ($P < 0.05$). ADC and DDC values were statistically different in the poor differentiation and moderate-to-well differentiation of cervical cancer ($P < 0.05$). The alpha value has the highest AUC (0.723) and diagnostic power (a sensitivity of 78.9% and a specificity of 77.5%) in the cervical squamous cell carcinoma and adenocarcinoma group.
Conclusion: The multiple quantitative parameters of multiple models of multi-b value DWI-MRI can show diffusion, perfusion, and heterogeneity changes of cervical cancer. They can identify the pathological type, grade, and clinical stage of cervical cancer, which is conducive to the choice of cervical cancer treatment and prognosis evaluation.
Limitations: A relatively small number of patients. MR imaging was mostly performed after cervical cancer biopsy.

The role of quantitative MRI in assessing radiation response in uterine cervix cancer
V. Mahawar, A. Jajodia, A. K. Chaturvedi, A. S. Rao, S. Chauhan*; [1]New Delhi/IN (drmahawarvivek@gmail.com)*

Purpose: To compare quantitative MRI (ADC values) and clinical parameters in patients with cervical cancer.
Methods and materials: This MR study was retrospectively analysed in cervical cancer patients (n=133). Patients included in the study were non-surgical candidates with a locally advanced stage of 2B to 4A. Baseline MR imaging was done to assess the status of parametrial and ADC values. Post concurrent chemotherapy (CCT) and EBRT (external beam radiotherapy) assessment MRI was done and the ADC values were analysed in the region of interest. As per the institutional protocol, brachytherapy (ICRT/MUPIT) was done depending on the extent of parametrial invasion. The change of ADC values was charted separately, dividing the study groups into ICRT versus MUPIT. ICRT was given 100 patients and MUPIT 33. The 2 study groups were compared for the occurrence of recurrence and metastasis, stage, and nodal status, and statistical analysis was done to identify any significant correlation between baseline ADC, follow-up ADC, change in ADC, and recurrence-free survival among the groups.
Results: The occurrence of recurrence and metastasis, stage, and nodal status correlated among 2 groups as p=0.002, 0.549, 0.029, and 0.184, respectively. 24/33 (72%) patients in the MUPIT group were stage 3 and 4. 49/100 (49%) patients in the ICRT group were stage 2. Age, baseline ADC, follow-up ADC, change in ADC, and recurrence-free survival among the groups were p=0.711, 0.931, 0.112, <0.0001, and <0.0001, respectively). The median recurrence-free survival for the ICRT group was 25 months and 9 months for the MUPIT group.
Conclusion: A change in ADC is a potential surrogate marker for identifying between different choices of radiotherapy in uterine cervix cancer.
Limitations: The small cohort.
Ethics committee approval: Ethics committee approval obtained.
Funding: No funding was received for this work.

Endovascular stenting of the main veins in urology
O. B. Zhukov*; Moscow/RU (ob.zhukov@yandex.ru)*

Purpose: Stenting of the main veins in urology is a responsible step that requires a clear understanding of the subsequent haemodynamic changes.
Methods and materials: We performed more than 67 stentings of the major pelvic veins and retroperitoneal organs regarding aortomesenteric compression of the left renal vein, progression of the pelvic venous disease, recurrent ovarian-varicocele, varicocele, and chronic pelvic pain syndrome.

Results: Of 67 patients, 23 had a double block of upper and lower nutcracker syndrome. After confirming phlebohypertension, these patients received a nitinol-nickel stent (Zilver Cook, Protehge). In several cases, venous stents Wallsten-Uni endoprosthesis (Boston Scientific) were used.
Conclusion: The optimal diagnostic algorithm for the early detection of May Turner syndrome is a thorough examination using compression tests, asymmetry of venous blood flow in the iliac veins of more than 8 cm/s, and MRI phlebography of the inferior vena cava system, with the aim of spatial orientation of the level and floor of possible compression. Then, after phlebography and phlebotonometry with a gradient of more than 10 mm RT and in connection with the clinical picture of the disease, the installation of a venous stent

INTACT-lymph: the current results of an interventional approach to lymphatic leakage
W. Flatz[1], T. Streitparth[1], M. Frölich[2], M. Seidensticker[1], J. Ricke[1], F. Streitparth[1]; [1]*Munich/DE,* [2]*Mannheim/DE (radiologie.muenchen@gmail.com)*

Purpose: To visualise the lymphatic vessels and detect lymphatic leakage, and to evaluate the therapeutic potential of intranodal and CT-guided lymphatic embolisation.
Methods and materials: In this prospective study, 16 patients suffering from lymphatic leakage due to different causes (e.g. nephrectomy, prostatectomy) resistant to conservative treatment were included. Intranodal lymphography using lipiodol, and in case of non-responding, a second intervention via CT-guided embolisation using lipiodol and/or histoacryl, was performed. Technical success was defined as a visualisation of the lymphatic system and visualisation of a leakage site. Clinical success was defined as a significant reduction of chylus collected via drainage (>90% reduction) with no significant increase of lymphatic leakage in control exams and an improvement in the quality of life (Karnofsky index).
Results: Lymphatic system visualisation and the detection of lymph fistula was successful in 94% of patients (15/16). The intervention was clinically successful in 81% of cases (13/16). One patient had to be treated for several other diseases and was lost to follow-up. One patient showed only a 25% reduction of chyle flow and was treated with a kidney transplant. A third patient had thoracic chyle leakage without visualisation of the site of leakage. Therapeutic embolisation using lipiodol alone was successful as a "one-stop-shop" in 63% of cases (10/16). In 8 patients, CT-guided embolisation was performed, 4 were clinically successful, 1 was partially successful, and 1 patient showed only partial improvement (Karnofsky-Index 50->70). Karnofsky-Index improved from 73 to 90 in all patients.
Conclusion: Direct intranodal lymphography is highly recommended for the visualisation and therapeutic occlusion of lymphatic leaks. Additional CT-guided embolisation using lipiodol and/or histoacryl improves the clinical outcome.
Limitations: A small patient number.
Ethics committee approval: Consent of local ethics committee was obtained (LMU Munich ethics commitee).
Funding: No funding was received for this work.

25-years experience with transpedal lymphangiography in the management of postoperative therapy-refractory lymphatic leakage: final results with subgroup analyses
C. M. Sommer[1], F. Pan[1], T. D. D. Do[1], G. M. Richter[2], H. U. Kauczor[1], T. Hackert[1], M. Loos[1]; [1]*Heidelberg/DE,* [2]*Stuttgart/DE (cmsommer@gmx.com)*

Purpose: During the DCK (Deutscher Chirurgen Kongress) 2019, the preliminary results of our 25-year experience on transpedal lymphangiography in the management of postoperative therapy-refractory lymphatic leakage were presented. In this update, the final results with subgroup analyses are summarised.
Methods and materials: The final cohort consisted of 355 patients who underwent transpedal lymphangiography with the intention to cure postoperative therapy-refractory lymphatic leakage in different locations. Study goals included patient demographics and technical results, as well as complication and cure rates. Dedicated subgroups analyses were performed to outline predictors for a cure.
Results: Postoperative lymphatic leakage resulted from different highly complex surgical procedures in the neck, thorax, abdomen, pelvis, and/or lower extremity. The daily drainage volume was 1124±1336 ml. The technical success rate of the amount of injected iodised oil used and major and minor complication rates of transpedal lymphangiography were 87.2%, 10.3±4.3ml, and 0%, and 0.3%, respectively. The cure rate of transpedal lymphangiography was 42.6%. Positive predictors for cure were radiological extravasation/pooling of iodised oil under fluoroscopy, radiography, and, especially, CT (yes vs no; p=0.006), the type of lymphatic leakage (lymphatic fistula vs lymphocele; p=0.033), and the daily drainage volume (845±1067 vs 1316±1399; p=0.001).
Conclusion: Transpedal lymphangiography is feasible, safe, and effective in the management of postoperative therapy-refractory lymphatic leakage. Under consideration of positive predictors for a cure, different lymphatic second-line interventions should be scheduled prospectively as, according to our data, lymphatic second-line interventions can dramatically increase the cure rate (e.g. CT-guided ethanol 95% sclerotherapy shows a cure rate of 76.9% after clinically ineffective transpedal lymphangiography).
Limitations: A retrospective cohort study.
Ethics committee approval: All procedures were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki declaration. Specific consent was obtained.

Early inferior vena cava filter retrieval strategy in trauma patients: the role of pre-retrieval contrast-enhanced CT
M. Kim, S. Y. Lee, H. Lee, J.-K. Lim*; Daegu/KR*

Purpose: To increase the retrieval rate of IVC filters with pre-retrieval contrast-enhanced CT evaluation.
Methods and materials: An active IVC filter retrieval strategy was established in March 2017. We reviewed pre-retrieval venous thromboembolism (VTE) CT findings, retrieval rate, indwelling time, anticoagulation therapy, and recurrence of VTE. Subgroup analyses were also performed before and after the active filter retrieval strategy establishment from 2010-2018.
Results: 177 IVC filter insertions were performed in trauma patients during the study period and all patients underwent CT prior to filter retrieval. CT findings were as follows: completely resolved VTE n=108 (61%), partially improved n=58 (33%), no change n=8 (5%), and aggravated n=3 (2%). The overall retrieval rate was 84% with a mean indwelling time of 32 days. In subgroup analyses, 95 (53%) were in the prior to strategy establishment (PSE) group and 82 (47%) were in the after strategy establishment (ASE) group. The retrieval rate was significantly higher in ASE than PSE 81/82 (99%) versus 68/95 (72%) (p<0.001). Anticoagulation therapy was applied in 63/95 (63%) of the PSE group and in 67/82 (82%) of the ASE group. The duration of anticoagulation was significantly reduced in the completely resolved VTE group (mean 78 days ± 126) than the residual VTE group (mean 133 ± 271) (p<0.001). There was no recurrent VTE during a mean follow-up of 24 month in the PSE group and 10 months in the ASE group.
Conclusion: This study showed an overall 84% IVC filter retrieval rate in trauma patients. After the active filter retrieval strategy setup, 99% of filters were safely retrieved in trauma patients. Pre-retrieval CT can help in the decision making of early filter retrieval and the planning of proper anticoagulation therapy.
Limitations: The inclusion of study subjects was restricted to trauma patients only. Our data was single institutional.

Endovascular percutaneous arteriovenous fistula creation: current evidence, technique, and single-centre experience

U. Salati, J. W. Ryan*; Dublin/IE (umersalati@gmail.com)*

Purpose: To assess endovascular arteriovenous fistula creation for haemodialysis in end-stage renal failure and compare its efficacy, primary and secondary patency, and cost-effectiveness to traditional surgically created arteriovenous fistulas (AVF).
We also present a systematic review of the current evidence for the effectiveness of endovascular fistula creation.
Methods and materials: The 4Fr WavelinQ (Becton, Dickinson and Company) device was used to create AVFs (radial artery-radial vein, ulnar artery-ulnar vein, and interosseous artery-interosseous vein) in all patients. Patients were followed for at least 3 months and primary and secondary patency was determined. Multiple patients were screened for suitability for the procedure and, ultimately, 7 cases were performed.
A cost comparison of percutaneous versus surgical AVF creation was also conducted.
Results: Procedural technical success was 100%. Primary patency at 6 weeks was 85%; coil embolisation of a venous pseudoaneurysm from a guidewire trauma, unfortunately, resulted in fistula thrombosis in one case. This patient went on to have a surgical fistula created.
2 needle cannulations were done in 2/7 patients at the time of this abstract (and expected to change).
A cost analysis of the procedure was performed and compared to surgically created AVFs; the percutaneous procedure cost an approximate €6,000 per patient, with 1 inpatient admission, and surgical fistulas cost an average of approximately €12,866 per patient with an average inpatient stay of 3 days.
Conclusion: Endovascular arteriovenous fistula creation is a safe and effective technique demonstrating at least non-inferiority to surgical AVFs and is significantly more cost-effective.
Limitations: A single-centre, single-arm study with limited numbers.
Ethics committee approval: Written informed consent obtained from all patients.
The device has CE Mark and FDA approval; ethics approval waived.
Funding: No funding was received for this work.

RPS 1009a-6 11:45

An alternative method for traditional surgical suturing in port catheter placement: glue

M. Aşık*; Istanbul/TR (muratasik219@yahoo.com)*

Purpose: A port catheter (PC) is a medical device that is used for long-term or short-term access to veins in patients having chemotherapy who require continuous medication. Our aim is to evaluate the efficacy and advantages of using glue for tissue adhesion in the closure of the skin incision for the reservoir when placing the PC.
Methods and materials: In all cases, except for 3 cases of the brand port catheter, a port reservoir was placed under the skin in the anterior wall of the chest. The subcutaneous fat tissue was covered with an absorbable suture to cover the reservoir. The skin tissue of the bioglue (Cryolife / Georgia-USA), which is ready in its injector, was closed by thinning.
Results: 39 patients (20 males, 19 females, mean age 57.1) who were scheduled to receive port catheter chemotherapy between January 2017 and December 2017 were included in the study. During the process, BioGlue was preferred for port closure of the skin tissue on the reservoir as tissue adhesion instead of surgical sutures. After the procedure, the patients were kept under observation for 1 hour to monitor for possible complications.
Conclusion: There are many complications, such as infection and especially bleeding, when placing a PC. The incidence of these complications increases with the traditional surgical suture closure of the skin. The vast majority of patients with PCs are immunosuppressed patients, where suture can cause opportunistic infections. Pain caused by skin closure with conventional surgical suture may also cause the procedure to be prolonged. Using glue instead of conventional suturing of the tissue is a cheaper and advantageous alternative.
Limitations: A retrospective, single-institutional, small-sample-sized study.
Ethics committee approval: Ethics committee approval obtained.
Funding: No funding was received for this work.

Dynamic MR lymphangiography: a new technique for the assessment of the central lymphatic system in adults

S. Katsari, D. K. Gordon, P. P. Mortimer, P. S. Mansour, F. Howe, L. A. Ratnam*; London/UK (Katsari.sofia@gmail.com)*

Purpose: To describe the technique and utility of dynamic contrast-enhanced MR lymphangiography (DCMRL).
DCMRL enables imaging of the central lymphatic system and its relationship to anatomical structures, demonstrating flow rate, obstruction, and leakage from the lymphatic system. This provides important diagnostic information and could inform treatment such as thoracic duct embolisation or lymphovenous anastomosis.
Methods and materials: 8 adult patients with lymphatic abnormalities were examined in a tertiary lymphovascular referral centre using DCMRL. 1 patient had Noonan's syndrome, 1 patient had chylous ascites and effusions, and 6 patients had a primary lymphatic abnormality. Bilateral ultrasound-guided access into inguinal lymph nodes was carried and ultrasound contrast injected to confirm the position. DCMRL was performed in a 3T MRI scanner by injecting gadolinium into the inguinal lymph nodes. The central lymphatic system, including the pelvis, retroperitoneal lymphatics, and thoracic duct were assessed. Patients with lymphoedema in the lower extremities were re-scanned after walking for a short period.
Results: In 7 patients, DCMRL was successful in providing information about the central lymphatic system. In 2 of these patients, leakage of contrast was seen into the mediastinum and into pleural effusions. Abnormal lymphatic drainage was noted in all patients in either thoracic or abdominal lymphatics, or in both. In 1 patient, no drainage was seen into the central lymphatics, however, the contrast was seen to reflux into the scrotum and superficial tissues of the legs.
Conclusion: DCMRL has been successfully used to provide information about central lymphatic anatomy and to identify obstruction and leakage of lymphatic fluid. This novel technique offers possibilities for both diagnoses and treatment options for patients with lymphatic abnormalities.

Venous access devices and thrombotic complications incidence: implantation technique does matter

M. Cherkashin, A. Nikolaev, N. Berezina, D. Puchkov, N. Nikitina, D. I. Kuplevatskaya, K. Suprun, P. Yablonsky*; St. Petersburg/RU (mikhail.a.cherkashin@gmail.com)*

Purpose: To assess the role of totally implanted venous access devices (TIVAD) implantation errors in thrombotic complications.
Methods and materials: In this prospective study, we screened 428 patients with implanted venous access devices (395 port-systems (PS) and 33 peripherally inserted central catheters (PICC)). 64 patients (61 PS and 3 PICC) had venous thrombosis or device malfunctions during follow-up. These patients were included in the final analysis. The mean patients' age was 45 years (6-73). In all cases, venous ultrasound examination and angiography were performed.
Results: Thromboses were treated by low-molecular-weight heparins. In 7 cases, local thrombolysis was effective. In 2 patients, we performed device explantation due to the risk of thrombosis progression. The mean time for venous thrombosis development was 3 months after the intervention. In 1 case, non-massive pulmonary embolism was revealed.
We analysed a small group of patients with catheter malposition (n=15). In 46.6% (n=7), thrombosis was identified and we suggested device malposition as a serious VTE risk factor.
Different types of malpositions were identified: catheter placement errors, capsule placement errors, and complex malpositions.
Conclusion: TIVAD implantation errors are characterised by a high rate of thrombotic complications. The main reason is an underestimation of imaging support during implantation. In most cases of malposition, interventions were performed by ECG or ultrasound without a final x-ray.
Based on our analysis, we suggest maximizing direct x-ray or CT imaging during intervention. At least one shot must be performed in the final stage of implantation to assess the catheter tip position.
Limitations: A non-randomised single-center study.
Ethics committee approval: Approved by a local ethics board.
Funding: No funding was received for this work.

The efficacy of cutaneous anaesthesia in endovenous laser ablation of the great saphenous vein.

K. Singh, R. Malik, A. Kumar, R. S. Gupta*; Bhopal/IN (drkjsrandhawa@gmail.com)*

Purpose: To evaluate the safety and efficacy of cutaneous anaesthesia for pain control during injectable tumescent anaesthesia in endovenous laser ablation of the greater saphenous vein (GSV).
Methods and materials: An evaluation of 35 patients (25 male, 10 female), who had undergone endovenous laser ablation for greater saphenous vein insufficiency was done. All of these patients had undergone cutaneous application of cream-based skin anaesthetics consisting of lidocaine 2. 5%W/W and prilocaine 2. 5%W/W (TOPLAP cream) along the length of GSV to be ablated. The cream was applied at least an hour before cleaning and draping the patient for the procedure. To facilitate the application of the cream, GSV was marked under USG guidance. All patients received tumescent anaesthesia. All patients were asked to record the pain or discomfort using the visual analogue score (VAS) from the start of the procedure until the end of the GSV ablation. No intravenous analgesia or sedation was used.
Results: The mean recorded pain score was approximately 2.2 (range 1-4). Most of the patients had tolerable mild pain/discomfort with a pain score of 1-3. 4 patients complained of moderate pain with a VAS score of 4. However, the overall experience of patients was satisfactory, with patients having the ability to resume immediate ambulation and making endovenous laser ablation a walk-in walk-out procedure.
Conclusion: Cutaneous anaesthesia is a safe, adequate, and effective option to decrease and/or eliminate the intraoperative discomfort associated with tumescent anaesthesia injections and laser ablation during endovenous laser ablation of the greater saphenous vein.
Limitations: A limited sample size. Ethnicity and socio-economic background of the participants was not taken into consideration.

Assessment of the effectiveness of pelvic vein embolisation: a single-centre experience

C. Leonard, D. C. O Neill, M. P. Brassil, M. J. Lee*; Dublin/IE (carolaleonardo@gmail.com)*

Purpose: Pelvic congestion syndrome can arise from incompetent valves, typically in gonadal veins, resulting in pain. Pelvic vein embolisation is a minimally invasive treatment for pelvic congestion syndrome by embolising incompetent pelvic veins. The purpose of this retrospective study was to assess the efficacy of pelvic vein embolisation in the treatment of pelvic congestion syndrome.
Methods and materials: All patients treated with pelvic vein embolisation for pelvic congestion syndrome were analysed (2011-2019) in a university teaching hospital. A standardised questionnaire using a 0-10 numeric rating scale was used to assess pain scores and the impact on activities of daily living (ADLs), including work, socialising, exercise, and sleeping, before and after embolisation.
Results: 28 embolisation procedures were performed in 23 women. 5 patients underwent repeat embolisation for ongoing symptoms. The technical success of the procedure was 100% and there were only minor complications in 2 patients. 74% (17/23) response rate. The median pre-procedural pain score was 8 (IQR 7-8). This significantly reduced at 1-months to 5 (IQR 2.5-7.5) and at 12-months to 5 (IQR 0-8). 35% (n=6) of patients reported complete resolution of pain at 1 year. Improvement in the impact on ADLs was demonstrated across all domains and significantly in the impact on the exercise median before 8 (IQR 1-9) to 5 (IQR 6-9) after p=0.00694.
Conclusion: Pelvic vein embolisation results in reduced pain scores compared to their pre-operative values. Given that 4 had repeat venography without embolisation suggests a multifactorial component to the symptoms. Improvement in the impact on ADLs is demonstrated across all domains, particularly exercise. Information from this study will allow clinicians to convey the potential improvements in symptom parameters for patients undergoing embolisation for pelvic congestion.
Limitations: The sample size.
Ethics committee approval: Ethical approval received.

Hydrophilic guidewire usage in facilitating catheter advancement during the endovenous treatment of varicose veins

K. Hwang, S. W. Park, J. H. Hwang, Y. W. Kwon, J. Min*; Seoul/KR*

Purpose: To investigate the use of hydrophilic guidewires for facilitating catheter advancement during varicose vein treatment using radiofrequency ablation (RFA) or cyanoacrylate closure (CAC).
Methods and materials: From March 2016-April 2019, 463 limbs in 286 patients (126 male, mean age 53.7 years, range 21-88 years) with incompetent great saphenous vein were subjected to either RFA or CAC. Procedure records were reviewed for the use of a hydrophilic guidewire, the reason for guidewire usage, and the choice of guidewire diameter.
Results: In total, a hydrophilic guidewire was used to facilitate catheter advancement in the treatment of 92 of 463 limbs (19.8%). For RFA, a guidewire was used in the treatment of 53 of 321 limbs (16.5%). Among them, 15 limbs were due to vasospasm, while 38 were due to venous tortuosity. A 0.025-inch guidewire was used in 42 of 53 limbs (79.2%), and a 0.018-inch guidewire in 11 of 53 limbs (20.8%). For CAC, a 0.035-inch guidewire was used in 39 of 142 limbs (27.5%). Among them, 10 limbs were due to vasospasm, 23 due to venous tortuosity, and 6 due to repeated varicose vein engagement. All varicose vein treatment sessions were technically successful. No major complications occurred.
Conclusion: Hydrophilic guidewire usage could facilitate catheter advancement when it is hindered by vasospasm, tortuosity of the saphenous vein, or repeated engagement into varicosity. For RFA, the use of a 0.018-inch guidewire could provide better catheter advancement when a 0.025-inch guidewire passage through the radiofrequency catheter is difficult.
Limitations: This is a retrospective study from a single institute. There is no comparison with other methods.
Ethics committee approval: n/a

Assessment and treatment of low-flow venous malformations

R. M. Mousa, B. Hawthorn, T. Cavenagh, L. Mailli, J.-Y. Chun, L. A. Ratnam, R. A. Morgan*; London/UK (rolamousa87@gmail.com)*

Purpose: To outline the diagnostic features of LFVM and describe the efficacy of percutaneous sclerotherapy in their management.
Methods and materials: This study was done over two years, including 28 patients with LFVM, diagnosed with MRI and US. These patients underwent a total of 54 treatments. Management was divided into sessions, with each session consisting of multiple treatments (1 to 4) with an 8-week interval in between. Sclerotherapy procedures were done under local anaesthesia using ultrasound guidance. Compression was applied after the procedure where practicable. Subjective response to treatment was based on improvement in pain, swelling, discomfort, discolouration, and improvement of movement where applicable. The objective evaluation was based on a decrease in the size of the lesion on examination, change in the ultrasound appearances, and change in vascularity on colour Doppler evaluation.
Results: Approximately 93% of the patients reported a significant improvement of symptoms, which correlated with changes in US appearance and a decrease in the number of cystic spaces. 2 patients reported no significant resolution of the symptoms, which were correlated with no significant changes on US; both lesions were in the extremities (wrist and leg). Most patients complained of pain and swelling which resolved within a week of the procedure. No significant post-procedural complications were reported.

Conclusion: Treatment of LFVM with percutaneous sclerotherapy results in good outcomes for patients with a low complication rate. Accurate diagnosis of these lesions is critical to guide management.
Limitations: n/a
Ethics committee approval: Written consent was obtained from all patients.

ADNEX MR scoring system in the characterisation of ovarian lesions: retrospective external validation of malignancy prediction accuracy
A. Solopova, U. Nosova, V. Bychenko*; Moscow/RU (dr.solopova@mail.ru)*

Purpose: To evaluate the ADNEX MR scoring system accuracy in predicting ovarian tumour malignancy.
Methods and materials: A retrospective study was conducted on the basis of the analysis of pelvic MRI results of patients with ovarian lesions sent for clarifying diagnosis after ultrasound from 2018 to 2019, after excluding incomplete study protocols and observations without diagnosis verification. All ovarian lesions were analysed using the ADNEX MR scoring system algorithm.
Results: The study included 118 patients (average age 48.6 (26-81)) and 136 lesions: 33 (24.3%) were malignant and 7 (21.2%) were borderline epithelial sex cord stromal tumours with a low degree of malignancy. The distribution of malignant tumours among the studied groups showed that lesions with a score of 2 were found in 1.37% (1/73), with a score of 3 were found in 11.5% (3/26), with a score of 4 were found in 62.5% (10/16), and with a score of 5 were found in 90.5% (19/21). The ADNEX MR scoring system demonstrated high accuracy: a sensitivity of 91.3% (95% confidence interval [CI], 86.1% -94.8%) and specificity of 96.7% (95% CI, 92.3% -98.6%) in the malignancy prediction.
Conclusion: ADNEX MR scoring system is an informative method of ovarian tumour malignancy prediction, therefore implementation in the algorithm of preoperative diagnosis can be important for optimising the management tactics. The greatest difficulties in assessing arose when characterising borderline epithelial mucinous tumours and non-epithelial tumours with a low degree of malignancy.
Limitations: A retrospective, single-institution study.
Ethics committee approval: Ethics committee approval was obtained.
Funding: The study was funded by the Grant of the President of the Russian Federation.

Diagnostic value of individual MRI findings in abnormally invasive placenta
S. Sefidbakht[1], P. Iranpour[1], A. Teimouri[1], E. Khabbazi[1], Z. Gholami Bardeji[1], F. Zarei[1], P. Pishdad[1], H. Vafaei[1], B. Bijan[2]; *[1]Shiraz/IR, [2]Sacramento, CA/US (Arashteimourirad@gmail.com)*

Purpose: To evaluate the predictive value and accuracy of individual MRI findings in the diagnosis of abnormally invasive placenta (AIP).
Methods and materials: A retrospective PACS-based search was done for all the MRIs performed over 5 years in a tertiary referral centre for evaluation of possible AIP. The normal outcome was defined as an eventless vaginal delivery or cesarian section without the need for transfusion or hysterectomy. AIP was considered positive if pathologic prove was present. Patients with complicated deliveries but no hysterectomy or pathologic proof were excluded from the study. Individual findings evaluated included heterogeneity, dark placental bands, rounded edges, lumpy margins, and bulging uterine outline. Chi-square was used to compare findings. Sensitivity, specificity, PPV, and NPV for each individual finding were determined.
Results: Over a period of 2 years, 392 MRIs were done to further evaluate for possible AIP, of which 152 cases had a final diagnosis of AIP and 38 were lost to follow-up. Sensitivity, specificity, and overall accuracy of MRI for diagnosis of AIP were 93, 90%, and 89%. Dark bands were most accurate (sensitivity, specificity, and overall accuracy of 91, 78%, and 82%). Lumpy margins and loss of retroplacental hypo intense band were least accurate. A combination of retroplacental dark bands, anteroinferior low-lying/previa, and bulging uterine margins were the most accurate combination, slightly increasing the sensitivity, specificity, and overall accuracy to 93, 92, and 91% (based on a logistic regression method).
Conclusion: Not all the individual signs of AIP have the same diagnostic value in predicting the diagnosis. The single most useful determinant for the diagnosis was dark placental bands. The most useful combination of findings were a history of previous C/S, placenta previa, and dark placental bands. Adding other findings did not significantly raise the accuracy.

Comparative analysis of placental volume and vasculature in normal and foetal growth restricted (FGR) pregnancies
S. Jain, S. Hota, R. C. Shukla, M. Jain, T. Singh*; Varanasi/IN (shivijain1103@gmail.com)*

Purpose: To evaluate differences in placental volume and vasculature between normal and FGR pregnancies by three-dimensional ultrasound (3D-USG).
Methods and materials: 703 pregnant women with singleton foetus at gestation age (GA) of 6-9 weeks (GA confirmed through transvaginal ultrasound) were enrolled. At 28-36 weeks, 3D-USG assessment of placental volume (PV), vascularisation index (VI), flow index (FI), vascularisation flow index (VFI), and an estimated foetal weight (EFW) was done. Those with EFW < 10^{th} percentile for GA were placed in the FGR group and the rest in the normal group. Follow-up till delivery was done in 121 FGR and 153 normal pregnancies. The diagnosis was confirmed through birth-weight in 107 and 111 women, respectively. Receiver operator characteristic (ROC) curves were plotted; correlation coefficients of PV, VI, FI, VFI with EFW were calculated. A Student t-test and Mann-Whitney U test were used.
Results: A mean of PV, VI, and VFI were significantly lower ($p<0.001$) in FGR than normal (PV: 192.67 ± 24.07 vs 275.08 ± 94.82, VI: 3.26 ± 1.48 vs 10.53 ± 7.94, VFI: 2.44 ± 1.61 vs 5.46 ± 3.07) while FI had no significant difference between the two (FI: 46.41 ± 7.70 vs 49.19 ± 7.08, $p=0.07$). Area under ROC curve (AUC) were VI: 0.860, VFI: 0.799, PV: 0.791, and FI: 0.690. Sensitivity and specificity of cut-off values for PV (208 ml), VI (5.0), and VFI (3.2) were 74% and 69%, 91% and 75%, and 75% and 71%, respectively. PV showed a maximum correlation with EFW; 0.829 for FGR and 0.911 for normal pregnancies ($p<0.05$ each).
Conclusion: 3D-USG assessment of placental volume and vasculature serves as a complementary tool to EFW in discriminating FGR from normal pregnancies.
Limitations: A tertiary hospital-based study; results cannot be generalised at a community level.

The role of sonosalpingography (SSG) using normal saline in female subfertility: diagnostic or therapeutic?

R. Rastogi, N. Jain*; Moradabad/IN (rajulrst@yahoo.co.in)*

Purpose: Sonosalpingography (SSG) has been a less commonly used tool for assessing the patency of fallopian tubes in subfertile females. Its significance is undermined by laparoscopic evaluation (LE) that allows simultaneous therapeutic procedures to restore its patency if the obstruction exists. But LE is invasive and expensive.
Methods and materials: We performed this study with the aim of evaluating the role of SSG in the diagnosis of tubal obstruction, its cause, and relieving the obstruction.
50 subfertile females with a normal-appearing uterus and ovaries on transvaginal ultrasonography were included in our study. SSG was performed with an infusion of normal saline to evaluate tubal patency by recording free peritoneal spill. If peritoneal spill was absent bilaterally then the patient underwent laparoscopic evaluation. However, if unilateral or bilateral peritoneal spill was noted, then the patient was recruited for assisted reproductive techniques (ART) and the results were correlated with pregnancy.
Results: Out of 50 patients, SSG demonstrated free peritoneal spill unilaterally in 46 patients who conceived with ART during the following six months. In the remaining 4 patients with a lack of bilateral spill on SSG, 2 revealed unilateral partial block and 2 revealed bilateral tubal block on LE. In all patients, SSG correctly depicted the site of obstruction. In 9 patients, it revealed PID (tubercular) by demonstrating flimsy peritubal adhesions and in 14 patients, higher pressure exerted during SSG restored the patency with sharp abdominal pain.
Conclusion: Our study reveals that SSG is not only diagnostic but may also be a therapeutic tool. SSG should be used more often and can be used to at least segregate patients who prudently need laparoscopic evaluation.

The accuracy of the characterisation of adnexal masses with non-contrast pelvic MRI: an 11-year experience from a tertiary referral centre in the United Kingdom

H. Şahin[1], C. Panico[2], H. C. Addley[1], S. Ursprung[1], J. Smith[1], S. Freeman[1], V. Simeon[2], P. Chiodini[2], E. Sala[1]; [1]*Cambridge/UK,* [2]*Naples/IT (hilalcimen@gmail.com)*

Purpose: To assess the accuracy of non-contrast pelvic magnetic resonance imaging (MRI) for the characterisation of adnexal masses and evaluate the reproducibility of a new non-contrast adnex MRI scoring system used in a tertiary referral centre.
Methods and materials: Pelvic MRI examinations performed for adnexal mass characterisation or follow-up of endometriomas between the years 2008-2018 in our institution were retrospectively reviewed. In total, 484 patients with an adnexal mass who were either treated surgically or followed-up for at least one year were identified. After exclusion of patients without diffusion-weighted imaging (DWI), the final cohort included 297 patients with 356 adnexal masses. A randomised set of 100 patients was chosen from this cohort to assess the reproducibility of the proposed five-category scoring system. Various MRI features were assessed in both sets.
Results: There were 303 benign and 53 malignant tumours in the study cohort. ROC analysis of the used scoring system for predicting overall outcome showed an AUC of 0.93. A cut-off score of ≥4 was associated with malignancy with an accuracy of 93.82% and PLR of 18 for predicting malignancy, with a sensitivity of 84.91% and a specificity of 95.38%. In the analysis of MRI features of the reproducibility set, inter and intraobserver agreement was moderate-almost perfect for most of the features and the repeatability of the scoring system.
Conclusion: Non-contrast MRI scoring for adnexal mass characterisation seems to be promising with high accuracy and reasonable inter and intraobserver agreement. The validity of the scoring needs to be tested in multicentre prospective studies.
Limitations: A single-centre, retrospective study.
Ethics committee approval: Service evaluation approval is present.

Integration of proteomics with CT-based qualitative and texture features in high-grade serous ovarian cancer patients: an exploratory analysis

L. Beer[1], H. Sahin[1], K. M. Darcy[2], J. B. Freymann[3], L. Maxwell[2], T. P. Conrad[2], E. Huang[3], E. Sala[1]; [1]*Cambridge/UK,* [2]*Bethesda/US,* [3]*Rockville/US (lucian.beer@meduniwien.ac.at)*

Purpose: To investigate the association between CT imaging traits and texture metrics with proteomic data in patients with high-grade serous ovarian cancer (HGSOC).
Methods and materials: This retrospective, hypothesis-generating study included 20 patients with HGSOC prior to primary surgery. Two readers independently assessed the contrast-enhanced computed tomography (CT) images and extracted 33 imaging traits. All sites of suspected HGSOC were manually segmented and grey-level correlation and matrix-based texture features were computed. 3 texture features that represented intra-and inter-site tumour heterogeneity were used for analysis. An integrated analysis of transcriptomic and proteomic data identified proteins with a conserved expression between primary tumour sites and metastasis. Correlations between protein-abundance and various CT features were assessed using the Kendall tau rank correlation coefficient and the Mann-Whitney U test, whereas the area under the receiver-operating characteristic-curve (AUC) was reported as a metric of the strength and the direction of the association.
Results: 8 proteins were identified as significantly associated with CT-based imaging traits, with the strongest correlation observed between the MRI1 protein and peritoneal disease in the liver/right upper quadrant (P<0.001, AUC=0.940). The abundance of 4 proteins was associated with texture features that represented intra and inter-site tumour heterogeneity, with the strongest correlation between the GSTM1 protein and cluster dissimilarity (p=0.024, =0.368).
Conclusion: This study provides the first insights into the potential associations between standard-of-care CT imaging traits and texture measures of intra-and intersite heterogeneity and the abundance of several proteins.
Limitations: A small sample, retrospective study.
Ethics committee approval: This was a multi-institutional, institutional review board-approved, and Health-Insurance Portability and Accountability Act (HIPAA)-compliant study.

Pre-treatment MRI radiomics-based response prediction model in locally advanced cervical cancer

L. Russo, B. Gui, S. Persiani, M. Miccò, L. Boldrini, D. Cusumano, R. Autorino, G. Ferrandina, R. Manfredi*; Rome/IT (lucarusso.md@gmail.com)*

Purpose: To investigate the potential of the radiomic approach to MRI to the predict pathological complete response to treatment (pCR) in patients with locally advanced cervical cancer (LACC). The second goal was to develop and validate this MRI signature, to apply the model out of the habitat where it was created.
Methods and materials: 183 patients with LACC (FIGO IB2-IVA) treated in two hospitals were enrolled, 156 patients for the training set and 27 for the validation set, respectively. All patients underwent neoadjuvant chemoradiation therapy followed by radical surgery.
For each patient, a staging 1.5T MR image was acquired. 230 radiomic features belonging to 4 families (fractal, statistical, textural, and morphological features) were extracted. Considering the application of all the filters used, 1,889 features were extracted. Features selection and model training were carried out following an iterative method, ad-hoc developed for this study. Model selection was

carried out using the area under the curve (AUC) of the receiving operator characteristic (ROC) curve as a target metric.
Results: 15 features were selected. The model showing the highest performance was a random forest with default parameters (RF_DEF). This model shows an AUC of 0.76 on the training and 0.82 on the external validation set.
Conclusion: Our radiomic model showed a good predictive value with a high AUCs both in the training and validation group, so it is able to predict the probability of pathological complete response in patients undergoing chemoradiation therapy using pre-treatment images.
The presented model is able to predict patients' response to treatment before commencement and use this information to support the clinical decision-making process.
Limitations: Further external validation cohort should be studied.
Ethics committee approval: Institutional ethics committee approved the study.

The variance of quantitative kurtosis imaging using ultra-high b-value DWI over the menstrual cycle: the influence of oral contraceptives

T. Mokry, A. Mlynarska-Bujny, J. Pantke, T. Kuder, J. Rom, H.-U. Kauczor, H.-P. Schlemmer, S. Bickelhaupt*; Heidelberg/DE*

Purpose: To evaluate the influence of contraceptives on the variability of quantitative kurtosis parameters of the ovaries over the menstrual cycle in diffusion-weighted magnetic resonance imaging (DWI).
Methods and materials: This IRB-approved prospective study included 30 volunteers with or without oral-contraceptives (n=15 for each group, mean 27.9y) from 07/2017-09/2019. MRI was performed using a 1.5T MRI (Aera) with a multi-b-value-epi-DWI 0,50, 100, 800, 1500, and 2000s/mm^2 at three timepoints during the menstrual cycle (T1=day 1-5, T2=day 7-12, and T3=day 19-24). Ovaries were 3D-segmented (b=800s/mm^2). Diffusion-kurtosis (K_{app}) was calculated. Quantitative parameters and coefficient-of-variation (CoeV) were analysed and compared between the groups using Students t-test after Shapiro-Wilk and Brown-Forsythe pretest.
Results: Amongst the women without oral contraceptives, the CoeV for kurtosis parameters was significantly elevated in comparison to the group with oral contraceptives at Timepoint1 (0.34 vs 0.30;p=0.04) and Timepoint2 (0.36 vs 0.32,p=0.018) of the menstrual cycle, however not at Timepoint3 (0.29 vs 0.30;p=0.28). Mean absolute K_{app} was not significantly different in between the women with and without oral contraceptives for Timepoint1=0.618±0.057 vs 0.637±0.039], p=0.14, and Timepoint2=0.606±0.062 vs 0.616±0.059, p=0.54, however, at Timepoint3, significant differences were observed (0.649±0.058 vs 0.596±0.062, p=0.0013).
Conclusion: Quantitative diffusion kurtosis imaging demonstrated a significantly higher coefficient of variation in women with a natural menstrual cycle compared to women using oral contraceptives in the follicular phase. The absolute mean values between the groups only differed significantly during the luteal phase. These findings should be considered when quantitatively applying kurtosis DWI in imaging of the ovaries.
Limitations: A limited number of volunteers, no intra-individual repeated measures, and the influence on suspicious lesions was not investigated.
Ethics committee approval: IRB approved.
Funding: No funding was received for this work.

Multiparametric MRI-based radiomics analysis for preoperative assessment of uterine cervical cancer aggressiveness

Y. Liu, Y. Zhang, Z. Ye*; Tianjin/CN (zywtj@hotmail.com)*

Purpose: To develop and validate models using multiparametric radiomic biomarkers to preoperatively evaluate cervical cancer aggressiveness regarding Ki-67 labelling index and lymphovascular invasion (LVI) status and to predict lymph node metastasis.
Methods and materials: 130 consecutive patients with biopsy-confirmed untreated uterine cervical cancer were enrolled in this prospective study. All underwent surgery within 2 weeks after MRI examination. Ki-67 index and LVI were assessed on whole-tumour slides with HE and IHC staining. Volumetric segmentation was performed by two radiologists who have proven consistency in a preliminary study. B1-field correction, cross-individual rescaling, and intensity normalisation were conducted to reduce the scanner-shifting variety and to promote reproducibility. 690 volumetric radiomic biomarkers were extracted from T1WI, T2WI, and DWI followed by a grouped-ElasticNet workflow to fuse multi-modality data. A structural equation model was used to infer model-wise relationships to validate the rationality of study hypotheses. Habitat descriptors were designed to visualise proposed integrated biomarkers.
Results: The radiomic model achieved AUC 0.79 (0.75, 0.83), a recall rate of 0.86 in LVI predicting, AUC 0.78 (0.74, 0.81), and a recall rate of 0.82 in Ki-67 predicting. 81% of metastatic lymph nodes were recognised with AUC 0.82 (0.74, 0.89), whereas only 33% had a minor-axis diameter greater than 1.0 cm. Among several priori hypotheses, LVI significantly mediated the predictive effect of Ki-67 on pelvic lymphonode metastasis status (p<0.01), which probably reflect pathophysiological facts.
Conclusion: It is feasible and effective to filtrate robust MR biomarkers to depict tumour aggressiveness and to predict lymph node metastasis risk, providing a non-invasive approach in clinical practice.
Limitations: Sample imbalance exists in metastatic lymph nodes that might limit efficiency.
Ethics committee approval: IRB approved with written informed consent from all patients.
Funding: Funded by NSFC Young Scientists Fund.

Diffusion-weighted imaging of cervical cancer: feasibility of ultra-high b value at 3T

Y. Qi, Y. He, C. Lin, X. Wang, H. Zhou, H. Xue, Z. Y. Jin*; Beijing/CN (qiyafei19910603@163.com)*

Purpose: To evaluate imaging quality and compare the signal intensity and ADC maps of ultra-high b-value (2,000 s/mm2; B2) images against those of 800 s/mm2 b-value (B1) images in DWI for cervical cancer.
Methods and materials: 60 patients diagnosed with cervical cancer by pathology were prospectively included. A female pelvis MRI using a 3T MR scanner was performed; B1 and B2 images were obtained for evaluation. Two radiologists blinded to scan parameters evaluated the images for background suppression, spatial distortion, image ghosting, lesion diagnostic confidence, and whole imaging quality using a 5-point scoring system. Scores were compared using a paired Wilcoxon test. Signal intensity (SI) of tumour tissue was measured in B1 and B2 images for tumour and normal reference tissues. Additionally, SI contrast ratios (CRs) were calculated and compared using the Mann-Whitney U test, ADC values of tumours, and normal tissues were measured, and tumour maximum diameters were calculated with T2W imaging.
Results: Background suppression, lesion diagnostic confidence, and whole imaging quality scores were higher in B2 than B1 images ($p < 0.001$). CRs of tumour-to-normal SI were also higher for B2 than B1 images ($p < 0.01$). Mean ADC values derived from B2 images showed better correlations with tumour differentiation grades than did those from B1 images. Tumour diameters measured by B2 imaging experienced a smaller bias.
Conclusion: B2 images in DWI demonstrated superiority in image quality and cervical cancer diagnosis to the commonly used B1 images in female pelvis.
Limitations: Though blinded, it is inevitable that observers could differentiate the B2 and B1 images. Pathologic diameters of the lesions were not available.
Ethics committee approval: This study was approved by ethics committee and written informed consent was obtained.
Funding: No funding was received for this work.

Contrast-enhanced mammography (CEM): a systematic review and meta-analysis of diagnostic performance

A. Cozzi[1], C. B. Monti[1], C. G. Monaco[1], M. Zanardo[1], S. Schiaffino[2], R. M. Trimboli[1], G. Di Leo[2], L. A. Carbonaro[2], F. Sardanelli[2]; [1]Milan/IT, [2]San Donato Milanese/IT (andrea.cozzi@gmail.com)

Purpose: To appraise the diagnostic performance of contrast-enhanced mammography (CEM) through a systematic review and meta-analysis.
Methods and materials: After study protocol registration on PROSPERO, we performed in September 2019 a systematic search on MEDLINE/EMBASE for articles reporting the independent diagnostic performance of CEM. We then excluded studies with temporal subtraction CEM, not focused on lesion detection, evaluating response to neoadjuvant therapy, and not providing data for sensitivity and specificity calculation. For multi-reader studies, we analysed results from the most expert reader. We computed Chi-squared for sensitivity and specificity heterogeneity. We calculated pooled sensitivity, specificity, positive and negative likelihood ratios (LR), and diagnostic odds ratio (DOR). Moreover, we constructed a summary receiver operating characteristics (sROC) curve. Data was reported as point estimates and their 95% confidence intervals (CIs). Risk of publication bias was assessed by visually inspecting the ROC ellipse plot.
Results: From a total of 98 studies, published between 2003 and 2019, we included 50 studies as depicted in the flowchart. These studies involved 7516 patients (mean age ranging from 46–62 years) for a total of 6915 lesions. Chi-squared was significant for sensitivity and specificity (both p<0.001). Pooled sensitivity was 94.1% (95% CI 92.1−95.6%), pooled specificity 66.6% (95% CI 59.6−72.9%), positive LR 2.81 (95% CI 2.28−3.52), negative LR 0.09 (95% CI 0.07−0.11), and DOR 31.8 (95% CI 21.0−47.8). The sROC curve had an area under the curve of 0.921. Visual inspection of the ROC ellipse plot revealed no risk of publication bias.
Conclusion: CEM showed high sensitivity, while its suboptimal specificity could be explained by a lack of standardised descriptors and diagnostic categories, as well as by biased population selection.
Limitations: Possible data duplication in some of the included studies.
Ethics committee approval: No ethics committee approval needed.
Funding: No funding was received for this work.

Impact of contrast-enhanced mammography as a work-up technique for women recalled at breast cancer screening: preliminary results

C. G. Monaco[1], L. A. Carbonaro[2], S. Schiaffino[2], A. Cozzi[1], D. Spinelli[1], R. M. Trimboli[2], G. Di Leo[2], F. Sardanelli[1]; [1]Milan/IT, [2]San Donato Milanese/IT (cristianmonaco87@gmail.com)

Purpose: To evaluate contrast-enhanced mammography (CEM) ability to reduce biopsy rate (BR) in women recalled after first-level screening mammography.
Methods and materials: Recalled women 40-80 yrs were screened to undergo CEM alongside standard assessment (SA: tomosynthesis, additional views, ultrasound, and/or core- or vacuum-assisted biopsy). Exclusion criteria were breast cancer symptoms, allergies to contrast agents, renal failure, pregnancy, or breast implants. One of three radiologists (6-15 years of experience) independently evaluated SA or CEM recommending biopsies or 2-year follow-up. SA was performed independently of, and blinded to, CEM results. Taking SA results as reference standard, we calculated the potential BR after CEM (women candidate to biopsy for positive CEM/women who had CEM) to be compared with the real BR after SA (women who had biopsy following SA/women recalled for SA).
Results: Since January 2019, 181 women were recalled, 102 (56%) being eligible for this study. Ultimately 69/102 (68%) were enrolled and performed CEM. Compared to SA, there 8 were true positives, 52 true negatives, 7 false positives, and 2 false negatives (both ductal carcinoma in situ, DCIS), resulting in 80% sensibility (95% confidence interval [CI] 44–97%), 88% specificity (95% CI 77–95%), 53% positive predictive value (95% CI 27–79%), and 96% negative predictive value (95% CI 87–99%). CEM-BR was 13/69 (18.8%, 95% CI 10.4–30.1%) and SA-BR was 19/69 (27.5%, 95% CI 17.5–39.6%).
Conclusion: With an 80% sensitivity (false negatives represented only by DCIS) and an 88% specificity, CEM in recalled patients showed a potential BR reduction of about one third in comparison to SA.
Limitations: Preliminary results: only one third (n=69) of the planned sample size (n=197). Non-randomised, monocentric study.
Ethics committee approval: Ethics Committee approval was obtained.
Funding: This study was funded by GE Healthcare.

RPS 1002a-3 11:27

Diagnostic value of the delayed image in contrast-enhanced spectral mammography for the assessment of malignancy in BI-RADS 4 mammographic findings

A. Ainakulova, Z. J. Zholdybay, D. Kaidarova, N. Inozemtseva; Almaty/KZ (ar89@list.ru)

Purpose: To assess the performance of the delayed image in CESM to diagnose breast cancer in BI-RADS 4 findings detected by mammography.
Methods and materials: Between May 2018 and May 2019, 150 women with BI-RADS 4 after standard mammography were performed CESM. CESM technique: image acquisition began at a 2-minute delay after the start of the contrast injection and was completed within 6 minutes after initiation of contrast administration. On 8-12 minutes, a set of additional bilateral (lesions of both breast) or monolateral (lesions of one breast) craniocaudal (CC) or mediolateral-oblique (MLO) views was acquired. All the lesions were histologically verified.
Results: 160 lesions were identified, 89 of which were malignant and 71 benign. Malignancy rates were 22.7% (10/44 BI-RADS 4a), 47.5% (29/61 BI-RADS 4b), and 90.9% (50/55 BI-RADS 4c). There were 86 true-positive, 63 true-negative, 8 false-positive, and 3 false-negative (one invasive cancer, two DCIS) CESM findings, effecting a sensitivity, specificity, PPV, and NPV of 96.9% (95%-CI 90.9–99.2%), 92.9% (95%-CI 86.5–97.9%), 92.2% (95%-CI 85.6–96.9%), and 97.2% (95%-CI 92.2–99.5%), respectively.
Conclusion: CESM is an accurate tool to further diagnose BI-RADS 4a and 4b lesions and may be helpful to avoid unnecessary biopsies. BI-RADS 4c lesions should be biopsied irrespective of CESM findings. Delayed image increases the specificity of the method by 10%.
Limitations: Small number of patients.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Diagnostic accuracy of contrast-enhanced digital mammography (CEDM) in breast cancer detection among women with dense breast in comparison to digital mammography and ultrasound

R. Sudhir, V. Koppula, K. Sannapareddy; Hyderabad/IN (rashmi4210@gmail.com)

Purpose: Comparative diagnostic accuracy of digital mammography, US, and contrast-enhanced digital mammography (CEDM) in breast cancer detection among women with dense breast with histopathological diagnosis as the gold standard.

Methods and materials: A prospective study on consecutive women >40 years with dense breast on conventional imaging who underwent CEDM and biopsy at our centre were included. Women with h/o pregnancy, renal insufficiency, or prior allergic reaction to iodinated contrast agent were excluded. On mammography and ultrasound, lesions were categorised based on ACR BI-RADS fifth edition. On CEDM, lesions were categorised based on the intensity and dynamic patterns of contrast enhancement. Moderate to intense enhancement with wash-out in delayed phase were considered malignant and lesions with no enhancement or progressive enhancement were considered benign lesions. Statistical analysis was done using SPSS software version 21.
Results: A total of 156 lesions, 87 malignant and 69 benign lesions, were included. For mammogram, US, mammogram and US combined, and CEDM, sensitivity was 92.7%, 71.3%, 94.2%, and 96.6%; specificity 52.2%, 75%, 82.6%, and 83%; and accuracy 73.5%, 76.3%, 85.7%, and 92%, respectively.
Conclusion: CEDM is an emerging tool with significantly better diagnostic efficiency and accuracy than the mammogram and US alone or combined, therefore it may play a promising role in early detection, diagnosis, staging, and follow-up of breast cancer in women with dense breast at lesser cost and much shorter examination time compared to MRI.
Limitations: Radiation exposure 1.5 times of conventional digital mammography. CEDM cannot be performed in women with renal insufficiency and a history of allergy to iodinated contrast. Depth of the lesion and chest wall invasion cannot be assessed as accurately as MRI.
Ethics committee approval: Approved from an ethics committee.
Funding: No funding was received for this work.

The comparative role of contrast-enhanced spectral mammography and contrast-enhanced MRI in preoperative diagnosis and management decision of sonomammography suspicious lesions

M. M. Gomaa, M. M. H. Hanafy, R. M. Kamal, S. A. Mansour, M. Hassan, G. Mohamed*; Cairo/EG (mohammedgomaa555@yahoo.com)*

Purpose: To compare the role of contrast-enhanced spectral mammography and dynamic contrast-enhanced MRI in the preoperative diagnosis of suspicious breast lesions detected on sonomammography and evaluation of disease extension of the proved breast cancer.
Methods and materials: This study included 171 lesions in 82 patients. All patients underwent digital mammography, breast ultrasound, CESM, and contrast-enhanced MRI breast. Results were correlated to histopathological details.
Results: Histological analysis: 51/171 (29.8 %) lesions were benign while 120/171 (70.2 %) were malignant.
The accuracy measures of CESM and DCE-MRI were higher than that of sonomammography. DCE-MRI sensitivity and NPV were significantly higher than CESM (p-value 0.014 and 0.013). The overall accuracy of MRI was better than CESM, however, no statistically significant difference was detected.
Axillary lymph nodes were assessed by SM, CESM, and MRI in cases with malignant lesions and their sensitivities were 93.8 %, 50 %, and 87.5 %, respectively, and their specificities were 90.3%, 93.5 %, and 93.5%, respectively.
Regarding multiplicity, both DCE-MRI and CESM were better than SM in their detection, with DCE-MRI superior to CESM.
Regarding size assessment, we found no correlation between SM and postoperative size, with weak agreement, high correlation, and agreement between CESM and postoperative size, slightly higher correlation and agreement between DCE- MRI and postoperative, with high correlation and agreement between CESM and DCE-MRI.
Conclusion: MRI is still the best study in preoperative diagnosis and management decision of breast cancer, however, contrast-enhanced spectral mammography is a feasible comparable technique with promising results.
Limitations: Different biological subtypes of included breast cancer patients.
Ethics committee approval: Approved by ethical committee of faculty of medicine at Cairo University. Written consent was obtained from all patients.
Funding: No funding was received for this work.

Contrast-enhanced digital mammography: what is the added value in the diagnostic work-up of microcalcifications?

A. Franconeri[1], D. de Benedetto[2], C. Bellini[2], M. C. Masciotra[3], R. Trapasso[2], G. Bicchierai[2], F. Di Naro[2], J. Nori[2], V. Miele[2]; *[1]Pavia/IT, [2]Florence/IT, [3]Campobasso/IT (afrancon88@gmail.com)*

Purpose: To assess the added value of contrast-enhanced digital mammography (CEDM) in the evaluation of microcalcifications.
Methods and materials: We retrospectively screened 1233 women who performed CEDM from September 2016 to August 2018. Inclusion criteria were the presence of microcalcifications on a mammogram, biopsy-proven histological diagnosis, and the absence of an associated mass. CEDM performed with no residual microcalcifications after biopsy were excluded. CEDM sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy were calculated. Microcalcifications morphology and associated enhancement were independently reviewed by 2 radiologists with 6 and 24 months of CEDM experience, respectively. Interobserver agreement was calculated with Cohen's kappa test.
Results: The final population included 138 women (52.99±9.92 years old). 87 microcalcifications presented enhancement: 45 out of 50 (90.0%) were carcinomas (B5), 26 out of 34 (76.5%) lesions with uncertain malignant potential (B3), and 16 out of 54 (29.6%) benign lesions (B2). All 5 B5 without enhancement were carcinomas in situ. Carcinoma in situ presented as mild to moderate progressive non-mass enhancement, invasive carcinoma as moderate to intense wash-out mass enhancement. Out of 8 B3 without enhancement, only 1 (12.5%) upgraded to carcinoma in situ. All morphologically different types of microcalcification presented high NPV and included rounded/punctiform calcification (VPN=94.4%). The overall diagnostic sensitivity of CEDM was 89.5%, with 57.0% specificity, 60.0% PPV, 88.2% NPV, and 70.6% accuracy. AUC was 0.81 according to ROC curve. Substantial agreement was observed between the two observers (K=0.71).
Conclusion: CEDM represents a novel technique with good ability in detecting and characterising microcalcifications. Morphology and distribution still play the most important role in the decision planning, however, CEDM can help when rounded/punctiform microcalcifications or B3 lesions are found.
Limitations: A retrospective study, small sample, and CEDM performed after biopsy.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Evaluation of contrast-enhanced digital mammography (CEDM) in the preoperative staging of breast cancer: large-scale single-centre experience

G. Bicchierai, P. Tonelli, D. de Benedetto, F. Di Naro, D. Cirone, V. Miele, J. Nori*; Florence/IT (giulia.bicchierai@gmail.com)*

Purpose: One of the most important indications for contrast-enhanced breast imaging is the pre-surgical breast cancer (BC) staging. This is the large-scale single-centre experience evaluating the role of CEDM in pre-surgical staging. The aims of this retrospective study were to define the diagnostic performance of CEDM in the pre-surgical setting and to identify which type of patient may have a greater advantage of having CEDM.
Methods and materials: We selected 326 patients with BC who performed CEDM as preoperative staging and had breast cancer-related surgery at our institution. We analysed when CEDM led to additional imaging or biopsy and when it changed the type of surgery that was planned according to conventional breast imaging (CI) techniques (digital mammography, tomosynthesis, and ultrasound). CEDM diagnostic performance in the correct preoperative staging of BC of the whole population and into various subgroups were calculated.

Results: CEDM sensitivity for the index lesion was 98.8%, which led to additional breast imaging in 23.6% and additional biopsies in 17.5%. CEDM changed the type of surgery in 18.4%. In the preoperative BC staging, CEDM sensitivity, specificity, PPV, and NPV and accuracy resulted in 93%, 98%, 90%, 98%, and 98%, respectively. CEDM performance was better in patients with palpable lesions.
Conclusion: CEDM has an excellent diagnostic performance in the pre-surgical staging of BC. Symptomatic patients with palpable lesions benefitted most from CEDM, with a statistically significant difference.
Limitations: The most important limitations are the patient population we selected i.e. patients with histological-proven BC, not a screening population, which may have influenced the high rate of surgical change and the retrospective nature of the study.
Ethics committee approval: The local institutional review board (IRB) approved this retrospective analysis.
Funding: No funding was received for this work.

Preoperative evaluation of breast cancer: diagnostic performance of contrast-enhanced digital mammography compared to magnetic resonance imaging

C. Depretto[1], A. Liguori[1], A. Borelli[1], G. Boffelli[2], C. G. Monaco[1], F. Cartia[1], C. Ferranti[1], G. Scaperrotta[1]; [1]Milan/IT, [2]Pavia/IT
(cathie.dp@gmail.com)

Purpose: To compare the diagnostic performance of contrast-enhanced digital mammography (CEDM) and magnetic resonance imaging (MRI) in preoperative evaluations and to evaluate the effect of each modality on surgical management.
Methods and materials: From January 2018 to July 2019, 96 patients with newly diagnosed invasive breast cancer underwent CEDM and MRI. Imaging findings were correlated with pathological results and compared. The diagnostic performance in the detection of index and secondary cancers and occult contralateral cancers was compared. We also evaluated whether CEDM or MRI resulted in additional imaging and in changes in surgical management. Patients also completed a questionnaire indicating their preference between CEDM and MRI.
Results: 96 women with 113 target lesions were included in the analysis. CEDM demonstrated a similar sensitivity to MRI (96% vs 100%) in detecting target lesions. For the detection of secondary cancers in the ipsilateral breast and occult cancers in the contralateral breast, no significant differences were found between CEDM and MRI. CEDM resulted in minor false-positive results at additional imaging compared with MRI (7% vs 12%) and in minor changes in surgical management compared with MRI (19% vs 26%). 93 women replied to the questionnaire regarding the preference between CEDM versus RM and most preferred CEDM (71% vs 12%), mainly for the shorter examination time (90%).
Conclusion: CEDM demonstrated a diagnostic performance comparable with MRI in depicting index cancers, secondary cancers, and occult cancers in the contralateral breast. CEDM demonstrated minor false-positive results and minor changes in surgical management and it was preferred by women.
Limitations: We have only one set of preliminary results.
Ethics committee approval: This single-centre prospective study was approved by the Institutional Review Board and informed consent was obtained from all patients.
Funding: No funding was received for this work.

RPS 1002a-9 12:03

Contrast-enhanced digital mammography (CEDM) for monitoring the response of breast cancers to neoadjuvant chemotherapy: a comparison with MRI

D. Bernardi[1], A. Acquaviva[2], M. Valentini[3], V. Sabatino[3], M. Pellegrini[3], C. Fantò[3]; [1]Milan/IT, [2]Naples/IT, [3]Trent/IT
(Daniela.Bernardi@humanitas.it)

Purpose: To compare the performance of CEDM and MR in estimating the response to neoadjuvant chemotherapy (NAC) and assessing the size of the residual tumour.
Methods and materials: 63 women who underwent NAC for breast cancer had both CEDM and MR before starting (PRE), during (MID), and at the end of NAC (POST). One radiologist looked at CEDM while another looked at MR. Both reported, for each exam and NAC step, the largest diameter of the target lesion. Response to therapy was finally classified according to RECIST criteria, comparing MID- with PRE-NAC, then POST- with MID-NAC lesion-size. Pathological results used as a reference standard for comparison with the last CEDM and MR controls. Statystical analysis: Pearson correlation and Bland Altman plot to test the agreement for measurements and Chi-square test to evaluate the agreement for RECIST classification.
Results: There was consistent correlation between CEDM and MR measurements in PRE (0.94, IC 0.90-0.96), MID (0.92, IC 0.86- 0.95), and POST-NAC (0.92, IC 0.86-0.95).
The correlation was less consistent when comparing CEDM and MR POST NAC measurements with those of pathologists (respectively 0.64, 95% CI 0.44-0.77 and 0.63, IC 95% 0.44-0.77).
Classifying the response to therapy according to RECIST criteria, there was significative agreement between CEDM and MR both at MID-NAC (88.2%, p <0.0001) and POST-NAC (84.6%, p <0.0001). Comparing POST-NAC controls with pathologist response, the agreement was higher for MR (84.6%, p <0.0001) compared to CEDM (77%, p <0.0001).
MR showed significant higher sensitivity (79% vs 69%) and specificity (100% vs 91%) than CEDM in assessment complete response (CR)
Conclusion: CEDM performed similarly to MR in evaluating the response to NAC and may represent an alternative in case of contraindications or when MR is not available.
Limitations: A single-institution experience.
Ethics committee approval: IRB approval.

Contrast-enhanced spectral mammography with a compact synchrotron source

L. Heck[1], M. Dierolf[1], T. Sellerer[1], K. Mechlem[1], B. Günther[1], S. Metz[2], D. Pfeiffer[2], K. Kröninger[3], J. Herzen[1]; [1]Garching/DE, [2]Munich/DE, [3]Dortmund/DE

Purpose: Contrast-enhanced spectral mammography (CESM) based on K-edge subtraction (KES) helps to identify uncertain findings in standard mammography. As CESM requires two acquisitions, dose reduction is a crucial issue. Here, two dual-energy dose-compatible CESM approaches were evaluated with a compact synchrotron source.
Methods and materials: In this study, two CESM techniques, the commonly used dual-energy KES imaging and a two-material decomposition, were evaluated at a quasi-monochromatic compact synchrotron x-ray source. For a better comparison to the laboratory results, clinical CESM images were performed. Low-energy attenuation-based images were acquired and images showing the contrast agent iodine were calculated with a modified mammographic accreditation phantom in both the clinical and the laboratory measurements.
Results: Confirmed by a higher contrast-to-noise ratio (CNR) and spatial resolution, improved image quality was achieved with both the aforementioned iodine image calculation methods. The spectral approach achieved even better results than KES. We demonstrate the reduction of the applied dose by up to 66% compared to the clinically applied dose at equal CNR. Additionally, the image quality of the laboratory results of the low-energy images also increased compared to the clinical examinations.
Conclusion: Our findings regarding the CNR and the spatial resolution suggest the great potential of the two-material decomposition approach as a means to improve the diagnostic quality and to reduce the dose in clinical examinations.
Limitations: This study suffers from the time-consuming energy change of the compact synchrotron x-ray source which takes about 30 minutes but can be reduced to a few seconds in the future. In addition, the energies could be optimised by oscillating directly around the absorption K-edge.

Dedicated spiral breast CT with a single-photon counting detector: initial results of the first 300 women
N. Berger, M. Marcon, T. Frauenfelder, A. Boss*; Zurich/CH*

Purpose: Initial clinical experiences using a dedicated spiral-breast CT (B-CT) with a single-photon counting detector.
Methods and materials: 300 consecutive women undergoing B-CT were evaluated on the reason of assignment for B-CT instead of mammography, a detection rate of breast cancer and, quality criteria of data acquisition. Furthermore, the number of additional ultrasound examinations due to unclear findings or dense breast tissue and reliability of the technical data acquisition were assessed.
Results: 591 B-CT acquisitions in 300 women were performed. The lack of breast compression (254 of 300, 84.7%) was the main reason to choose this method over mammography, which was desired due to personal reasons or mastodynia. 10 patients (0.3%) had implants hampering mammography. 102 possible lesions were detected in B-CT, including 4 cases of breast cancer (1.3% of all patients). Additional ultrasound was performed in 226 patients (102 due to detected lesions and 124 due to dense breast tissue). 3 malignant lesions were detected in an additional ultrasound (1% of all patients). As quality-criteria, the pectoralis muscle was included in 341 of 591 examinations, but a complete assessment of breast tissue was only possible in 149 examinations. No movement artifacts were noted. In 99% of all women, the examination could be realised.
Conclusion: The dedicated B-CT provides high-quality images and can be used as an alternative, in particular in those patients not otherwise willing to perform mammography because of the breast compression.
Limitations: Single-centre and retrospective study.
Ethics committee approval: The institutional review board approve this retrospective study.
Funding: No funding was received for this work.

Optimisation of photon-counting breast CT for spectral single-scan contrast-enhanced imaging: a phantom study
V. Ruth, D. Kolditz, C. Steiding, W. A. A. Kalender*; Erlangen/DE*

Purpose: Optimising the settings of a photon-counting breast CT (pcBCT) for spectral contrast-enhanced imaging from a single scan and evaluating the accuracy according to iodine quantification and the creation of virtual-unenhanced images (VNC).
Methods and materials: The settings of a pcBCT with 100µm detector element size and integrated charge-sharing correction were adapted to maximize the signal to noise ratio (SNR) between the contrast agent and soft tissue. Therefore, the energy threshold separating the x-ray spectrum was swept from 23.1keV to 50.6keV. Validation measurements were performed with contrast agent samples (2.5 to 25mg Iodine/ml) in phantoms with a 7.5 cm and 12 cm diameter. Iodine maps and VNC images were generated from a single scan using image-based material decomposition. Iodine concentrations and CT values were measured and compared to the known concentrations and reference CT values.
Results: Spectral single-scan contrast-enhanced pcBCT was feasible. Maximal SNRs were found at a threshold position of 32.5keV. Accurate iodine quantification (average RMSE of 0.56mg/ml) was possible down to 2.5 mg Iodine/ml. Minor changes of CT values compared to non-enhanced CT scans were observed in the VNC images -1.2±21.6HU and 4.9±67.4HU (7.5 and 12 cm phantom). The noise was increased by the decomposition by a factor of 2.62 and 4.87 (7.5 and 12 cm phantom) but did not compromise accurate iodine quantification.
Conclusion: Accurate iodine quantification and the creation of VNC images can be achieved using contrast-enhanced pcBCT from a single CT scan under the complete absence of temporal or spatial misalignment. Using iodine maps and VNC images, pcBCT has the potential to reduce dose, shorten examination and reading time, and to increase cancer detection rates.
Limitations: The CT scans presented were performed on a bench testing model of a commercially available pcBCT system.

Motion correction for super resolution 2D multislice MRI: application to prostate
S. Riederer, E. Borisch, R. Grimm, S. Kargar, A. Kawashima*; Rochester, MN/US (riederer@mayo.edu)*

Purpose: Describe how slice-to-slice displacement occurring in 2D multi-slice acquisition of overlapped slices can be corrected, allowing high quality reformats in other orientations.
Methods and materials: Super-resolution is a method which provides improved through-plane resolution in a 2D acquisition by using input data comprised of overlapped slices. T2-weighted spin-echo (T2SE) imaging is typically acquired in multiple passes to avoid slice-to-slice interference. The resultant e.g. axial images can be reformatted into other orientations, e.g. sagittal or coronal. For static objects, this can be effective. However, for subtle (≈1 mm) motion as in T2SE of the prostate, the reformats can have objectionable “scalloping” artefact. Here we describe a correction algorithm. Because consecutive axial slices are overlapped, they are highly correlated. Using cross-correlation we determine and correct for slice-to-slice displacement between adjacent slices. The knowledge that subsets of slices are acquired within the same pass allows additional constraints on the correction. The method was assessed in 16 patients undergoing prostate MRI. Each was imaged using 78 3-mm thick slices with 2 mm slice-to-slice overlap. Slice sets with and without motion correction were subjected to super-resolution processing, and sagittal reformats were evaluated for artefact inhibiting visualisation of the margin between the prostate and anterior rectal wall.
Results: In 13 of the 16 studies, the level of the artifact was reduced modestly or significantly. Plots displacements, used for correction, from a fiducial (X, Y) mean value in the transverse direction of all 78 slices acquired. Figure 2 compares sagittal reformats using uncorrected (left) and corrected (right) axial image sets.
Conclusion: Retrospective motion correction of T2SE axial images of the prostate allows high-resolution artefact-suppressed reformatting in other orientations.
Limitations: Limited number of studies.
Ethics committee approval: This study was approved by the IRB.

Dynamic contrast-enhanced magnetic resonance imaging during free breathing for hepatic lesions: clinical applicably and limitations

M. C. Langenbach[1], L. Basten[2], D. Maintz[1], T. J. Vogl[2], T. Gruber-Rouh[2], J.-E. Scholtz[2], B. Kaltenbach[2]; [1]*Cologne/DE,* [2]*Frankfurt am Main/DE (marcel.langenbach@me.com)*

Purpose: To evaluate the clinical applicability and limitations of this new prototype volume-interpolated breath-hold examination (VIBE) with compressed sensing (VIBEcs) for rapid multiphase MRI with a free selectable variable temporal resolution for hypervascularised hepatic lesions.
Methods and materials: Twenty patients with hypervascularised hepatic lesions were included in this prospective study and underwent contrast-enhanced liver MRI at 3T. In all patients, VIBEcs was used for rapid arterial multiphase imaging. Results were analysed regarding image quality and clinical applicability of the dynamic lesion evaluation. Evaluation of image quality, visibility and conspicuity were performed by three independent radiologists, each with more than 5 years of experience, based on a 5-point Likert scale (5=excellent). Results were correlated with the lesion entity. Limitations for the use of VIBEcs in image acquisition were defined. Time curves of dynamic contrast enhancement were plotted for each patient and quantification of attenuation performed to isolate the optimal time-point for image acquisition.
Results: All patients were successfully evaluated. Individual setting of acquisition time point (best point 40.6 seconds) instead of fixed delay allowed high reading scores for image quality, visibility and conspicuity for all lesions (mean score >4). Lesion entity showed no significant impact on the reading performance (p=0.765). The limitation was defined as follows: small lesion size (<8mm), subdiaphragmatic localisation, large necrotic area (>80% of the lesions).
Conclusion: Free-breathing MRI with VIBEcs allows image acquisition with high temporal and spatial resolution using individual acquisition time points during contrast phase to gain optimal results with a robust acquisition protocol.
Limitations: The intention was to test the feasibility. Small patient cohort and a single centre.
Ethics committee approval: The study protocol was approved by the institutional review board. Written obtained consent was obtained by all patients prior to inclusion.
Funding: No funding was received for this work.

Radiomics and 3T DCE-MRI in breast cancer: is it possible to predict the response to neo-adjuvant chemotherapy?

C. Cavedon, M. V. Bisighin, G. Benetti, C. Zerbato, L. Camera, S. A. Montemezzi; *Verona/IT (carlo.cavedon@aovr.veneto.it)*

Purpose: To obtain a predictive model based on MRI radiomic features for classification of new patients between responders and non-responders to neo-adjuvant chemotherapy (NAC).
Methods and materials: 60 patients who underwent pre-NAC 3T DCE-MRI and NAC due to breast cancer between January 2015 and October 2018 were included in the study. Two radiologists contoured the lesion in both the pre-contrast and third DCE-MRI scan with a semi-automatic tool. Images were resampled with square voxels (0.9 mm). 214 radiomic features were extracted for each patient, including textural metrics of GLCM, GLRLM, GLSZM, NGTDM and GLDM. Least absolute shrinkage and selection operator (LASSO) was used to select the most suitable grey-level quantization and for feature reduction. Logistic regression and support vector machine (SVM) were used to build a model based on the most significant features. The performance of the multivariable models was assessed by means of ROC analysis, using a leave-one-out cross-validation.
Results: Features including sphericity of the lesion, kurtosis and several higher order metrics turned out to be correlated with the radiological complete response to NAC ($p<0.05$). The multivariable logistic model, built with the 8 LASSO-selected features, showed sensitivity, specificity, and area under the ROC curve of 0.74, 0.79, and 0.76, respectively, whereas for the SVM model they were 0.67, 0.88, and 0.80.
Conclusion: The presented predictive model provides an indication on the potential of 3T DCE-MRI-based radiomics to predict NAC outcome. Even though the sensitivity of the model is not high enough to grant clinical use, it can provide a substantial support on decision making.
Limitations: This is a single-institution study.
Ethics committee approval: This study was approved by the institutional review board of the "Azienda Ospedaliera Universitaria Integrata - Verona".

A correction of MR field non-uniformity dedicated to breast imaging

F. Khalid[1], P. Akl[2], D. Sebbag Sfez[2], C. Malhaire[2], F. Frouin[1]; [1]*Orsay/FR,* [2]*Paris/FR (frederique.frouin@inserm.fr)*

Purpose: The aim of the study was to compensate for MR field non-uniformities of breast MRI on retrospective data sets, a prerequisite step to compute robust radiomic features.
Methods and materials: The N4ITK algorithm, widely used to correct for bias field in brain studies, was tested on breast images. As the preset values of the hyperparameters (adapted to cerebral MRI) were not relevant for breast, a grid search of hyperparameters was applied to define corrections relevant for different types of MR breast images. The method was applied to T1-weighted images acquired on a breast phantom and a retrospective dataset of 41 T1-weighted DCE MRI, acquired in our institution with a 1.5 T Magnetom MRI scanner, using two different coils. The impact of the correction was assessed by computing relative image intensities variation between left and right normal tissues in the pectoral muscles (PMr) and the healthy breast parenchyma (BPr), and in the inner and outer layers in the phantom.
Results: New default parameters of N4ITK (5 fitting levels, 50 iterations, mask on the breast region) were necessary for bias field correction. The comparison of PMr and BPr values before and after correction showed a significant reduction after N4ITK (p-value =0.05 for PMr, $< 10^{-5}$ for BPr). Similar trends were found on the phantom images.
Conclusion: Retrospective studies need a posteriori algorithms to correct for spatial non-uniformity. Optimised values of N4ITK correction were proposed for breast MRI. Even if perfectible, this fully automatic solution is already useful and should be easily embedded in further radiomic studies.
Limitations: Further investigations should characterise bias fields for each coil.
Ethics committee approval: Institutional Review Committees approved this retrospective study and waived informed consent.
Funding: No funding was received for this work.

Investigation of radiomic features repeatability and reproducibility in MRI with a dedicated pelvis phantom

L. Bianchini[1], J. Santinha[2], N. Loucao[2], F. Botta[1], D. A. Origgi[1], M. Cremonesi[1], N. Papanikolaou[2], A. Lascialfari[1]; [1]*Milan/IT,* [2]*Lisbon/PT (linda.bianchini@unimi.it)*

Purpose: The aim of this study was to evaluate the repeatability and the reproducibility of radiomic features on two 1.5 T MRI scanners of different vendor.
Methods and materials: T_2-weighted images of a dedicated pelvis phantom were acquired on scanner A, repeating the acquisitions 10 times without changing the sequence parameters. The phantom was repositioned and the acquisitions repeated. 16 regions of interest were drawn on the phantom inserts. PyRadiomics was used to normalise images and extract radiomic features on original and filtered images. The phantom was acquired on scanner B and the procedure repeated in the same way. To test repeatability - with and without phantom repositioning - the interclass correlation coefficient (ICC) for an absolute agreement was calculated pairwise for each radiomic feature comparing the acquisitions intra-scanner. In order to test reproducibility, the ICC (consistency and absolute agreement) was determined to compare the acquisitions inter-scanner.
Results: Repeatability: the features showing excellent repeatability (ICC > 0.9) were on average 97% for scanner A and 92% for scanner B (no repositioning). The features showing excellent repeatability when repositioning the phantom were 24% (scanner A) and 36% (scanner B). Reproducibility: the features with excellent consistency and agreement were 19% and 10% of the total

respectively. The most stable features were those extracted from wavelet filtered images and belonging to the first order and glrlm categories.
Conclusion: The radiomic features showed excellent repeatability when the experiment was performed without any variation. However, less than a quarter of the features proved excellent repeatability when the phantom was repositioned. A selection of the reproducible features should be carried out in case of multicentric studies, given the low reproducibility observed comparing two different scanners.

Transchelation of gadolinium ions from GBCA to glycosaminoglycans: linear vs macrocyclic GBCA

P. Schuenke, P. Werner, M. Taupitz, L. Schröder*; Berlin/DE (schuenke@fmp-berlin.de)*

Purpose: Several studies reported that gadolinium (Gd) can be retained in various tissues in patients treated with Gd-based contrast agents (GBCA). However, the exact mechanism of Gd deposition in tissue is not fully understood. In this study, we quantitatively investigate the transchelation of Gd ions from GBCA to glycosaminoglycans (GAGs) as a potential explanation for observed long-term enhancements in vivo.
Methods and materials: Linear and macrocyclic GBCAs were dissolved in water and GAG solutions with different concentrations of $ZnCl_2$. Using a saturation recovery MRI sequence, ROI-averaged, quantitative, time-resolved R_1 values were extracted from T_1-weighted image series. All MR measurements were performed on a 9.4T preclinical MRI system (Bruker, Germany).
Results: Using MR relaxometry, the release of Gd ions from GBCA was quantified and the higher stability of macrocyclic GBCAs was confirmed. The individual contributions to observed relaxation rates could be quantified. Further, the chelation of Gd ions in GAGs was proven using MR relaxometry and confirmed by means of isothermal titration calorimetry (ITC) measurements. The relaxivities of resulting Gd-GAG complexes were determined and found to be about eight times higher compared to GBCAs. At a physiological $ZnCl_2$ concentration (2 mM), about 20% of Gd ions were shown to be translated from Gd-DTPA to GAGs.
Conclusion: We could prove the transchelation of Gd ions from (linear) GBCA to glycosaminoglycans, which are ubiquitous in the human body. The fact that the resulting Gd-GAG complexes have very high relaxivities means that small amounts (~20% of linear GBCA dissociated) can have huge effects on T_1-weighted contrasts and thus could be an explanation for the observed long-term enhancements in vivo.
Limitations: The simple model system does not fully describe the in vivo situation.

Diffusion tensor distribution imaging: a novel framework for quantifying microscopic tissue heterogeneity in brain tumours

J. P. de Almeida Martins[1], S. Lasic[1], Y. Zheng[2], Q. Wei[3], S. Li[4], W. Sun[4], H. Xu[4], D. Topgaard[1]*; [1]Lund/SE, [2]Houston, TX/US, [3]Shanghai/CN, [4]Wuhan/CN (daniel.topgaard@fkem1.lu.se)*

Purpose: Conventional diffusion tensor imaging (DTI) metrics are challenging to interpret in terms of specific tissue properties. Here, we address this problem by designing novel acquisition and analysis protocols that quantify the sub-voxel composition of the living brain with nonparametric diffusion tensor distributions (DTDs).
Methods and materials: We used a UIH uMR 790 3T MRI system to scan three patients with biopsy-proven pathologies: meningioma, glioblastoma, and intracranial cyst. Data was acquired with a custom diffusion-weighted EPI sequence in less than five minutes and converted to voxel-wise DTDs using a model-free inversion algorithm. The spatially-resolved DTDs were converted to a novel set of 15 parameter maps informing about the diffusivity, anisotropy, and orientation of the microscopic tissue environments.
Results: Healthy tissues are all characterised by distinctive distributions that accurately capture their corresponding diffusion properties; white-matter: low diffusivity, high anisotropy; grey-matter: low diffusivity, low anisotropy; cerebrospinal fluid: high diffusivity, low anisotropy. The investigated pathologies showed different diffusion properties: meningioma presents low diffusivity and high anisotropy, glioblastoma exhibits low diffusivity and low anisotropy, and intracranial cyst displays an isotropic core enveloped by anisotropic tissue. Maps derived from the DTDs allowed a compact visualisation of sub-voxel composition and displayed good agreement with the expected tissue properties.
Conclusion: The proposed framework with spatially-resolved DTDs is capable of resolving and characterising sub-voxel tissue environments that are indistinguishable in conventional DTI. The novel statistical maps derived from the distributions displayed good contrast between different tissues types and provided valuable insight into the structural properties of the studied pathologies.
Limitations: This pilot study is limited by the low number of investigated patients.

Diffusion-tensor imaging, fibre tracking: differences between probabilistic and deterministic approaches for neurosurgical planning

L. Berta, D. Lizio, L. Gennari, M. Rizzi, C. Regna Gladin, E. Marcati, M. Cenzato, G. Lo Russo, A. Torresin*; Milan/IT (alberto.torresin@unimi.it)*

Purpose: The reconstruction of fibre tracts (FT) of white matter in the brain from diffusion tensor imaging (DTI) data is daily performed at our centre for neurosurgery and stereo-electroencephalography planning in epilepsy patients. Aim of this study is to compare two different algorithms for FT.
Methods and materials: We selected 16 patients planned for neurosurgery and acquired with an echo-planar imaging sequence using a receive coil head SENSE 8-channel on a Philips Achieva 1.5T scanner (64 directions, b-value 1000mm^2/s). Cortico-spinal tracts were reconstructed with different algorithms using the same input data (i.e. DTI images and regions of interest for seed and waypoints). We used Intellispace Portal v8.0 (Philips Healthcare), a commercial platform for medical image management with a module for the deterministic reconstruction of FT, and the probabilistic algorithm PROBTRACKX by FSL v5.0.6, a free-distributed software for analysis of MRI brain images (https://fsl.fmrib.ox.ac.uk/fsl/fslwiki). For each patient, the tracts were compared in terms of the distance of their centre of gravity (DCoG) and Dice index (DI) calculated within each axial slice of the brain peduncle (BP), internal capsule (IC) and cerebral cortex (CC).
Results: The average DCoG in the BP, IC and CC were, respectively 5.2, 5.5, 9.3mm. The average DI values for the same anatomical sites were 30%, 43%, 12% with values within 0% and 70%, meaning a partial or absence of overlap of the FT reconstructed with the two methods.
Conclusion: The two algorithms for FT shows geometrical differences that cannot be ignored and should be discussed with the neurosurgery team.
Limitations: Clinical validation of FT reconstructed from DTI acquisition with neurophysiological data is mandatory.

Orientation-resolved means of diffusivities and transverse relaxation times in heterogeneous brain tissue

A. Reymbaut[1], J. de Almeida Martins[1], C. Tax[2], F. Szczepankiewicz[1], D. Jones[2], D. Topgaard[1]; [1]*Lund/SE,* [2]*Cardiff/UK*
(alexis.reymbaut@fkem1.lu.se)

Purpose: In white matter, the millimetre-scale resolution of diffusion MRI may encompass myelinated axons and unknown fractions of grey matter, cerebrospinal fluid, or pathological tissue. To tackle this heterogeneity, conventional approaches rely on assumptions regarding tissue properties. This work combines novel MRI acquisition and processing methods to extract voxel-scale nonparametric 5D distributions of diffusion tensors (microstructure) and T_2 (chemical composition) without the use of limiting assumptions. Orientation-resolved (fiber-specific) means of diffusivities and T_2 are then defined via orientation clustering within the 5D distributions.
Methods and materials: A healthy volunteer was scanned on a 3T Siemens MAGNETOM Prisma using an EPI sequence customised for tensor-valued diffusion encoding and variable echo times. A nonparametric 5D distribution of diffusion tensors and T_2 is estimated in each voxel via a Monte-Carlo inversion algorithm. This algorithm also provides uncertainty on the estimated distribution and orientation distribution functions (ODFs) of anisotropic components. Finally, orientation-resolved means of isotropic diffusivity ("size"), normalised anisotropy ("shape") and T_2 are computed using an in-house orientation-clustering algorithm.
Results: ODFs present orientations that are consistent with the known anatomy, and are estimated in all areas of the brain, including heterogeneous voxels that comprise white matter, cerebrospinal fluid and/or grey matter. In parallel, our clustering procedure yields the median and interquartile range (uncertainty) of the orientation-resolved means of sizes, shapes and T_2.
Conclusion: We tease apart intra-voxel fibres and separately characterise their respective microstructure and chemical composition. This work shows potential in the understanding and longitudinal tracking of brain development and neurodegenerative diseases.
Limitations: Pilot study limited by the low number of investigated subjects.
Ethics committee approval: Approved by the IRB of Cardiff University School of Medicine.

Natural abundance C13 magnetic resonance spectroscopy quantification of mono-and polyunsaturated fatty acids: influence of diet

R. Garcia-Alvarez[1], B. Bartnik-Olson[2], A. F. Rodríguez-Hernández[3], C. Modroño[3], J. L. González-Mora[3], N. Sailsuta[4]; [1]*Madrid/ES,* [2]*Loma Linda, CA/US,* [3]*Santa Cruz de Tenerife/ES,* [4]*Pasadena, CA/US (R.Garcia@ge.com)*

Purpose: Lipid composition of body fat can be a key indicator of nutritional status and other related human disorders. In vivo C13 magnetic resonance spectroscopy (MRS) enables the non-invasive study of fatty acids, notably two key unsaturated fatty acids: monounsaturated fatty acids (MUFA) and polyunsaturated fatty acids (PUFA). The purpose of this work is to utilise C13-MRS to quantify MUFA and PUFA in a cohort of healthy volunteers with well-established diets.
Methods and materials: A total of 13 carnivores (6 males, 7 females; mean age 49 ± 17 years) and 14 vegetarian (9 males, 5 females; mean age 43 ± 19 years) subjects were scanned on a clinical 3.0T GE Signa-HD scanner using a dual-tuned C13-H1 coil. The MRS acquisition consisted of a natural abundance non-decoupled C13 pulse sequence. MUFA and PUFA peaks were quantified in the frequency domain using a Marquardt fitting algorithm. Between-group differences in the PUFA/MUFA ratio were compared using a paired t-test.
Results: A non-decoupled, natural abundance C13-MRS spectrum from the calf muscle of a vegetarian subject in the region of mono and polyunsaturated lipid resonances was observed. Compared to carnivores, vegetarian subjects showed a lower PUFA/MUFA ratio (using 2-sided student t-test, p = 0.06).
Conclusion: This study demonstrated the feasibility to perform and quantify in-vivo non-decoupled natural abundance C13-MRS in the mono and polyunsaturated lipid region. PUFA/MUFA ratio differences between recruited carnivores and vegetarians were found to be non-statistically significant (p=0.06). Future work aims to increase statistical power by increasing the number of subjects. In general, this method can be used to monitor changes in lipid composition with diet.
Limitations: n/a
Ethics committee approval: All subject gave their informed consent.
Funding: No-funding was received for this work.

Multimodal multi-parametric phantom of the fatty liver disease

O. Dynnyk, O. Omelchenko, O. Solodovnik, N. Marunchi; *Kiev/UA*
(Ol.Omelchenko@Gmail.Com)

Purpose: Fatty liver disease (FLD) inevitably leads to steatohepatitis, fibrosis, and cirrhosis. The main trend of FLD diagnosis by ultrasound is a multi-parametric approach (mp-US) with the simultaneous application of 4 techniques: B-mode, shear wave elastography (SWE) for fibrosis, SW dispersion for inflammatory activity (SWD), attenuation coefficient (AC) for steatosis. Proton density fat fraction (PDFF) MRI recognised as a reference method. The aim was to create multimodal training phantom for mp-US and correlation of the steatosis degree between AC and PDFF.
Methods and materials: We propose a phantom container of non-magnetic material with a filler. We used milk fat based phantoms with different fat concentration, as far as milk composed of spherical drops of triglycerides comparable to fat vacuoles in hepatocytes. 35 phantoms with different fat concentrations were studied: milk 2.5%, 3.2% and cream 5%, 10%, 12%, 15%, 20%. We simultaneously used SWE, SWD and AC by US equipment Aplio i-800 (Canon Medical) with a PVI-475BX convex probe. PDFF was performed using Titan 1.5T MRI (Canon Medical). Mass fraction of fat filler was also biochemically evaluated. Spearman's rank correlation coefficient was applied.
Results: Close correlation was obtained of the filler fat concentration between the AC (dB/cm/MHz), chemicaly mass fraction of fat (%) - 0.700 and PDFF (average value - 0.782, minimum - 0.747, maximum - 0.782), respectively.
Conclusion: A training phantom was created for the simultaneously used the mp-US technologies: SWE, SWD and AC. A high degree of correlation between the values of AC and MR-PPDF is determined our phantom as multimodal for steatomery.
Limitations: An additional variety of fat concentration might increase the accuracy of correlation.
Ethics committee approval: No patients or animals were tested in study.
Funding: No external fundings were used for the conduction of the study.

Bone marrow signal on whole-body MRI in healthy asymptomatic children: a prospective observational study establishing novel reference standards

E. V. Brandis[1], P. K. K. Zadig[2], K. Rosendahl[3], D. Avenarius[2], B. Nguyen[1], L.-S. O. Müller[1]; [1]*Oslo/NO,* [2]*Tromsø/NO,* [3]*Bergen/NO (elisabeth@vonbrandis.net)*

Purpose: WBMRI enables the depiction and characterisation of diseases at an early stage and is embraced for use in children by many centres, although no studies addressing its precision, accuracy, and clinical validity are published. The signal in the bone marrow that may be interpreted as pathology is shown to be present in healthy children. We set out to examine healthy, asymptomatic children with WBMRI to establish normal reference standards for the skeleton in children.

Methods and materials: From 2018-2019, 160 volunteers 6-18 years were recruited for research-purposes only. Coronal T2dixon, T1tse, and DWI (b50 and b1000) from skull base to toes, on state of the art 1.5T scanners (Siemens and Philips), whole body-coil, no sedation, were performed. The scantime was 40-45 minutes. Scoring was performed by two radiologists in consensus, assessing the presence of signal changes suggestive of bone marrow oedema.
Results: All examinations were successful and high-quality images were obtained. Preliminary results of 80 children showed several expected and surprising signal changes that could be mistaken for pathology in a clinical setting.
Conclusion: Signal change is frequently seen on WBMRI in the skeleton of healthy children. This knowledge is crucial to avoid the overstaging of disease, particularly when assessing for lesions at a preclinical stage.
Limitations: Norway is a relatively homogeneous society regarding social status, physical activity, and body-habitus. The definition of "healthy" is challenging. The majority of children report minor intermittent musculoskeletal symptoms. We defined "asymptomatic" as no symptoms impairing everyday activity or necessitating consulting a doctor in the last 6 months. No histological correlation could be made.
Ethics committee approval: Approved by the Regional Committees for Medical Research Ethics, South East Norway, informed consent obtained from all participants/carers.
Funding: National grant (Helse Sør-Øst) for a three year PhD-program.

Whole-body MRI of bone manifestations in patients with Gaucher disease type 1 after long-term treatment with enzyme replacement therapy

A. Lollert, K. Laudemann, E. Mengel, C. Hoffmann, M. Brixius-Huth, J. Hennermann, C. Düber, G. Staatz; *Mainz/DE*
(andre.lollert@unimedizin-mainz.de)

Purpose: To assess bone manifestations in patients with Gaucher disease type 1 (GD1) with whole-body magnetic resonance imaging (WB-MRI) and to evaluate the effects of different timing in initiating long-term enzyme replacement therapy.
Methods and materials: In 17 long-term treated (enzyme replacement therapy with alglucerase/imiglucerase for a median of 13 years) patients with GD1, we performed 2 WB-MRI examinations at a median interval of 13 months. MRI results were retrospectively stratified based on treatment initiation into two groups: "early" (age ≤ 12 years) and "late" (during adulthood). We assessed the occurrence of irreversible avascular necroses (AVN) and applied several semi-quantitative scores: the bone-marrow-burden (BMB) score, the Düsseldorf-Gaucher score (DGS), the vertebra-disc-ratio (VDR), and the Gaucher disease type 1 severity scoring system (GD-DS3).
Results: MRI assessments showed no AVN in the "early" treatment group. AVN were observed in 2 patients of the "late" group. The follow-up examinations showed slight improvements in the BMB-score (P=0.039), DGS (P=0.011), and VDR (P=0.047), with similar tendencies in both treatment groups. The GD-DS3 score only improved in the "late" treatment group (P=0.043).
Conclusion: The ongoing clinical value of enzyme replacement therapy with alglucerase/imiglucerase is supported by our data as WB-MRI-based scores stayed constant or slightly improved even after long-term treatment. Complications (i.e. AVN) were only observed in the "late" treatment group. The early initiation of enzyme replacement therapy may protect the bone.
Limitations: The relatively small study cohort and retrospective study design. The interval between MR examinations was rather short. However, we provided data from patients with very long treatment courses.
Ethics committee approval: Approval of the local independent ethics committee was not necessary due to the retrospective study design.
Funding: This study was financially supported by Genzyme GmbH.

Radiological investigation of suspected physical abuse in children

S. Drew[1], K. Stafford[2]; [1]*Cambridge/UK*, [2]*Camberley/UK*
(Stephdrew09@gmail.com)

Purpose: Radiological investigation should be performed where physical abuse of a child is suspected. Appropriate timely imaging is vital in view of the social and legal implications of the accompanying radiological reports. The aim of this work is to audit practice in a UK district general hospital and evaluate its adherence to national standards. These standards are set by the joint Royal College of Radiologists (RCR) and Royal College of Paediatrics and Child Health (RCPCH) publication: 'The radiological investigation of suspected physical abuse in children'.
Methods and materials: Patients who received an x-ray skeletal survey for suspected non-accidental injury from the 1st February 2017-26th March 2019 (n=27) were identified using the software Sunquest Integrated Clinical Environment (ICE). The mean age was 10 months, with a range of 11 days to 3 years and 5 months. The radiological reports and notes of these patients were analysed and used to evaluate adherence to standards.
Results: Good practice identified in this audit was that skeletal surveys were double reported 92.6% of the time. Areas requiring improvement included the speed of double reporting, attendance for the follow-up skeletal survey, and performance of CT head in the under 1-year-old group, with a follow-up MRI head and spine where indicated.
Conclusion: Improving adherence to standards requires co-operation between radiological and paediatric departments. Additional qualified radiologists can improve reporting speeds, as can appropriate outsourcing to local hospitals. Where CT or MR scans are decided against for clinical reasons, this should be clearly documented in the notes, and the integrity of 'the net' should be improved to avoid a loss to follow-up in children who are potentially at risk.

MRI patterns of muscle involvement in type 2 and 3 cohorts of patients with spinal muscular atrophy

L. Cristiano[1], T. Verdolotti[1], C. Brogna[1], T. Tartaglione[1], A. Pichiecchio[2], C. Cinnante[3], C. Colosimo[1], E. M. Mercuri[1]; [1]*Rome/IT*, [2]*Pavia/IT*, [3]*Milan/IT*
(laralu84@hotmail.it)

Purpose: To define a specific pattern of muscle involvement on MRI, assessing both fatty replacement and muscle atrophy, in a cohort of type 2 and type 3 SMA children and adults including both ambulant and non-ambulant patients.
Methods and materials: In this multicentric study, we prospectively enrolled consecutive SMA patients (March 2018-January 2019). Muscle MRI consisted of TSE/FSE T1-weighted sequences covering the entire lower limb. Each muscle was examined through its whole extension using Mercuri classification for fatty infiltration. Thigh muscles were also grouped in anterior, posterior, and medial compartments for atrophy classification.
Results: 55 patients were included and divided in 3 subgroups: 18 type 2 SMA, 11 type 3 who had lost ambulation, and 26 type 3 ambulant patients. The results showed large variability in type 2 and type 3, with various degree of proximal to distal gradient. At thigh level, the anterior compartment was more often involved while the adductor longus and other medial muscles were relatively spared. In the posterior compartment, the semitendinosus muscle was the most involved. At leg level, the soleus was predominantly involved. ANOVA was used to assess heterogeneity among different SMA types. A non-parametric Wilcoxon signed-rank test was used to compare difference according to an individual compartment.
Conclusion: Our results suggest that although there is an overall recognisable pattern of muscle involvement with abnormal signal within individual muscles associated with atrophy, there is a marked variability across patients with different age, functional level, and type of SMA. The variability observed may help to understand natural history and response to new treatments.
Limitations: A lack quantitative sequences (Dixon).
Ethics committee approval: Ethics committee approval obtained.
Funding: No funding was received for this work.

Diagnostic performance of morphometric vertebral fracture analysis (MXA) in children using a 33-point software program

F. F. Alqahtani[1], N. J. Crabtree[2], P. Bromiley[3], T. Cootes[3], P. Broadley[1], I. Lang[1], A. C. Offiah[1]; [1]Sheffield/UK, [2]Birmingham/UK, [3]Manchester/UK

Purpose: To evaluate the diagnostic accuracy of morphometric vertebral fracture analysis (MXA) using a 33-point software program designed for adults on dual-energy x-ray absorptiometry (DXA) images of children.
Methods and materials: Lateral spine DXA images of 420 children aged 5-18 years were retrospectively reviewed. VFA by an expert paediatric radiologist using Genant's SQ scoring system served as the gold standard. All 420 DXA scans were analysed by a trained radiographer, using semi-automated software (33-point morphometry). VFA of a random sample of 100 DXA was performed by an experienced paediatric clinical scientist. MXA of a random sample of 30 DXA images were analysed by 4 additional observers. Diagnostic accuracy and inter and intraobserver agreement (kappa statistics) were calculated.
Results: Overall sensitivity, specificity, false-positive (FP) and false-negative (FN) rates for the radiographer using the MXA software were 80%, 90%, 10%, and 20%, respectively, and for mild fractures alone were 46%, 92%, 8%, and 54%, respectively. Overall sensitivity, specificity, FP, and FN rates for the 4 additional observers using MXA were 89%, 79%, 21%, and 11%, respectively, and for mild fractures alone were 36%, 86%, 14%, and 64%, respectively. The agreement between the two expert observers was fair to good for VFA and MXA [kappa=0.29 to 0.76 (95% CI: 0.17-0.88) and 0.29 to 0.69 (95% CI: 0.17-0.83)], respectively.
Conclusion: MXA using a 33-point technique developed for adults is not a reliable method for the identification of mild vertebral fractures in children. A paediatric standard is required which not only incorporates specific vertebral body height ratios but also the age-related physiological changes in vertebral shape that occur throughout childhood.

Magnetically-controlled growing rods in early-onset scoliosis: the clinical utility of ultrasound in monitoring distraction

F. Messina, F. Pucciarelli, L. Labianca, V. Giuliani, G. Moltoni, E. Rosati, D. Caruso, A. Laghi, G. Argento; *Rome/IT*
(fil.messina91@gmail.com)

Purpose: Magnetically-controlled growing rods (MCGR) are currently used as the gold standard for the treatment of progressive early-onset scoliosis (EOS) in skeletally immature patients. The goals of this study are to verify ultrasound's accuracy compared to the plain radiographs in distraction measurements and to evaluate the effectiveness of distraction procedures and determine the disparity between total length increase and programmed increase.
Methods and materials: Distraction procedure was performed at 2-monthly intervals with an increase of 3 mm in length at each occasion. At each follow-up, pre- and post-distraction assessment was performed with ultrasound and plain radiographs in order to confirm distraction length. Ultrasound evaluation was performed through two measurements with two different landmarks (called US-M1 and US-M2). Radiographic measurements were achieved on anteroposterior plain radiographs and were calibrated and corrected for magnification.
Results: 6 patients with EOS were included, 4 with a dual-rods system and 2 with a single rod. 16 distraction procedures were performed. The increase in total length compared to the planned distraction was 83.48%, measured on plain radiographs, 95.24% and 87.61%, respectively on US-M1 and US-M2 ultrasound measurements. Length increases in patients with dual rods were 75.76% on plain radiographs, 95% on US-M1, and 87.22% on US-M2, and in the case of patients with a single rod were, respectively, 98.9%, 96.67%, and 90%.
Conclusion: Ultrasound assessment in distraction measurement was as accurate as plain radiographs. The US-M1 landmark was found to be more reliable than US-M2. Increases in rod length were 16.52% and 4.76% lower than that programmed, measured respectively with plain radiographs and ultrasound (US-M1). With reference to the value of plain radiographs, a difference was found between dual rods versus single rod groups.
Limitations: The limited number of patients in rare conditions.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Radiological and clinical prognostic factors in children with atlantoaxial rotatory subluxation/fixation

L. Lotrecchiano[1], S. Guerri[1], M. Molinari[1], P. Zarantonello[1], A. Giugliano[2], L. Ceccarelli[1], G. Vara[1], G. Facchini[1], P. Spinnato[1]; [1]Bologna/IT, [2]San Gennaro Vesuviano/IT (ludovica.2611@gmail.com)

Purpose: Atlantoaxial rotary subluxation/fixation (AARS/F) is a rare cause of torticollis in children. Patients usually present with their head fixed in rotation with some degrees of flexion ('cock-robin' head position). CT permits the diagnosing and grading of the disease.
The purpose of our study was to evaluate the correlations between radiological and clinical factors and patients' prognosis.
Methods and materials: We retrospectively reviewed all CT studies and all clinical reports from our hospital archive of children diagnosed with AARS/F in the last 15 years.
Two expert musculoskeletal radiologists reviewed all CT studies, grading AARS/F according to the Fielding-Hawkins system. Moreover, C1-C2 rotation-degrees were calculated.
The outcome assessments were positive (complete clinical/radiological recovery at three months follow-up), and negative (disease persistence or relapse at three months follow-up).
All patients were treated conservatively after diagnosis (cervical traction/neck collar).
Results: We included 53 patients (mean age=8.7y – 26F, 27M) diagnosed with AARS/F in the study. In 7/53 subjects (13.2%), a negative clinical outcome was observed.
The presence of concomitant infection or inflammation at the head and neck region (Griesel's syndrome) was significantly associated with a negative outcome (p=0.001). Fielding-Hawkins grading was also well correlated with the patients' outcome (p=0.01). C1-C2 rotation-degrees was rather associated with the outcome, without reaching statistical significance (p=0.056). The presence/absence of a traumatic event that triggered AARS/F was not correlated with the patients' outcome (p=0.171).
Conclusion: The presence of concomitant infection/inflammation at head and neck regions in patients with AARS/F is the most important prognostic factor and is associated with poorer outcomes. The Fielding-Hawkins radiological grading system well correlates with the patients' outcome.
Limitations: A retrospective study.

Morphometric assessment of the face with 3D "black bone" magnetic resonance imaging in patients with juvenile idiopathic arthritis

M. J. Kupka, J. Aguet, M. W. Wagner, C. J. J. Kellenberger; *Zurich/CH*
(michaeljkupka@gmail.com)

Purpose: To evaluate the feasibility of "black bone" magnetic resonance imaging for assessing craniofacial deformity in children with juvenile idiopathic arthritis.
Methods and materials: Black bone three-dimensional gradient-echo images (flip angle 5°, submillimetre isotropic resolution) from 10 children (median age 13 years, range 2-16 years), who underwent MRI of the temporomandibular joints, were evaluated with the multiplanar reconstruction tools of SECTRA PACS and Advantage Workstation. Intra- and inter-rater reliability was

investigated for measuring the height of the mandibular ramus and condyle, basal length of the mandible, gonion angle, and mandibular inclination angle by Bland Altman analysis and intraclass correlation coefficient.
Results: Black bone images required inversion of the signal intensity and removal of air before they could be processed with standard volume rendering tools. The reliability for linear measures was best on thin minimum intensity projection images (agreement bias <1 mm , range 4 mm, ICC 0.97–0.99). The variability of angle measures was higher (agreement bias <4°, range±8°, ICC 0.99).
Conclusion: Morphometric measures of the face can be obtained from black bone MRI with comparable reliability to that reported for cone-beam CT. Black bone MRI may be considered as a radiation-free alternative to CT in children with JIA.
Limitations: The small sample size.
Ethics committee approval: n/a

The presence of globally-decreased perfusion on post-reduction MRI does not reliably predict proximal femoral growth disturbance at midterm follow-up in developmental dysplasia of the hip

F. Schmaranzer[1], M. Ferrer[2], P. Miller[2], S. Bixby[2], Y.-J. Kim[2], E. Novais[2]; *[1]Berne/CH, [2]Boston, MA/US*

Purpose: Post-reduction perfusion MRI has been previously introduced to assess femoral head perfusion but its prognostic value is unclear. We sought to determine whether globally-decreased femoral head perfusion predicts femoral growth disturbance at a minimum of 5 years after closed/open reduction for DDH.
Methods and materials: A retrospective analysis of patients undergoing closed/open reduction for DDH and post-reduction perfusion MRI within 24 hours was conducted. 94 hips (83 patients, mean 11±4 year follow-up) had a minimum 5-year radiographic follow-up. Of these, 45/49 hips had open/closed reduction. The Kalamchi/MacEwen classification of the proximal femoral deformity was used (grade 4; total damage to femoral epiphysis, -physis, -neck) at latest the radiographic follow-up. 1.5T MRI was performed including 2D coronal-, axial PD-w, and T1-w TSE images, before/after i.v. contrast injection (0.2 mmol/l Gd-DTPA^{2-}). Femoral head enhancement was graded as normal/asymmetric/focally/globally decreased. Multivariate regression analysis was performed and the diagnostic performance calculated.
Results: At follow-up, 11 hips (12%) had femoral growth disturbance. The prevalence of globally-decreased perfusion was higher (p=0.016) in hips with (36%, 4/11) compared to hips without growth disturbance (10%; 8/75) and was independently associated with femoral growth disturbance (OR: 6.2; 95%CI, 2 to 27; p=0.014). While the negative predictive value of globally-reduced perfusion was high (92%), its positive predictive value was low (36%) in predicting femoral growth disturbance.
Conclusion: Globally-decreased perfusion on post-reduction MRI does not reliably predict proximal femoral growth disturbance in DDH at mid-term. The aetiology of femoral growth disturbance after treatment of DDH is likely a multifactorial problem not solely attributed to decreased femoral head perfusion after closed/open reduction.
Limitations: A singe-centre study at a tertiary centre.
Ethics committee approval: IRB approaval was granted under a waiver for informed consent.

RPS 1012a-10 12:09

Which risk factors predict hip instability or developmental dysplasia of the hip in newborns?

C. Zichichi, G. Como, I. Mauro, L. Cattarossi, R. Girometti, C. Zuiani*; Udine/IT (clara.zichichi@gmail.com)*

Purpose: To investigate which risk factors are predictive of developmental dysplasia of the hip (DDH) or hip instability (HI) in newborns using hip ultrasound (HUS)-based diagnosis.

Methods and materials: We retrospectively analysed the clinical data of 1,017 newborns who underwent HUS from August 2016-December 2018. Included patients showed dependent risk factors (familiarity, macrosomia, twins, and podalic presentation), independent risk factors (doubt or positive Ortolani manoeuvre, hip click, skin folds asymmetry, and others), or coexistence of two or more risk factors (dependent or independent) for DDH. Each hip was analysed by one of two operators with 3- and 7-years' experience, respectively, using a high-frequency linear probe and the graft technique. Patients were divided into three groups according to HUS-related categorisation (1a-1b versus 2a-2b versus >2c).
We used the χ^2 test and built two different logistic regression models to asses which risk factors were predictive of HUS categorisation 2a-2b (HI) or >2c group (DDH).
Results: HUS categorised patients as 1a-1b in 872/1017 (85.7%), HI in 126/1017 (12.4%), and DDH in 19/1017 (1.9%), respectively. On multivariate analysis, HI was independently predicted by positive Ortolani manoeuvre (OR=10.16; p<0.0001) and the coexistence of two risk factors (OR= 2.64; p=0.014), which occurred in 15/126 (11.9%) and 10/126 (7.9%) cases, respectively. DDH was independently predicted by positive Ortolani manoeuvre (OR=74.64; p<0.0001), coexistence of > 3 risk factors (OR=186.6; p<0.0001), and skin folds asymmetry (OR=10.36; p=0.037), which occurred in 8/19 (42.1%), 2/19 (10.5%), and 1/19 (5.3%) cases, respectively.
Conclusion: HI and DDH are predicted by a limited number of risk factors, suggesting that indication of HUS should be restricted accordingly.
Limitations: A monocentric and retrospective design.
Ethics committee approval: Informed consent waived because of the retrospective design.
Funding: No funding was received for this work.

Single fast high-resolution 3D T1 VIBE FS MR sequence versus CT in the evaluation of tarsal coalition in children and adolescents: a reliable radiation-free alternative?

V. Caturano, A. Bartoloni, A. Magistrelli, D. Barbuti, P. Toma, A. Bozzao, M. Cirillo*; Rome/IT (ale.bartoloni@gmail.com)*

Purpose: To evaluate the accuracy of a fast MR T1 VIBE fat-saturated (FS) 3D sequence in paediatric patients with tarsal coalition compared to CT.
Methods and materials: 15 patients (age range 9-18 years; 9 females, 6 males) with a diagnosis of the tarsal coalition on x-ray and CT were included in the study.
All patients underwent 3T MRI (Siemens Magnetom Vida).
Both feet were simultaneously examined with a single volumetric T1 VIBE FS sequence (acquisition in axial plane; TR: 9.42ms, TE: 4.92 ms, and voxel size <1 mm) using an 18-channel surface coil.
The time scan for the single sequence varied between 120-150 sec, depending on the size of the feet and patient age.
Images were independently evaluated by 3 paediatric musculoskeletal radiologists and the findings were compared with CT imaging.
Results: Of the 9 patients with calcaneonavicular coalition (unilateral: 5 cases, bilateral: 4 cases), 7 had a non-osseus type and 2 had an osteofibrous type. In 1 patient, an os calcaneus secondarius was detected.
Of the 5 patients with the talocalcaneal coalition (unilateral: 3 cases, bilateral: 2 cases), 4 had a non-osseus coalition and 1 had an osseous type.
1 patient had a bilateral non-osseus coalition involving the calcaneocuboid joint.
Providing a high contrast between bone and cartilage, the single volumetric MRI sequence of our protocol (T1 VIBE FS 3D) was comparable to CT both in the diagnosis of tarsal coalition and in the assessment of its location, extent, and type (osseus/non-osseous) in all patients.
Conclusion: Paediatric patients with tarsal coalition can be accurately studied with a single T1 VIBE FS 3D MR sequence instead of CT, without radiation exposure.
Limitations: Few cases were included in the study.

The triangular fibrocartilage complex on high-resolution 3T magnetic resonance imaging in children: what is normal?
A.-S. van der Post, S. Jens, F. Smithuis, M. Obdeijn, M. Maas*; Amsterdam/NL (a.vanderpost@amsterdamumc.nl)*

Purpose: To define normal age-related triangular fibrocartilage complex (TFCC) morphology, homogeneity, and signal intensity on high-resolution 3.0 Tesla (3T) magnetic resonance imaging (MRI) in children.
Methods and materials: This cross-sectional study included 24 healthy children, aged 12-18 years, that did not participate in wrist-loading sports more than two times a week. They underwent a 3T MRI of one wrist, including proton-density (PD)-weighted images in three planes without fat saturation and PD-weighted coronal and T2-weighted axial images with fat saturation. Morphology, homogeneity, and signal intensity of TFCC components were assessed by 3 radiologists and 1 hand surgeon independently using a standardised score form that was developed by 1 physician experienced in TFCC-research and the 4 observers with several consensus meetings and test rounds.
Results: The cohort consisted of 12 girls and 12 boys with a mean age of 13.5 (SD, 1.1). Observers were consistent in defining anatomical variants and measurements. The observers reported anatomical variations in a substantial number of children. For instance, linear vertical increased the signal with disruption of the articular disc and diffuse increased the signal of the disc not extending to the joint surface. Also, general TFCC disc morphology, proximal and distal lamina, radio-ulnar ligaments, prestyloid recess, and meniscus homologue showed anatomical variants.
Conclusion: This study shows normal TFCC variation on high-resolution 3T MRI in healthy children, such as focal articular disc perforations. When interpreting MRI of the wrist in children, it is important to be aware of the TFCC anatomy and its normal variations.
Limitations: The sample size. Observers were aware that children were healthy and asymptomatic.
Ethics committee approval: Approved by the local medical ethical committee (reference number 2014_382#B2015303).

Shifting from double-rule-out towards whole body check-up: diagnostic yield of CT in patients with suspected aortic dissection
J. Vosshenrich, G. Sommer*; Basel/CH (jan.vosshenrich@usb.ch)*

Purpose: To assess the diagnostic yield of double-rule-out-CT in patients with suspected aortic dissection in an emergency setting.
Methods and materials: A total of 437 double-rule-out-CT studies performed from 09/2018 to 09/2019 at our institution and four remote hospitals (teleradiological coverage during on-call hours), were included. All studies were ordered by the respective emergency department to rule out aortic dissection. Images were acquired according to our routine double-rule-out protocol. Final radiological reports were manually reviewed to identify diagnoses that may explain patients' symptoms noted in the order sheet (severe chest pain or chest and abdominal pain). Total numbers of vascular and nonvascular findings were calculated.
Results: In 178 patients (40.7%) at least one finding that could explain patients' symptoms was identified. Vascular pathologies represented 16.0% (70) of findings and included 26 aortic dissections (5.9%), 20 pulmonary embolisms (4.6%), 16 aortic aneurysms (3.7%), 2 intramural aortic hematomas (0.5%), 2 aortic ruptures (0.5%) and 4 Leriche syndromes (0.9%). In contrast, 128 findings (29.3%) were of nonvascular origin, i.e. 21 pulmonary (4.8%), 42 cardiac (9.6%), 58 gastrointestinal or genitourinary (13.3%) and 7 musculoskeletal pathologies (1.6%). These included a variety of neoplastic, inflammatory and infectious diseases. 259 studies (59.3%) were negative without any relevant vascular or nonvascular finding.
Conclusion: Our results suggest that suboptimal patient preselection and inflationary use of double-rule-out-CT is an emerging issue in busy emergency departments.
Radiologists thus need to be aware to regularly encounter a vast amount of relevant nonvascular findings in these exams, some of which may be more difficult to detect than usual, as double-rule-out-CT is not considered the optimal imaging protocol for these pathologies.
Limitations: Retrospective, correlation with final radiologic reports only.

RPS 1017-2 11:31
Diagnostic performance of different low-dose levels for the detection of pulmonary embolism in computed tomography
M. T. Winkelmann, S. Afat, S. Walter, E. Stock, A. B. Brendlin, A. Othman*; Tübingen/DE (moritz.winkelmann@med.uni-tuebingen.de)*

Purpose: To evaluate the effects of dose reduction on diagnostic accuracy and image quality of pulmonary angiography CT(CTPA) in adults with suspected pulmonary embolism (PE) in clinical routine.
Methods and materials: 52 consecutive patients received CTPA for suspected PE. Realistic low-dose CT images were generated using an offline software (ReconCT, Siemens Healthineers), as either filter back projections(FBP) or as ADMIRE (strength 3 or 5) with 25%, 50% and 75% of the original dose. To assess image quality (overall image quality, noise, artefacts, and sharpness) and diagnostic confidence, a five-point scale was used. Patient-based and segment-based diagnostic accuracy was calculated for LDCT-reconstruction with original dose CTPA as a standard of reference.
Results: Among 52 patients, the prevalence of acute pulmonary embolism was moderate (15.5%). The median dose-length product and effective dose for all 52 scans was 275.3±140.5 mGy·cm and 3.9±1.9mSV. Overall subjective image quality was highest for ADMIRE 5 with 75% and lowest for FBP with 25% of the original dose (median [interquartile range]:5[5]vs.3[2-3], p<0.001. Patient-based diagnostic accuracy was high for all all LDCT datasets down to 25% for ADMIRE 3+5 (sensitivity:100%, negative predictive value [NPV]: 100%), and lower for FBP with 25% dose reduction (sensitivity: 93%; [NPV]: 97%). Segment-based diagnostic accuracy was high for ADMIRE 3+5 down to 25% dose reduction (sensitivity: 91.9%, specificity: 98.9%) and lowest for FBP with 25% dose reduction (sensitivity: 87.8%, specificity: 99%). Inter-rater agreement regarding the detection of PE was almost perfect at all doses and recons (kappa>0.95).
Conclusion: Our findings indicate that radiation dose reduction down to 25% of the original data via iterative reconstruction algorithms on a 3rd generation DE-CT scanner maintained the diagnostic accuracy and image quality for the assessment of PE in CTPA.
Limitations: Retrospective study design.
Ethics committee approval: Approved by the Ethics Committee (University of Tübingen).

What about incidental findings on emergency CT scanners?
P. Berge, A. Darsonval, C. Nedelcu, A. Paisant, C. Aubé*; Angers/FR (pierre.berge@chu-angers.fr)*

Purpose: The objective was to evaluate the prevalence and determinants of incidental findings (IFs) on MDCTs performed for an emergency department (ED). The secondary aims were to inventory additional investigations, their benefits, side effects, costs and the final diagnoses.
Methods and materials: One thousand consecutive patients (51.9-year-old +/- 22.7, 477 women) who underwent MDCT in the ED of our institution from January 2011 to November 2011 were retrospectively included. We collected: IFs (divided into low and high clinical significance), body areas covered, availability of prior imaging, radiologist's experience and subspecialty. In the subgroup of patients followed in our institution, we recorded the additional

investigations and their outcomes. Their costs were assessed according to the French health care system.
Results: Among the 1000 included patients, 232 had at least one IF and 122 at least one IF of high clinical significance (IFCS). A significant association with the presence of at least one IF was noted for the older patient, less-experienced radiologist, no subspecialty of the radiologist, abdominopelvic area, and the absence of prior imaging. In the subgroup of 16 patients followed in our institution, two diagnoses of malignancy were made (a gastro-intestinal stromal tumour and a Bosniak IV cystic renal lesion). One iatrogenic complication occurred (an acute urinary retention following the radiofrequency ablation of the Bosniak IV kidney cyst). Cost of the additional investigations was €41,247 (with an average of €2,578 per patient).
Conclusion: IFs on emergency MDCTs were frequent, rarely severe, rarely iatrogenic and costly.
Limitations: The subgroup of patients followed in our institution was small compared to the number of patients included.
Ethics committee approval: This study was approved by our local institutional ethics review board.
Funding: No funding was received for this work.

CT-aortography as the diagnostic tool to determine the instability of the arterial wall in abdominal aortic aneurysms
D. Tutova, R. Muslimov, L. Kokov*; Moscow/RU (Danifo@mail.ru)*

Purpose: The purpose of this study is to explore and to reveal specific structural changes in the aorta and surrounding tissues with CT scans, which can be regarded as signs of aortic wall instability.
Methods and materials: CT studies were performed by a 160-slice CT scanner with native and arterial contrast phases. CT data of 104 patients with confirmed abdominal aortic aneurysm (AAA) were retrospectively studied. The assessment of such signs of instability of the aortic wall was based on the following findings: hyperattenuating crescent sign, fissuration of parietal thrombotic masses, draped aorta sing, aortic bleb, and periaortic stranding. In addition, the treatment tactics of patients were also studied.
Results: According to these findings, the patients were divided into 3 groups: 1. with ruptured AAA - in 28 (26.9%) cases. 2. with unruptured AAA, with one sign of instability - in 50 (48%) cases. 10 (20%) patients from this group underwent surgical treatment. 3. with unruptured AAA, with several signs of instability - in 26 (25.1%) cases. In this group, 6 patients underwent urgent surgical treatment, and 4 non-treated patients developed a rupture of AAA in the next few days, i.e. 38.4% of the cases.
Conclusion: CT can make a quick and comprehensive diagnosis of AAA. The high frequency of occurrence of signs of instability in the ruptured AAA indicates their high prognostic significance. The combination of 2 or more signs indicates a high risk of threatening rupture, which in combination with other factors can be considered as an indication for urgent surgical treatment. The most common CT signs of instability of the AAA include hyperattenuating crescent sign, a draped aorta sing and periaortic stranding.

RPS 1017-5 11:49
Prognostic value of CT pulmonary angiography parameters in acute pulmonary embolism.
D. Cozzi, C. Moroni, E. Cavigli, A. Bindi, V. Miele, C. Caviglioli, P. Nazerian, S. Vanni, M. Bartolucci*; Florence/IT (dilettacozzi@gmail.com)*

Purpose: Patients with acute pulmonary embolism (APE) present with a different broad spectrum of prognoses. Computed tomographic pulmonary angiography (CTPA) is the first-line test in APE diagnostic algorithm, but its correlation with short-term outcome remains not clear at all. The aim of this study is to determine if CTPA findings can predict 30-day mortality of patients with APE in the emergency department.
Methods and materials: This is a retrospective, monocentric study involving 780 patients with APE, diagnosed at the emergency department of our institution between 2010 and 2018. These CTPA findings were evaluated: embolic-obstruction burden score (Qanadli score), common-pulmonary artery trunk diameter, right-to-left ventricular ratio, diameters of the azygos vein and coronary sinus. Comorbidities and fatal/non-fatal adverse outcomes within 30 days were recorded. Troponin I values were investigated and correlated with angiographic parameters with multiple logistic regression analysis.
Results: The all-cause and APE-related 30-day mortality rates were 5.9% and 3.6% respectively. Patients who died within 30 days were older and had higher prevalence rates of malignancy. Qanadli score and all CTPA parameters correlate with Troponin I level and the presence of RVD at echocardiography (p-values< 0.0001). Instead, RV/LV ratio and coronary sinus diameter correlate with 30-day mortality (p-values< 0.005). At the multivariate-logistic regression analysis, only coronary sinus and RVD remained significant with an HR = 2.5 (95% CI 1.1-5.6) and HR = 1.9 (95% CI 0.95-3.7), respectively.
Conclusion: These results suggest that CTPA quantification of right ventricular strain is an accurate predictor of 30-day mortality. In particular, it seems that a dilated coronary sinus (> 9 mm) has an additional prognostic value in association with echocardiographic signs of right-heart disfunction and high Troponin I levels.

Present limitations of Artificial Intelligence in the emergency setting: performance study of a commercial, computer-aided detection algorithm for pulmonary embolism
K. Mueller-Peltzer[1], G. Negrao de Figueiredo[2], C. G. Trumm[2]*; [1]Freiburg/DE, [2]Munich/DE (katharina.mueller-peltzer@uniklinik-freiburg.de)*

Purpose: Since Artificial Intelligence is moving from an experimental stage to clinical implementation, the aim of our study was to evaluate the performance of a commercial, computer-aided detection (CAD) algorithm of pulmonary CT angiograms (CTPA) regarding the presence of pulmonary embolism (PE) in the emergency department.
Methods and materials: In this retrospective study, we included all CTPA studies performed in a large emergency department over a period of 36 months, which were analysed by two radiologists experienced in emergency radiology to set a standard reference. Original reports and CAD-results were compared regarding the detection of lobar, segmental and subsegmental PE. All CAD-findings were analysed concerning the underlying pathology. False-positive (FP) CAD findings were correlated to the contrast-to-noise-ratio (CNR).
Results: Expert reading revealed PE in 182 of 1,229 patients (49% men, 10-97 years) with a total of 504 emboli. The CAD algorithm reported 3,331 findings, of those 258 (8%) were true-positive (TP) while 3,073 (92%) were FP. CAD analysis showed a sensitivity of 47% (95% CI: 33-61%) on a lobar and 50% (95% CI 43-56%) on a subsegmental level. On average, there were 2.25 FP findings per study (median 2, range 0-25). There was no significant correlation between the number of FP and CNR (Spearman's Rank Correlation Coefficient = 0.09). Soft tissue (61.0%) and pulmonary veins (24.1%) were the most common underlying pathologies of FP findings.
Conclusion: Applied on a collective of a large emergency department, the tested commercial CAD algorithm faced relevant performance challenges that need to be addressed in future CAD development projects.
Limitations: A limiting factor of our study is its retrospective single centre study design.
Ethics committee approval:
The study was approved by the local institutional review board.

The role of a computer-assisted detection algorithm for the diagnosis of peripheral pulmonary embolism
A. Richter, F. Rengier, H.-U. Kauczor, T. F. Weber*; Heidelberg/DE*

Purpose: Aim of this study was to evaluate the performance of a computer-assisted detection algorithm (CAD) for the diagnosis of peripheral pulmonary embolism (PE) using a reduced contrast material dose CT acquisition protocol.
Methods and materials: Retrospective analysis of patients referred to CT for assessment of PE from July 2018 to December 2018. Patients with evidence of central PE at CT were excluded. CT pulmonary angiograms were obtained using a dual-layer detector CT and an injection technique comprising 55 ml contrast material (iodine concentration, 350 mg/ml) and 50 ml saline chaser with 4 ml/s flow rate. PE-CAD was performed using a dedicated image processing software designed for peripheral PE detection (Philips Intellispace Portal version 10, Haifa, Israel). Test performance statistics were calculated for PE-CAD detection of peripheral emboli with a radiologists' read serving as reference standard.
Results: 130 patients were included. 21 patients with 151 peripheral emboli were diagnosed with peripheral PE using the reference standard. 20 patients with peripheral PE were correctly identified by PE-CAD. PE-CAD was false positive in 46 patients without a final diagnosis of peripheral PE. On a per-patient basis, sensitivity, specificity, negative likelihood ratio, and positive likelihood ratio for PE-CAD were 95%, 58%, 0.08 and 2.26, respectively. On a per-embolus basis, sensitivity, specificity, negative likelihood ratio, and positive likelihood ratio for PE-CAD were 60%, 33%, 1.22, and 0.89, respectively.
Conclusion: Using a reduced contrast material dose CT acquisition protocol, PE-CAD is valuable for the exclusion of peripheral PE on a per-patient basis. Use of PE-CAD as a screening tool is limited by false positive findings.

Dual-energy CT for wrist fracture patients with negative radiographs: a prospective diagnostic test accuracy study

C. F. Müller[1], K. K. Gosvig[1], H. Børgesen[1], J. S. Gade[1], M. W. Brejnebol[1], A. Rodell[2], M. C. Nemery[1], M. Boesen[3]; [1]*Herlev/DK,* [2]*Ballerup/DK,* [3]*Frederiksberg/DK*

Purpose: To evaluate dual-energy CT (DECT) in diagnosing bone marrow edema (BME) and fractures in patients with clinical suspicion of a fracture but negative radiograph.
Methods and materials: 46 consecutive adult patients (50 wrists) with recent trauma and clinical suspicion of a fracture, but negative radiograph, were prospectively enrolled between January and November 2018. Wrists were evaluated with DECT (80kV and 150kV with tin filter) and MRI (1.5T) and images read independently by four blinded readers. Presence of BME and fracture was rated per bone. Reference standard for BME was the combined reading of MRI scans by all readers; for fracture a combined reading of MRI and DECT scans by all readers. A fifth radiologist arbitrated results in case of discrepancies. Diagnostic test accuracy (DTA) was calculated per reader and for readers combined.
Results: 750 bones in 50 wrists were assessed. 52 bones (18 radius, 15 scaphoid, 19 others) had BME and 41 bones had fractures (16 radius, 11 scaphoid, 14 others). For BME detection DECT had combined accuracy 95%, sensitivity 68% and specificity 98%. For fracture detection MRI had combined accuracy, sensitivity and specificity (97%, 76% and 99%) and DECT (97%, 85%, and 99%). Sensitivity for fracture detection was higher with DECT for all readers, but McNemar's tests were not significant.
Conclusion: DECT has a very high specificity and moderate sensitivity in detecting traumatic BME of the wrist. DECT and MRI have similar high sensitivity and specificity in detecting wrist fractures and are equivalent for the workup of patients with suspected wrist fractures with negative radiographs.
Limitations: NA
Ethics committee approval: The study was approved by the regional ethical review board. All patient gave written informed consent.

Pulmonary embolism: epidemiology, use of clinical probability scores, and correlation between clinical, radiological and analytical variables. A retrospective, single-centre study

A. J. Láinez Ramos-Bossini, M. D. C. Pérez García, F. Garrido Sanz, S. Suárez Moreno, R. Gálvez López, M. Rivera Izquierdo*; Granada/ES (ajbossini@ugr.es)*

Purpose: To evaluate factors related to pulmonary embolism (PE), the explicit use of clinical probability scores (CPSs), and relevant CT findings in patients that underwent chest computed tomography angiography (CTA) for suspected PE in our hospital.
Methods and materials: Retrospective observational study of chest CTAs ordered for suspected PE in a Spanish tertiary hospital during 2018. Epidemiological, clinical, radiological and analytical variables, and the explicit use of CPSs were analysed. Four two-level CPSs were retrospectively calculated, and guideline adherence was analysed accordingly.
Results: In total, 534 patients (52.8% women, median age: 73 years) were included. PE prevalence was 23.0%. PE-exclusive and all-cause early mortality (<6 months) in patients with PE was 15.4% and 22.8%, respectively. CPSs were explicitly used in 15.2% of all cases. D-dimer tests were ordered in 88.2% of all cases. Although significant differences were observed among scale values, most CTA orders were justified according to retrospective CPSs and standard D-dimer values. Significant differences in clinical, analytical and CT findings were observed depending on PE subtype. RV/LV ratio >1 was significantly associated with cardiac damage markers and with other CT findings of right ventricular strain.
Conclusion: Despite the poor explicit use of CPSs, our results suggest that the yield of clinical gestalt assessment may be similar to that of CPS. PE subtype and CT markers of right ventricular strain should be always included in the radiological report given their prognostic implications. Prospective studies are further required to validate our results.
Limitations: The main limitations of the study concern its retrospective nature and the fact that it was performed at one institution.
Ethics committee approval: This study was approved by our Institutional Review Board.
Funding: No funding was received for this work.

Efficiency and impact of CT in ICU patients with unknown inflammatory focus

R. Martin[1], J. A. Luetkens[2], A. Faron[2], D. K. Thomas[2], D. Kuetting[2]; [1]*Dresden/DE,* [2]*Bonn/DE (ronmartin.uni@gmail.com)*

Purpose: To evaluate the efficiency and impact of computerized tomography (CT) on diagnosis and further diagnostic/therapeutic regimen in ICU patients with fever, systemic inflammatory response syndrome (SIRS) or sepsis with unknown focus of infection.
Methods and materials: Non-ECG-gated chest/abdominal CT examinations of ICU patients (internal medicine, surgery, heart surgery, neurology/neurosurgery) were prospectively analyzed for inflammatory foci. Both CT findings and changes in diagnostic/therapeutic regimen were analyzed. Prior CT, X-Ray, MRI, ultrasound examinations, bronchioalveolar lavage and urine analysis performed during the same ICU treatment but prior to the CT, were cross-checked to verify whether foci were actually new.
Results: In 99 out of 112 (88,4%) prospectively examined patients (34,8% female, mean age 64,8 years), a total of 147 possible foci (thoracic: n=92; abdominal: n=55) were detected. Of the 147 foci (58,5% defined as definite, 41,5% as questionable), prior examinations had suspected inflammatory focus in 80 cases. CT diagnosis led to 74 changes in therapy regimen in 58 of 99 Patients (59%): change/initiation of antibiotics: 52,7%, CT guided thoracic/abdominal puncture: 21,6%, operation: 8,1%, change in patient positioning: 8,1%; other: 9,5%. In 24 patients, CT findings led to 33 diagnostic follow-ups: endoscopy: 45,5%, microbiological testing: 24,2%, additional imaging: 18,2%, others: 12,1%.
Conclusion: CT examinations in ICU patients with unknown focus of infection leads to diagnosis in most cases as well as to adaption in therapy regimen and thus should be considered in patients with obscure clinical infection.
Limitations: Further research has to be done with a higher number of CTs and patients to outline the specific role and impact of CT in patients of unknown Focus of Infection.

Ethics committee approval: The Ethics Committee of the University Clinic of Bonn approved the study.

Occupational burnout among radiographers: findings from a national survey

L. P. V. Ribeiro[1], A. M. Baltazar[2], K. B. Azevedo[2], A. F. Abrantes[2], S. Rodrigues[2], O. Lesyuk[3], R. P. P. Almeida[2], J. Pinheiro[3];
[1]Parchal/PT, [2]Faro/PT, [3]São Brás de Alportel/PT
(luispedroribeiro@hotmail.com)

Purpose: Burnout is a complex phenomenon characterised by emotional exhaustion, social detachment, and feelings of low personal achievement. In this study, we aim to establish the prevalence of burnout among radiographers and to explore the factors influencing its development.
Methods and materials: A total of 205 radiographers from the country answered the Maslach Burnout Inventory (MBI), composed of 3 dimensions: emotional exhaustion, depersonalisation, and personal achievement associated with a sociodemographic and professional characterisation questionnaire. The questionnaire was made available online and confidentiality was assured to all participants.
Results: The global internal consistency of MBI accessed by the Cronbach's alpha was 0.776. Statistically significant differences were observed between rotational shift work and depersonalisation (t=2.482; p=0.014) and personal achievement (t=2.352; p=0.020). Using the one-way ANOVA, significant differences were observed between professional experience and professional satisfaction and the three MBI dimensions. The average burnout value was 22.9 (three levels, where the middle level ranges from 34-66). Regarding the burnout dimensions, emotional exhaustion was positioned in the middle level (out of three levels), while depersonalisation and personal achievement scored the highest level.
Conclusion: Radiographers in this research suffer from burnout syndrome. Rotational shiftwork is the major cause of depersonalisation and reduces the sense of personal achievement. Professional satisfaction is negatively affected by this syndrome. High emotional exhaustion and depersonalisation, and the low sense of personal achievement, are also common among professionals that work for more years. The health promotion for healthcare professionals should be addressed by healthcare facilities across the country.

Purpose: A complete overview of the radiographers' professional profile plays a fundamental role in the assessment of possible development and growth of radiographers' skills. The aim of this study was to assess the Italian radiographers' profile.
Methods and materials: The Italian Federation of Scientific Radiographers Societies (FASTeR) proposed a national online survey, including 64 questions and sub-divided into different topics. Italian radiographers count around 28,000 individuals.
Results: We obtained 872 (3.1%) answers, 480 (55%) males, 392 (45%) radiographers had been working for less than 10 years, 610 (70%) had a bachelor degree, and 358 (41%) were highly specialised with a master degree (European qualification framework level 7). A total of 602 (69%) radiographers worked mostly as an employee in the public health sector, 637 (73%) in hospitals, and 732 (84%) full-time, earning in 40% of cases between 22,001-28,000€ gross per year. Radiographers have a good knowledge of the institutional/hospital organisation chart (663, 76%) and management (knowledge of the budget) of the employment institution. Radiographers duties included the optimisation and control (680, 78%) of the technological equipment. Selected future areas of professional growth were the technological sector with new technologies development (576, 66%), as well as healthcare professions management (567, 65%).
Conclusion: When analysing the actual role and skills of Italian radiographers, it is evident that the professional responsibility will increase through scientific research, management of new technologies, and department governance in the next years.
Limitations: An Italian survey.
Ethics committee approval: n/a
Funding: This study was supported and promoted by the Italian National Radiographers Federation and Technical, Rehabilitation and Prevention Health Professions (FNO TSRM PSTRP).

Advanced and consultant AHP practice: a vision for the future

N. Barlow, R. Milner*; Rotherham/UK (nicholas.barlow@nhs.net)*

Purpose: Due to increasing clinical pressures, high vacancy rates, and significant referral growth, the Rotherham NHS foundation trust (TRFT) designed and implemented a new allied health professional (AHP)-led plain film (PF) reporting service. The aim was to increase performance, reduce clinical risk, improve quality, and increase value through lower cost per report.
Methods and materials: Following the appointment of the trust's first AHP consultant, the AHP PF workforce was restructured. This included increasing the scope of practice, increasing the number of reporting sessions, delivering in-service training, providing dedicated reporting sessions, and internally promoting and training new members of staff. Key stakeholders included radiologists/radiographers, referring clinicians, patients/the public, health education institutes, local commissioning bodies, and professional colleges.
Results: Since its implementation, there have been no serious incidents, complaints, or near misses. AHP's doubled the percentage of plain film reports from 40% to 80% of the total reports undertaken. The percentage of reports by medical colleagues reduced from 35% to 5%. Based on model hospital data, TRFT now has the highest proportion of reports provided by AHP's of any secondary care acute provider. The cost per report reduced by approximately 50%.
Conclusion: The results of this service re-design are highly encouraging through high levels of accuracy, reduced risk, a significant reduction in report TaT, patient satisfaction, and cost-effectiveness. Increased staff morale and major improvements in recruitment and retention have also been encountered.
Limitations: Support from local radiologists and clinicians was significant, as the pervading biases within some professional bodies worked against the overall plan. This service design was limited to a single hospital, however, we believe this service can easily be replicated in larger trusts within Europe.
Ethics committee approval: n/a
Funding: Trainee reporting radiographer posts were partly funded by Health Education England.

N. Barlow: Consultant at Rotherham Hospital
R. Milner: Consultant at Rotherham Hospital

RPS 1014a-4 11:33

Patterns of movement of radiographers and professional qualifications recognition across the European Union

J. G. Couto[1], S. L. Mc Fadden[2], P. Bezzina[1], P. McClure[2], C. Hughes[2]; *[1]Msida/MT, [2]Newtownabbey/UK (jose.g.couto@um.edu.mt)*

Purpose: The 2005/36/EC directive established the process for the recognition of academic qualifications between EU member states, facilitating the movement of radiographers. The aim of this study was to investigate the patterns of movement of radiographers across the EU.
Methods and materials: A review of the Regulated Professions Database (RPD) was performed for 2015-2017. Data extracted included the number of radiographers applying for recognition of qualification that achieved recognition, required compensation measures (exam or adaptation period) before recognition, or were denied recognition. The direction of professional movement across countries was also investigated.
Results: 510 radiographers achieved recognition in another EU country each year. The UK, Ireland, and Germany are the countries receiving the most radiographers annually (203, 96, and 42, respectively). Most radiographers move away from Italy, Portugal, and the UK (108, 90, and 89, respectively).
France, Italy, and Finland required a higher proportion of applicants to undergo compensation measures (94%, 83%, and 80%, respectively). The countries of origin with a higher proportion of radiographers undergoing compensation measures were Estonia, Belgium, and Bulgaria (86%, 61%, and 50%, respectively).
The applicants with the highest proportion of rejected recognitions come from Romania (14%), Germany (13%), and the Czech Republic (11%).
Conclusion: Radiographers move between all EU member states. Two patterns of movement were identified: south to north, possibly due to higher wages, and between neighbouring countries, possibly as language was not a barrier. Negative replies and compensation measures seem to be caused by differences in training or lack of regulation of the profession.
Limitations: Data was not available for 21% of the EU countries. Some of the radiographers that achieved recognition may not move.
Ethics committee approval: n/a
Funding: PhD funded by the University of Malta.

Awareness of medical radiation exposure among patients

L. P. V. Ribeiro[1], D. V. Mestre[2], R. P. P. Almeida[2], A. F. Abrantes[2], O. Lesyuk[3], S. Rodrigues[2], K. B. Azevedo[2]; *[1]Parchal/PT, [2]Faro/PT, [3]São Brás de Alportel/PT (luispedroribeiro@hotmail.com)*

Purpose: Ionising radiation is widely used to diagnose many diseases and relevant hazards are known to be an important limitation to its application. It is believed that the awareness of radiation dose value is one of the main stages in patient radiation protection. Therefore, the main goal of this study was to survey patients' current knowledge level of medical exposure to ionising radiation.
Methods and materials: A self-applied questionnaire was used and assigned to the participants. The questionnaires consisted of two main sections to evaluate the sociodemographic data and the radiation knowledge/awareness and risks associated to medical imaging procedures. A total of 181 valid questionnaires were interpreted and statistically analysed through descriptive statistics and correlation tests.
Results: Most of the respondents were aware that general radiology uses ionising radiation (94.5%). Regarding magnetic resonance imaging, 49.3% of the participants thought that it used ionising radiation. Participants were quite divided when asked who should provide radiation information (54.14% chose the physician and 45.86% the radiographer). Furthermore, 27.62% and 45.3% think that they are not exposed to radiation at home and on a plane, respectively.
Conclusion: Patients had inadequate knowledge and mistaken beliefs about various aspects of ionising radiation and its effects. To communicate effectively, it is essential to devise methods and adequate resources for radiographers to convey correct and effective information. Furthermore, it would be appropriate to include lessons about radiation and side-effects in national education programs.
Limitations: The patients' literacy.
Ethics committee approval: The ethics committee approved the study and written informed consent was obtained.
Funding: No funding was received for this work.

RPS 1014a-6 11:45

An investigation of Irish radiographers' attitudes and opinions towards taking on the role of referrers

K. Davies; *Prosperous,Co. Kildare/IE (keisha.davies@ucdconnect.ie)*

Purpose: An amendment to S.I. 256 was introduced early in 2019 giving Irish radiographers the ability to refer patients for radiological examinations. The study gathered Irish radiographers' opinions and attitudes on this change in legislation and preparedness to taking on the role of referring.
Methods and materials: The questionnaire was distributed to 154 basic and senior grade radiographers in a total of 6 regional and local/rural hospitals in Ireland. The questionnaire consisted of 3 sections: awareness of the legislation, radiographers' opinions and attitudes towards the legislation, and preparedness to take on the role of referring.
Results: The study response rate was 31% (n=48). 56% of respondents were unaware of the incoming legislative change. 76% (n=38) were in agreement with the legislative change. 58% (n=28) stated 'better workflow' as the main benefit. 'Medico-legal risks' were cited by 40% (n=19) and 27% (n=13) cited 'lack of training' as their main concerns. 67% (n=32) said they felt prepared to take on the role of referring, with 83% (n=40) stating that they would require further training before taking on the role. Ongoing CPD was cited as the most suitable form of training by 44% (n=21).
Conclusion: Irish radiographers have a positive attitude towards taking on the role of referrers and believe it will benefit patient care. Concerns about medico-legal risks and lack of training were expressed. Attempts should be made to facilitate forms of training for Irish radiographers prior to the implementation of this legislation.
Limitations: The small sample size has an impact on the generalisability of results. A response rate of greater than 95% is considered excellent and reduces the likelihood of a non-response bias (Plantly and Carson, 2010).
Ethics committee approval: UCD ethics committee approval.
Funding: No funding was received for this work.

RPS 1014a-7 11:51

A national course for radiographers/radiographer students for acting as an RPO

T. S. Schroderus-Salo[1], P. Leppäsaari[2], M. Petäjäjärvi[3], T. Saloheimo[4], S. Törnroos[5], L. Walta[6], K. Vironen[7], A. Henner[1]; *[1]Oulu/FI, [2]Kuopio/FI, [3]Tampere/FI, [4]Helsinki/FI, [5]Kirkkonummi/FI, [6]Turku/FI, [7]Vasa/FI (tanja.schroderus-salo@oamk.fi)*

Purpose: EU-directive was given on 13/12/2013 (2013/59/EURATOM) and it was meant to be implemented in national legislation by the latest on 06/02/2018. In Finland, the directive was implemented on 15/12/2018. This change in legislation offers radiographers the possibility to act as radiation protection officers (RPO) in plain radiography, veterinary, dental imaging, and mammography. The purpose of this study was to evaluate the pilot execution of the course made by 6 institutions.
Methods and materials: To the pilot course built on a Moodle platform involved 7 student radiographers, 5 radiographers, 2 teacher students (radiographers), and 1 teacher. All materials were performed in a group of teachers from 6 universities of applied sciences in Finland. All lectures were recorded. Students had tasks (measuring of scattered dose, HVL, and use of different QA phantoms) to do in groups in simulation environments or at radiological departments in hospitals.
Data was collected during the course from emails, discussion areas, and at the end of the written exam. The data was analysed by qualitative content analyse methods.
Results: According to the first results of the data, students felt the workload to be quite heavy and the time period too short. The exact number of workhours are available after the exam. Physics, optimising methods, and patient dose calculations are the most difficult parts, although they should be familiar to everyone. More results will be available when the course ends.
Conclusion: This course will be included in the radiography program in all Finnish UAS and it will run 3 times per academic year. The written exam will be held at the same time in all institutions. For students, this enables the possibility for individual participation in the course.

Limitations: The pilot is a small group.

Patient-centred care in diagnostic radiography: perceptions of service users, service deliverers, students, and educators
M. Hardy[1], E. Hyde[2]; *[1]Bradford/UK, [2]Derby/UK (M.L.Hardy1@bradford.ac.uk)*

Purpose: To elicit the meaning of patient-centred care (PCC) from the perspectives of service users (patients), service deliverers (radiographers and managers), radiography students, and educators, and determine whether these are aligned in terms of attached importance.
Methods and materials: A 2 stage approach was adopted.
Stage 1 was a web-based attitudinal survey to explore the understanding of PCC. Respondents were asked to indicate their level of agreement to paired (positive and negative phrasing) statements. The survey content was the same across participant groups but the phrasing was tailored to the respondent group. Pre-distribution piloting ensured the suitability of the survey language and questions. Data was analysed using descriptive statistics with the impact of statement phrasing analysed using a Wilcoxon signed-rank test.
Stage 2 was focus groups and telephone interviews with volunteer participants from stage 1. Situational vignettes were developed from stage 1 responses and participants were asked to discuss these to elicit a deeper understanding of PCC priorities from the differing perspectives. The interviews were audio-recorded and transcribed verbatim before being analysed thematically to draw out key themes. These were compared and contrasted across the participant groups.
Results: While the core components of PCC identified by all groups were technical competence, dignity and privacy, and human interaction, the interpretation and meaning placed on these and their relative importance within PCC varied. Importantly, only patients identified the environment as important to PCC. Similarly, only radiographers and radiography managers identified efficiency as important.
Conclusion: Patient-centred care does not hold the same meaning for the different participant groups. In order to truly deliver PCC, the differing values and interpretations need to be aligned.
Limitations: n/a
Ethics committee approval: Ethical approval was granted by the University of Derby.
Funding: This research was funded by the UK College of Radiographers Industry Partnership scheme.

RPS 1014a-9 12:03
Compassionate patient care in diagnostic medical imaging
J. Bleiker, K. Knapp, S. Morgan-Trimmer, S. J. Hopkins*; Exeter/UK (j.bleiker@exeter.ac.uk)*

Purpose: Compassion is a poorly understood concept in medical imaging research, but an increase in its focus was recommended in the Francis report (2013). This study aimed to conceptualise compassion in diagnostic imaging.
Methods and materials: The project was conducted from within a constructivist paradigm. 34 semi-structured interviews were conducted with a purposive sample of DI ex-patients. 5 focus groups with approximately 6 student radiographers and 1 group of post-graduate radiographers were facilitated. Data was harvested from a Twitter journal club discussion between radiographers of the author's published literature review. Data was transcribed and analysed thematically.
Results: Compassion in DI is conceptualised according to three themes constructed from the data: 1) perceptible elements of the procedure, 2) underlying qualities, skills, and abilities of radiographers, and 3) moral and ethical foundations. Perceptions of an impersonal 'production line' technical procedure can be avoided and rapport developed by developing skills and abilities in asking targeted clinical questions and explanations, particularly during the introductory stage. Offering information about patients' x-ray images during the closing stages may compassionately reduce uncertainty and anxiety. Ethical practice need not necessarily include in every interaction expressions of compassion, feelings in a radiographer of caring about their patient, or feelings in patients of being valued. Contradictory organisational values were revealed in the data with an over-emphasis on an individuals responsibility for providing compassionate care.
Conclusion: The concept of compassion has depth, with surface appearances underpinned by moral values and behaviour-motivating drivers. The findings have implications for the scope of practice around training and competence in image interpretation and could inform future interventions to re-structure the communication and interpersonal components of patient examinations in DI.
Limitations: Maintaining focus in interviews.
Ethics committee approval: UoE approval granted.
Funding: No funding was received for this work.

RPS 1014a-10 12:09
The EFRS Research Hub: promoting research in radiography
L. A. Rainford, R. J. Toomey*; Dublin/IE (louise.rainford@ucd.ie)*

Purpose: The importance of radiographer involvement in research, and research in radiographer practice, has long been recognised, although there continues to be calls for further development of a research culture in the profession. Imaging research often requires access to large numbers of radiographers or other professional participants, which can be very difficult, time-intensive and expensive to achieve.
The European Federation of Radiographer Societies (EFRS) in 2019 launched the inaugural EFRS Research Hub 2019 at the European Congress of Radiology, Vienna. The Hub aims to provide radiographers and allied researchers with opportunities to conduct and take part in high-quality research, thereby raising research awareness and involvement, and expanding the professional evidence base. The development of the Hub and a summary of research outcomes to date will be provided.
Methods and materials: A venue adjacent to the Radiographers' Lounge at ECR 2019 was secured and arranged at the congress venue. 7 research projects, catering to a spectrum of radiographer participants, were devised by researchers across 3 institutions. These included projects supported the work of 2 radiographer PhD researchers. Specialist software and equipment were supplied through in-kind vendor support.
Results: The Hub 2019 attracted 249 radiographer/radiography student participants hailing from over 30 countries. These participants participated 437 times over the 7 studies. The success of the Hub is a testament to the enthusiasm of radiographers. The EFRS approved the continuation and expansion of the Hub for ECR 2020.
Conclusion: The EFRS Research Hub offers a valuable opportunity for imaging researchers, promoting a research culture in radiography. The diversity of research undertaken at ECR2020 will expand and an activity review will be disseminated.
Limitations: n/a
Ethics committee approval: n/a
Funding: Partial funding: EFRS for the Research Hub.

RPS 1014a-11 12:15
Ethical evidence in radiology research
A. M. M. Quadrado, J. Figueiredo, A. Santos*; Coimbra/PT (ana.m.quadrado@gmail.com)*

Purpose: As scientific research papers produce vital benefits for society, it is of utmost importance that researchers respect ethical parameters. Thus, the distribution of the response pattern of each project to the ethical precepts, previously defined as fundamental in a scientific investigation, should be evaluated.
Methods and materials: An original observational studies checklist was produced and validated to be fulfilled with the main ethical aspects of each research paper. The study sample comprised all research projects developed in the medical imaging and radiotherapy course, in 50 research projects in the areas of radiology, radiotherapy, and nuclear medicine, in Coimbra Health School. Descriptive analysis, using qualitative nominal variables and consisting of an exploration of absolute and relative frequencies, was implemented. Data collection was accomplished in a retrospective, observational, descriptive, and exploratory manner.
Results: The majority of papers didn't reveal ethical concerns. Only about 1/3 of scientific research revealed compliance with ethical aspects. As a positive standard of compliance, there was evidence of beneficence, non-maleficence, non-discrimination, respect for anonymity, and proportionality principle. As a negative pattern of compliance, there was no proof of respect for autonomy and

individual responsibility, free, informed, express and written consent, no stigmatisation, and neither respect for privacy nor respect for confidentiality.
Conclusion: Unfortunately, this research exposes the predomination of a lack of ethical indications produced by researchers investigations, revealing ethical culture failure.
It also shows the Institutional Research Ethics Committees and the National Data Protection Commission's flaw in allowing the publication of scientific papers without ethical evidence and orientation.
Without doubt, the Institutional Review Committees should undertake the review of such investigations to safeguard the rights and well-being of stakeholders.
Limitations: A large sample size.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Postgraduate education in radiography: what is the bigger picture?
J. M. Grehan, M.-L. Ryan, J. Last, L. A. Rainford*; Dublin/IE*
(jennifer.grehan@ucd.ie)

Purpose: The roles of allied health professionals are changing constantly and radiographers today find themselves working in one of the fastest evolving professions in healthcare. In a technology-led environment, postgraduate education alongside continuing professional development (CPD) is fundamental to ensuring competency and high standards within diagnostic imaging. Following a European-wide EFRS radiography education survey, McNulty et al (2015) raised concerns as a lack of postgraduate radiography offerings were identified. This study was conducted to gain a snapshot of the landscape of radiography postgraduate education across Europe and internationally.
Methods and materials: A single page questionnaire totalling 13 closed questions was developed, comprising 4 topic areas: demographics, working practices, postgraduate education, and funding. This was administered over 4 days to radiographers as part of the EFRS Radiographers Research Hub at the European Congress for Radiology conference 2019. 100 responses were received.
Results: Participants from 27 countries completed questionnaires. The mean number of years qualified was 14 across a range of grades. 67% of participants had postgraduate qualifications with 45% stating they used their postgraduate education daily. 55% of countries stated having senior grade radiographers in charge of modalities, while only 20% required that these senior posts have postgraduate qualifications. 37% of countries reported no formal postgraduate offerings in the modalities of CT/MR/NM/US/IR. There was no standardisation of postgraduate funding with the majority of self-funding (36%).
Conclusion: This study identified a lack of standardisation across funding, representation in radiography departments, and availability. A positive perception towards postgraduate education was noted, however, barriers identified require strategic consideration.
Limitations: Participants were professionally active and attending ECR 2019. The data represents this subset of radiographers and further research is warranted outside of a conference setting.
Ethics committee approval: n/a
Funding: No funding was received for this work.

The effect of time-of-flight on reducing the injected [^{18}F] FDG activity for whole-body PET/CT imaging of paediatric oncology patients
H. Kertész[1], T. Beyer[1], T. Traub-Weidinger[1], J. Cal-Gonzalez[1], M. Hacker[1], T. Kitsos[2], K. London[2], P. Kench[2]; *[1]Vienna/AT, [2]Sydney/AU*
(hunor.kertesz@meduniwien.ac.at)

Purpose: To assess the effect of time-of-flight (TOF) on image quality at reduced count levels for whole-body [^{18}F] FDG-PET/CT studies of paediatric oncology patients.
Methods and materials: 29 paediatric oncology patients (12F/17M, (12±5)-y/o, 13≤BMI≤28) who underwent routine whole-body PET/CT examinations on a Siemens Biograph mCT system with TOF capability (500ps) were included. The mean activity concentration was (3.8±08) MBq/kg. Events were randomly removed from the LM data to simulate reduced levels of [^{18}F] FDG activity. All data was reconstructed using the vendor e7-tools with standard iterative image reconstruction OSEM, OSEM plus resolution recovery (PSF), and with and without TOF information. A 5 mm FWHM Gaussian post-filter was applied to all reconstructions. The reconstructed images were evaluated for noise, signal-to-noise-ratio (SNR) (liver), contrast-to-noise-ratio (CNR) (all lesions), and the SNR and CNR gains with TOF were calculated.
Results: When using OSEM, the mean noise level was 11% (6%-18%) and when adding the TOF information, the noise was reduced to 9% (6%-15%). For PSF reconstructions, the lowest noise level was obtained with PSF+TOF 8%. At 50% counts, the PSF+TOF mean noise level of 10% was close to 11% for the 100% counts OSEM images. A mean gain in the SNR and CNR of 1.2-1.3 was obtained when the TOF information was included. Assuming that image noise levels below 10% are acceptable for clinical work-up, VOI analysis of the liver indicated this level be achieved at 50% counts or more when using PSF+TOF.
Conclusion: A 50% dose reduction potential in paediatric PET/CT is possible when using a 10% acceptable threshold on noise levels and iterative reconstruction with PSF+TOF. This quantitative analysis will be complemented by the qualitative grading of image quality by clinical experts.

Oncologic imaging and H2020: the PRIMAGE project helping childhood cancer research with artificial intelligence
L. Marti-Bonmati[1], A. Alberich-Bayarri[1], R. Ladenstein[2], L. Cerda Alberich[1], B. Hero[3], B. Martínez de las Heras[1], G. Marti-Besa[1], M. Aznar[4], E. Neri[5]; *[1]Valencia/ES, [2]Vienna/AT, [3]Cologne/DE, [4]Madrid/ES, [5]Pisa/IT*
(Luis.Marti@uv.es)

Purpose: Digital clinical data (imaging, pathology, genomic analytics, and wearable sensors) and patient electronic records (clinical profiling, treatment, and endpoints) are key enabling factors in clinical practice. This change is promoting clinical innovation models via real-world data-driven inferences. PRIMAGE, a 4-year European Commission-financed project having 16 European partners, is one of the more ambitious medical imaging research projects dealing with artificial intelligence in the paediatric cancer environment: neuroblastoma and diffuse intrinsic pontine glioma (DIPG).
The aim was to construct as an observational in silico study involving high-quality repository with anonymised data (imaging, clinical, molecular, and genetics) for the training of machine learning and multiscale algorithms to finally have a clinical decision support (CDS) tool.
Methods and materials: The use of computational imaging allows the extraction of multiparametric data, multiscale models, visual analytics, and artificial intelligence, leading to a new era in radiomics, characterised by high-throughput extraction, storage, and analysis of a large amount of quantitative imaging features and parameters (imaging biomarkers).
Results: The new platform will able to provide quantitative relevant information (virtual biopsies) for early disease diagnosis, disease phenotyping, disease grading, targeting therapies, and the evaluation of disease response to treatment in children with neuroblastoma and DIPG.
Conclusion: PRIMAGE's CDS system, offered as an open cloud-based platform, will provide precise clinical assistance for phenotyping, treatment allocation, and patient endpoint estimations based on imaging biomarkers, tumour growth simulation, advanced visualisation, and machine-learning

approaches. Final results will be available for the scientific community at the end of the project, ready for translation to other malignant solid tumours.
Limitations: GDPR limitations on patients recruitment will be commented.
Ethics committee approval: The project has the ethics committee approval of the coordinator hospital and reserach institute.
Funding: H2020-SC1-DTH-2018-1 GA 826494.

Computer-aided detection (CAD) of pulmonary nodules in paediatric ultra-low-dose chest CT: a performance analysis
P. J. Kuhl, H. Huflage, T. A. Bley, S. Veldhoen; *Würzburg/DE (kuhl_p@ukw.de)*

Purpose: To evaluate the dose-dependency of a computer-aided detection (CAD) system for identifying pulmonary nodules in paediatric ultra-low-dose chest CTs (ULDCT).
Methods and materials: Two scan protocols for 100kV ULDCT using tin filtration differing in the reference mAs (ref.mAs) setup for automatic tube current modulation were compared.
146 consecutive scans of paediatric patients who underwent ULDCT were included and divided into 2 study groups: 48 patients (11.1±5.5 years) underwent ULDCT with 30 ref.mAs while 98 patients (13.5±5.5 years) were scanned using 96 ref.mAs.
Patients with inflammatory consolidations were excluded. Each scan was assessed for pulmonary nodules by two radiologists and each lesion was categorised by size (2-3 mm vs ≥3 mm). Each nodule marked by the CAD system was validated in consensus. The radiation dose was estimated in size-specific dose estimates (SSDE).
Results: Radiation dose in the 30 ref.mAs group was significantly lower (0.16±0.09 mGy) than in the 96 ref.mAs group (0.56±0.22 mGy, p<0.001).
There was no significant difference between the groups regarding total CAD errors (mean per scan 1.44±3.50 vs 1.37±2.24 for NS ≥2 mm and 0.85±2.24 vs 0.71±1.59 for NS ≥3 mm) resulting in resembling CAD sensitivities (0.43 vs 0.45 in nodule size (NS) ≥ 2mm; 0.65 vs 0.74 in NS ≥3 mm).
There was no significant correlation between SSDE and CAD errors for NS ≥2 mm (r=-0.054) and NS ≥ 3mm (r=-0.067).
Conclusion: Lowering the parameters for automatic tube current modulation in paediatric ULDCT results in significant dose reduction without compromising the evaluated CAD system.
Limitations: CAD sensitivity and specificity in this oncology-dominant study group was not satisfying in both scan protocols assessed.
Ethics committee approval: n/a

The value of diffusion-weighted MRI in the response assessment of nephroblastoma
A. M. Hötker[1], Y. Mazaheri[2], A. Lollert[3], J. Zheng[2], S. Müller[4], J.-P. Schenk[5], O. Akin[2], N. Graf[4], G. Staatz[3]; *[1]Zurich/CH, [2]New York, NY/US, [3]Mainz/DE, [4]Homburg (Saar)/DE, [5]Heidelberg/DE (andreas.hoetker@usz.ch)*

Purpose: To assess the value of diffusion-weighted MRI (DW-MRI) in the prediction of viable blastemal remnant after neoadjuvant chemotherapy in patients with nephroblastoma, which is considered a poor prognostic marker and may result in additional adjuvant treatment.
Methods and materials: This IRB- approved study included 37 paediatric patients who underwent DW-MRI prior and after completion of neoadjuvant chemotherapy for nephroblastoma and subsequent surgical resection. Two blinded radiologists volumetrically assessed each tumour and the parameters mean ADC, median ADC, 12.5th/25th/75th percentile, skewness, and kurtosis were calculated. The associations between the imaging features and blastemal remnant fraction were examined using over-dispersed Poisson regression.
Results: Inter-reader agreement was high for mean ADC, volume, skewness, and kurtosis (ICC: 0.74-0.96). In univariable analysis, pre-therapeutic ADC mean, median, 12.5th percentile, and skewness were significantly associated with the presence of blastemal remnant for reader 1 (p=0.009-0.044) and pre-therapeutic ADC mean, median, 12.5th/25th/75th percentile, and skewness for reader 2 (p=0.009-0.026). In a multivariable analysis, the ADC mean was significantly associated with blastemal remnant for both readers (reader 1: fraction ratio 1.33 (1.07, 1.65), p=0.014; reader 2: fraction ratio 1.1 (1.01, 1.2), p=0.034). Post-therapeutic MRI parameters were not significantly associated with blastemal remnant.
Conclusion: A higher pre-therapeutic ADC was significantly associated with a larger fraction of a blastemal remnant after neoadjuvant chemotherapy. This could allow for a more personalised chemotherapeutic regime in these patients and offer predictive information at the time of the initial diagnosis.
Limitations: The retrospective study design.
Ethics committee approval: IRB approved.
Funding: No funding was received for this work.

Radiomic features as a marker of metastatic spread in Wilms' tumours
G. Fichera[1], L. Baffoni[2], T. Toffolutti[1], M. Zuliani[1], B. Giorgi[1], E. Quaia[1], C. Giraudo[1]; *[1]Padua/IT, [2]Montebelluna/IT (gfichera90@gmail.com)*

Purpose: To assess the role of radiomic analyses for characterising metastatic and localised paediatric renal Wilms' tumours.
Methods and materials: Paediatric patients affected by Wilms' tumours referred to our tertiary centre for staging (i.e. treatment naïve) from 2012-2018 and examined by contrast-enhanced computed tomography were included in this retrospective study. Patients matching the inclusion criteria were then subdivided according to the presence of metastases (i.e. mW and lW). One radiologist expert in paediatric imaging drew regions of interest along the margins of all primary tumours covering the entire volume using open-source software (3D Slicer). The same software was applied to extract 33 radiomic features from each patient belonging to three categories: first-order statistics, grey-level co-occurrence matrix (GLCM), and the grey-level run-length matrix (GLRLM). The Student's t-test was used to compare mW and lW patients for each radiomic feature (p<0.05). The accuracy of the variables showing a statistically significant difference was assessed by receiver operating characteristic curves.
Results: 32 patients (16 females, mean age±SD, 4±2.27 yrs) met the inclusion criteria and were analysed in this study. 10 patients were affected by metastatic disease (i.e. mW) and 22 by localised tumours (i.e. lW). Two features (one FOS, one GLRLM) showed a statistically significant difference between mW and lW: variance (p=0.043) and grey-level non-uniformity normalised (GLNUN; p=0.008). The area under the curve was good for GLNUN (AUC=0.805) and fair for the variance (AUC=0.655)
Conclusion: GLNUN can be considered as a robust radiomic marker of metastatic spread in Wilms tumours.
Limitations: Future studies addressing the clinical implications and considering the impact on the therapeutic treatment of our findings should be performed.
Ethics committee approval: Ethics committee approval obtained.
Funding: No funding was received for this work.

RPS 1012b-7 11:55
The feasibility and value of quantitative semi-automated diffusion-weighted imaging volumetry of neuroblastic tumours
S. Gassenmaier[1], I. Tsiflikas[1], J. Fuchs[1], R. Grimm[2], C. Urla[1], M. Ebinger[1], S. W. Warmann[1], J. F. Schäfer[1]; *[1]Tübingen/DE, [2]Erlangen/DE (sebastian.gassenmaier@med.uni-tuebingen.de)*

Purpose: To assess the feasibility and value of semi-automated diffusion-weighted imaging (DWI) volumetry of whole neuroblastic tumours with an apparent diffusion coefficient (ADC) map evaluation after neoadjuvant chemotherapy.
Methods and materials: Paediatric patients who underwent surgical resection of neuroblastic tumours at our institution from 2013-2019, and who received a preoperative MRI scan with DWI after chemotherapy, were included. Tumour volumetry was assessed with a semi-automated approach in DWI using a dedicated software prototype. Quantitative ADC values were calculated automatically of the total tumour volume after manual exclusion of necrosis. Manual segmentation in T1-weighted and T2-weighted sequences was used as a reference standard for tumour volume comparison.
Results: 27 patients with 28 lesions (neuroblastoma (NB): n=19, ganglioneuroblastoma (GNB): n=7, and ganglioneuroma (GN): n= 2) could be evaluated. The mean patient age was 4.5±3.2 years. The median volume of standard volumetry (T1w or T2w) was 50.2 ml (interquartile range (IQR): 91.9 ml) vs 45.1 ml (IQR: 98.4 ml) of DWI (p=0.145). Mean ADC values ($x10^{-6}$ mm^2/s) of the total tumour volume (without necrosis) were 1,187±301 in NB vs 1,552±114 in GNB/GN (p=0.037). The 5^{th} percentile of ADC values of NB (614±275) and GNB/GN (1,053±362) provided the most significant difference (p=0.007) with an area under the curve of 0.848 (p<0.001).
Conclusion: Quantitative semi-automated DWI volumetry is feasible in neuroblastic tumours with an integrated analysis of tissue characteristics by providing automatically calculated ADC values of the whole tumour as well as an ADC heatmap.
Limitations: Although the number of subjects is small, it represents one of the largest published cohorts with ADC analysis of neuroblastic tumours due to the low incidence of this disease.
Ethics committee approval: IRB approval obtained. Written informed consent waived.
Funding: No funding was received for this work.

Dynamic contrast-enhanced perfusion MRI and diffusion-weighted imaging as an imaging biomarker for paediatric cancer

L. Cerda Alberich, G. Marti-Besa, A. Alberich-Bayarri, L. Marti-Bonmati*; Valencia/ES (leogibi230@gmail.com)*

Purpose: Neuroblastomas are the most frequent solid extracranial cancer in childhood. Its diagnosis, prognosis, and monitoring are based on the information provided by multiparametric magnetic resonance images. Our focus is to explore the utility of diffusion and perfusion changes in neuroblastomas as an early biomarker of diagnosis, using diffusion-weighted and dynamic contrast-enhanced MRIs.
Methods and materials: Multiple MR imaging real-word sequences were used from 30 patients. Volumes-of-interest were calculated and transferred to DCE perfusion and apparent diffusion coefficient (ADC) maps. Histogram analysis and clustering unsupervised ML algorithms were used to determine the values of the mean and standard deviation of the initial area under the curve at 60 seconds (IAUC60) and ADC for automatic differentiation of neuroblastic tumours. The resolution was estimated and the data was smeared accordingly to identify and remove the noise and low-quality voxels.
Results: Significant differences in the mean ADC were found for neuroblastic tumours: 1.0 for ganglioneuroma, 0.82 for ganglioneuroblastoma, and 0.52 for neuroblastoma, with an uncertainty of 0.11%, 42%, and 16%. This result improves tumour differentiation with respect to state-of-the-art voxel-by-voxel methodologies, which were found to be: 1.6 for ganglioneuroma, 1.7 for ganglioneuroblastoma, and 1.3 for neuroblastoma, with an uncertainty of 3.6%, 12%, and 17%. THe mean IAUC60 was found to have a value of 43 (and 14% uncertainty) for neuroblastoma, as opposed to a value of 17 (and 17% uncertainty) with state-of-the-art voxel-by-voxel methodologies.
Conclusion: The proposed novel technique to determine IAUC60 and ADC parameters holds promise for differentiating benign and malignant neuroblastic tumours.
Limitations: The dataset size and harmonisation among different machines and data collection techniques.
Ethics committee approval: La Fe Hospital received approval from the hospital's ethics committee.

The differentiation of low- and high-grade paediatric brain tumours by using intravoxel incoherent motion imaging and diffusion kurtosis imaging

D. She*; Fuzhou/CN (shedejun@126.com)*

Purpose: To demonstrate that a new set of parameters from IVIM and DKI can be used to improve the accuracy of MR imaging for differentiating among low- and high-grade paediatric brain tumours.
Methods and materials: 49 paediatric patients with histologically-proved brain tumours who underwent IVIM and DKI were recruited in this study. The mean, minimum, maximum IVIM [pure diffusion coefficient (D), pseudo-diffusion coefficient (D*), and perfusion fraction (f)], and DKI [diffusion kurtosis (K) and diffusion coefficient (Dk)] parameters were measured. The IVIM and DKI values were measured in solid tumour regions and in normal-appearing grey matter as a control. These values were compared between the low-and high-grade paediatric brain tumours by using the Mann-Whitney U test. Receiver-operating characteristic (ROC) analysis and logistic regression analysis were performed to evaluate the diagnostic performance of single-parametric and multiparametric models.
Results: None of the IVIM and DKI parameters exhibited significant differences in normal-appearing grey matter (P>0.05). The Dk and D values were lower, whereas the K and f_{min} values were higher in high-grade paediatric brain tumours than those in low-grade paediatric brain tumours (all p<0.05). The combination of DK_{min} and K_{max} provided the largest area under the ROC curve (0.955) in the ROC analysis compared with individual parameters (D_{min} 0.891, DK_{min} 0.933, K_{max} 0.923, and f_{min} 0.734), indicating an improved diagnostic performance for tumour grading.
Conclusion: The parameters derived from IVIM and DKI can be used to distinguish low-grade paediatric brain tumours from high-grade paediatric brain tumours. The combination of DKI parameters may serve as non-invasive and quantitative imaging parameters for grading paediatric brain tumours in vivo.
Limitations: A retrospective study covering a relatively small sample of subjects.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Post-transplant thymus restoration is a really good predictor of transplant outcomes?

M. Cuccaro, F. F. Zennaro, R. Simeone, F. M. Murru, N. Maximova*; Trieste/IT (michele.cuccaro1992@gmail.com)*

Purpose: To find a correlation between post-transplant thymic volume and thymopoiesis, to associate thymic renewal with early and long-term transplant outcomes, and to expand the role of the radiology team in transplant clinical decisions and the post-transplant management of paediatric patients.
Methods and materials: Thymic volume assessment and thymocytes analysis were performed before HSCT (baseline volume), at 3, 6, 12 months, and long-term after HSCT.
74 paediatric patients who underwent an allo-HSCT from 2002-2018 were included. The control group consisted of 311 paediatric patients undergoing chest MRI for orthopaedic reasons.
The analysis was performed with HOROS software. Manual thymus tracing was performed for each cut, with the generation of a 3D reconstruction and a volume calculation.
Statistical analyses were performed using WinStat and MedCalc.
Results: There is a statistically significant correlation between thymus volume and thymopoiesis with p<0.0001 and r=0.5720.
The average thymic volume at all evaluations is significantly greater in the subgroup without GVHD: 16.1 (±10.0) cm^3 vs 11.2 (±8.7) cm^3; p<0.05.
There is a significant difference in the average thymic volume between patients who survived after the HSCT (68.8 ± 48.46) and patients who did not (2.9 ± 2.11); p<0.0001.
Conclusion: The restoration of thymic volume is a good indicator of positive outcomes in allogeneic HSCT, while a restoration failure is related to transplant-related mortality.
Thymic MRI assessment is now part of the current clinical management of transplanted patients and improves their integrated care pathways.
The next aim will be to create specific sequences that allow us to analyse the microenvironment of thymic tissue (“virtual biopsy”).

Limitations: A monocentric and retrospective study with a limited sample of subjects.
Currently, our MRI protocol allows us to study only the thymic morphology but not the microenvironment of the thymic tissue.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Ultrasound-guided core biopsy with smear cytology: the fastest route for diagnosis in paediatric oncology
A. Ilivitzki, B. Sokolovski, A. Ben Barak, S. Postovski, M. Ben Aarush*; Haifa/IL (ailivitzki@gmail.com)*

Purpose: In our hospital, ultrasound-guided fine-needle biopsy (US-guided FNB) is the first choice for tissue diagnosis in the paediatric population. In 2018, we added smear cytology in some of our biopsies, allowing for an immediate primary diagnosis. We retrospectively reviewed our experience with FNB assessing the accuracy rate, safety, and availability of the procedure, as well as the accuracy of the smear cytology and its added value for patient management.
Methods and materials: Paediatric ultrasound-guided biopsies done in our hospital from 01/2018-09/2019 were studied. Data collection included demographics, clinical and procedural data, and follow-up.
Results: 106 biopsies were performed on 91 patients, 15 of them on known oncologic patients. 96.2% of biopsies were performed within 36 hours. 79 tumours were correctly diagnosed and 1 malignancy was misdiagnosed as a benign lesion. 23 biopsies were correctly diagnosed as non-tumour. Smear cytology was performed in 30 cases; 25 tumours and 5 reactive lymph nodes. The cytologist correctly differentiated the tumour from inflammation in all cases and diagnosed the tumour in 24 of the cases. The sensitivity of ultrasound-guided FNB is 98.7%, specificity 100%, and accuracy 99%. The accuracy of smear cytology for differentiating tumours from non-tumours is 100% and for final diagnosis 97%.
Conclusion: We find ultrasound-guided FNB for suspected malignancy in the paediatric population highly available, safe, and accurate. In our small cohort, smear cytology was an excellent, real-time tool for differentiating tumour and non-tumour tissue, and in most cases allowed for early correct tumour diagnosis. This procedure may accelerate patient management and improve patient care.
Limitations: A retrospective study with a small cohort.
Ethics committee approval: All biopsies were done under informed consent. The local Helsinki committee approved the study.
Funding: No funding was received for this work.

Ultrasound practice in Europe: an EFRS survey
G. Harrison[1], M. R. V. Pedersen[2], B. Kraus[3], R. Martins Dos Santos[4], S. Noij-Rijkes[5]; *[1]London/UK, [2]Vejle/DK, [3]Vienna/AT, [4]Coimbra/PT, [5]Haarlem/NL (gillhaha@gmail.com)*

Purpose: The European Federation of Radiographer Societies (EFRS) are carrying out 3 on-line surveys to determine current views and practice of radiographers undertaking ultrasound examinations. The results of the first survey of EFRS national societies is presented here.
Methods and materials: An on-line survey was sent to 54 EFRS radiographer societies, asking for opinions and practice within their country to explore the actual and perceived role of radiographers within ultrasound.
Results: 27 countries responded (50% response rate) with 40 individual respondents providing valuable information. Radiologists perform ultrasound examinations in all but one county, 'specialist doctors' scan in 80% of countries followed by radiographers in 59%. Limitations to radiographer ultrasound practice included shortages of high-quality educational opportunities, legislation stating that only doctors can scan, and resistance from some clinical colleagues. Team working with radiology colleagues was seen as good practice to develop radiographers' skills and competence in ultrasound. Further advice was to gradually develop radiographer skills led by a few centres, ensure a rigorous audit is undertaken, and publish the outcomes to help build the case for wider implementation.
Conclusion: Radiographers' role extension into ultrasound is evident in some countries to a high level of independent practice. In other countries, radiographers either have some involvement in ultrasound scanning but not independent report writing or have no involvement at all. The results of the survey will be discussed within the presentation and suggestions provided for countries wanting to explore radiographer advancement in ultrasound.
Limitations: The survey was in English, which led to different interpretation of some questions.
Ethics committee approval: GDPR and consent were explained at the beginning of the voluntary, anonymous survey.
Funding: No funding was received for this work.

Eye assessment by B-mode ultrasound and elastography
R. A. M. Santos, A. R. R. R. Garcês*; Coimbra/PT (rutemartinssantos@gmail.com)*

Purpose: To analyse and characterise ocular structures, namely the eyeball, optic nerve head, and periorbital fat by B-mode ultrasound and sonoelastography in healthy young subjects.
Methods and materials: 240 images were collected by B-mode ultrasound and by elastography in 30 healthy subjects. The exclusion criteria was an eye surgery whose procedure leaves this very sensitive. After collection, measurements were made for the thickness and echogenicity of the intraorbital fat, eyeball, and optic nerve, as well as the colour (RGB) fraction and strain-ratio elastography of the globe and ocular nerve.
Results: The values of elasticity vary from 36.24±11.71 a.u. for the red colour in the right eyeball to 102.42±15.72 a.u. for the green colour in the left eyeball, whereas for the optic nerves they range from 38.57±8.22 a.u. for the red colour of the left optic nerve up to 141.26±23.65 a.u. for the blue colour of the right optic nerve.
Conclusion: Sonoelastography is an imaging ultrasound exam capable of analysing ocular structures and measuring values that in the future may serve as a comparison for the analysis of ophthalmological pathologies.
Limitations: It is important to have a higher age range.
Ethics committee approval: Participants were fully informed of the purpose and procedures of the study and provided written informed consent. The study conformed to the guidelines of the declaration of Helsinki and was approved by the ethics committee of the Polytechnic Institute of Coimbra (No 42/2018).
Funding: No funding was received for this work.

RPS 1014b-3 11:27
Association between risk factors and testicular microlithiasis
M. R. V. Pedersen*; Vejle/DK (Malene.Roland.Vils.Pedersen@rsyd.dk)*

Purpose: Testicular microlithiasis (TML) and its clinical significance is not fully understood. TML and risk factors have been associated with testicular cancer. This study investigated the association between TML and socioeconomic and other pre-diagnostic factors.
Methods and materials: All men who had a scrotal ultrasound examinations at the department of radiology, Vejle Hospital, from 2001-2013 were included. They were categorised as patients with and without TML and compared with pre-diagnostic data from a nationwide registry.
Results: A total of 2,404 men (283 (11.8%) with TML and 2,121 (88.2%) without TML) were included. Overall, we found no statistically significant differences in demographics, socioeconomic characteristics, or testicular diseases in men with and without TML. Men with TML had more often been treated for infertility (OR

2.09, 95% CI 0.84-5.24) and testicular torsion (OR 1.58, 95% CI 0.34-7.36) compared to men without TML.
Conclusion: Treatment for infertility and torsion was non-significantly associated with TML and no other association was found. This data does not suggest early exposure to be related to TML.
Limitations: No information in the Danish National Patient Registry or PACS was available on testicular volume, because the testicular volume is not a standard record. Selection bias may be present. However, to compensate for this, a high number of patients were included in this study and the patients were included from a long interval (2001-2013).
Ethics committee approval: The study was approved by the Danish Data Protection Agency (2008-58-0035/2009-41-3471). According to Danish law, the study did not require patients consent or approval from the Committee on Health Research Ethics of Southern Denmark, since no biomedical intervention was performed.
Funding: The Region of Southern Denmark, the Danish Council of Radiographers, and the Lillebaelt Hospital Research Council.

RPS 1014b-4 11:33
An ultrasound study to evaluate the effects of pulmonary rehabilitation in muscle mass in people with chronic obstructive pulmonary disease
P. M. Martins[1], A. A. André[2], S. de Francesco[1], P. Rebelo[1], C. Paixão[1], L. Noronha[3], A. Marques[1]; [1]Aveiro/PT, [2]Coimbra/PT, [3]Canoas/BR (pmartins@ua.pt)

Purpose: To evaluate the effects of pulmonary rehabilitation (PR) on the structure and function of the diaphragm, quadriceps, and biceps brachii muscles in people with chronic obstructive pulmonary disease (COPD).
Methods and materials: People with COPD were recruited from primary centres and hospitals. A group of age- and gender-matched healthy people were recruited. An US equipment (LogiqP6PRO, GE) with linear (11L) and convex (4C) probes was used. Rectus femoris and biceps brachii thickness (RF_T, BB_T) and their cross-sectional areas (RF_{CSA}, BB_{CSA}) were measured 3 times. Right diaphragmatic thickness at maximal inspiration (DT_{Insp}) and expiration (DT_{Exp}) were obtained. Diaphragmatic excursion (DE) was measured during normal breathing (DE_NB) and at maximal inspiration (DE_max_insp) using M-mode US. Quadriceps (QMS) and elbow (EMS) muscle strength were assessed with a handheld dynamometer, exercise tolerance with the 6-min walk test (6MWT) and 1-min sit-to-stand, before (T0) and after a 12-weeks PR programme. Non-parametric tests were used for data analysis (statistical significance was set to $p<0.05$).
Results: 25 people with COPD (9 female) aged 66.3±10.4 years, BMI=24.7±4.5 kg/m^2, and 10 healthy volunteers (4 female) aged 65.9±7.3 years, BMI=28.4±3.4 kg/m^2, were enrolled. Significant differences between COPD and healthy volunteers at baseline (T0) were found for thickness, RF_{CSA}, and BB_{CSA}. Significant increases were observed in people with COPD after PR for RF_T, RF_{CSA}, BB_T, BB_{CSA}, DT_{Insp}, 1 min sit-to-stand, 6MWT, and QMS ($0.001 \leq p \leq 0.019$). No other significant differences were found. Significant and moderate correlations were found between strength measures and muscle size ($0.404 \leq r_s \leq 0.580$).
Conclusion: There was an overall increase in muscle sizes after the PR programme. US measurements have shown to be a promising outcome measure for pulmonary rehabilitation.
Limitations: n/a

RPS 1014b-5 11:39
Skin layer evaluation by ultrasound
R. A. M. Santos, V. Fonseca; *Coimbra/PT (rutemartinssantos@gmail.com)*

Purpose:
To evaluate the aging changes of the skin by ultrasound with B-mode.
Methods and materials: 28 participants were divided into 2 groups: 18-35 years and 35-70 years. Participants who had scars and/or tattoos were excluded. All participants answered personal and sociodemographic questions, such as age, ethnicity, sun exposure, and their use of sunscreen among others. Then, an ultrasound examination was performed on different areas of the skin.
Results: There was a higher subepidermic low echogenicity band index in the age group 18-29 years in the right hand, flexing of the right and left arms, and the neck. The epidermis was superior in the age group 37-64 years and, in relation to the neck, the hyperechogenic line was less visible also in this age group, which is suggestive of cutaneous aging.
Conclusion: This study showed that there are layers of skin, especially in the age group 18-29 years, that are aged. High-frequency ultrasound is an effective method for identifying and evaluating the different layers of the skin.
Limitations: The inability to have older individuals, upwards of 70 years, for comparing with the other age ranges.
Ethics committee approval: Participants were fully informed of the purpose and procedures of the study and provided written informed consent. The study conformed to the guidelines of the declaration of Helsinki and was approved by the ethics committee of the Polytechnic Institute of Coimbra (No 36/2019).
Funding: No funding was received for this work.

Variability in liver transient elastography and acoustic radiation force impulse (ARFI) imaging-based elastography measures in a healthy paediatric cohort
A. McGee, M. Rowland, B. Bourke, L. A. Rainford; *Dublin/IE (allison.mcgee@ucd.ie)*

Purpose: In children, FibroScan transient elastography (TE) and acoustic radiation force impulse (ARFI) ultrasound elastography techniques are attractive, non-invasive tests for liver disease assessment. Since repeatability and reproducibility are hallmarks of any clinical test, this study aimed to determine the normal range of liver TE and ARFI measurements in healthy children and evaluate their repeatability and reproducibility.
Methods and materials: Healthy volunteer children had 2 independent measurements of liver stiffness, utilising FibroScan TE and ARFI imaging-based elastography, independently performed by two operators according to a protocol designed to reduce measurement confounders. For each elastography technique, the upper limit of normal (ULN) liver stiffness was determined. Measurement repeatability and reproducibility for both methods and multiple operators were examined with Bland and Altman plots and Lin's concordance correlation coefficient (CCC).
Results: 101 healthy children had two valid, independent liver stiffness measurements with TE and ARFI (Mean age: 12.4 years, SD: 2.57, M:F: 36%:65%). ULN values for liver stiffness were TE: 6.5 kPa and ARFI: 1.21 m/s. For repeat measurements, the 95% limits of agreement ranged from -0.72 kPa-+0.79 kPa for TE and from -0.13 m/s-+0.15 m/s for ARFI. Lin's CCC was p=0.85 (95%CI 0.81-0.89) for TE and p=0.61 (95%CI: 0.46-0.71) for ARFI-derived measures.
Conclusion: Despite operator expertise and efforts to reduce confounders, TE and ARFI measurements of liver stiffness in healthy volunteer children were not repeatable. Prescriptive elastography technique guidelines and the evaluation of the operator training protocol with a continued review of the operator performance to identify less expert operators is recommended to maintain and enhance diagnostic accuracy.
Limitations: n/a
Ethics committee approval: Full institutional ethical approval was obtained. Written informed consent from parents and informed assent from children were obtained.
Funding: The Health Research Board (Ireland) partly funded this research.

The impact of ageing on muscle morphology: an ultrasound study
R. A. M. Santos; *Coimbra/PT (rutemartinssantos@gmail.com)*

Purpose: To characterise the quadriceps muscle morphology in older institutionalised individuals and to evaluate the morphological muscle changes with physical activity.
Methods and materials: 36 older participants from a daycare centre were divided into two groups (18 subjects each). One of the groups performed an exercise program intervention for 8 weeks. All participants were submitted to ultrasound evaluation of the quadriceps femoris bilaterally, before and after the intervention program.
Results: 36 participants were recruited, with a mean age of 73.0±6.0 years. Vastus medialis (VM) and Vastus lateralis (VL) showed the largest, and the rectus femoris (RF) the smallest, muscle thickness (MT) for both right and left sides. For echo-intensity (EI) values, VL showed the highest values and VM the

lowest. When the two groups were compared, there were significant differences between the groups for MT and EI values ($p<0.05$).
Conclusion: There is a higher prevalence of sarcopenia in the elderly and institutionalised population. Ultrasound can be one of the strategies to prevent the sarcopenia showing positive effects on the practice of physical activity.
Limitations: The inability to use a data from the young group to compare and analyse the results.
Ethics committee approval: Participants provided written informed consent. The study conformed to the guidelines of the declaration of Helsinki and was approved by the ethics committee of the Polytechnic Institute of Coimbra.
Funding: On behalf of the AGA@4life Consortium. This work is co-financed by the European Regional Development Fund through the partnership agreement Portugal 2020-Regional Operation Program CENTRO2020 under the project CENTRO-01-0145-FEDER-023369 AGA@4life: AGA-comprehensive geriatric approach to promote an active and healthy ageing implementation of an integrated and multidisciplinary intervention program.

Ultrasound evaluation of muscular mass and strength in handball players and sedentary age-matched controls
P. M. Martins[1], S. de Francesco[1], A. Baptista[1], I. Silva[1], L. Noronha[2], A. A. André[3]; [1]*Aveiro/PT,* [2]*Canoas/BR,* [3]*Coimbra/PT (silvia.francesco@ua.pt)*

Purpose: To evaluate quadriceps and biceps brachii muscle mass and quality in athletes and sedentary young controls in ultrasound (US) images. Furthermore, we aimed to establish a correlation between US and strength variables.
Methods and materials: 16 male handball players (20.25±1.77 years; BMI=26.16±3.02 kg/m^2) and 16 sedentary age-matched university students (20.94±2.96 years; BMI=23.35±3.10 kg/m^2) volunteered to participate in this study. An US equipment (LogiqP6PRO, GE) with linear (11L) probe was used. Three measures of quadriceps thickness (Q_T), rectus femoris thickness (RF_T), RF cross-sectional area (RF_{CSA}), vastus lateralis thickness (VL_T), and pennation angle of the RF (RF_{PA}) and VL (VL_{PA}) were obtained. Of the upper limb, biceps brachii thickness (BB_T) and BB_{CSA} were measured. The echo intensity of the RF and BB were evaluated (RF_{EI}, BB_{EI}). Isometric knee extension strength (IKES), isometric elbow flexor strength (IEFS), and handgrip strength (HGS) were determined with a hand-held dynamometer. Statistical significance was set to 0.05.
Results: Statistically significant differences between athletes and controls were found in BMI ($p=0.015$) and in the strength variables HS, IEFS, and IKES ($p<0.001$), and in the US variables RF_T, RF_{CSA}, RF_{PA}, BB_{CSA} ($p<0.001$), VL_T ($p=0.008$), and VL_{PA} ($p=0.004$). There was no significant difference between groups regarding muscle echo intensity variables BB_{EI} and RF_{EI}.
Positive and strong correlations were found for BB_{CSA} and IEFS ($r=0.75$; $p<0.001$) and RF_{CSA} and IKES ($r=0.76$; $p<0.001$). A moderate correlation was found between HGS and RF_{CSA} ($r=0.57$; $p=0.001$) and BB_{CSA}($r=0.58$; $p=0.001$).
Conclusion: The results shows that regular exercise has great impact in muscle size and strength. Furthermore, muscle architecture parameters evaluated with US can be used to non-invasively evaluate athlete performance.

The role of physical activity on hamstring muscle morphology: a pilot ultrasound study
R. A. M. Santos, A. C. Tavares*; Coimbra/PT (rutemartinssantos@gmail.com)*

Purpose: To characterise and evaluate the morphological changes of the hamstring muscles through ultrasound parameters such as the pennation angle, fascicle length, cross-sectional area, echo-intensity, and muscle thickness.
Methods and materials: 22 young female divided into two groups (control group=11; athletes group=11) were submitted an ultrasound examination at 50% of the posterior region of the thigh for the semimembranosus and long portion of the femoral biceps muscles in the longitudinal and panoramic views.
Results: 22 athletes with a mean age of 23.27 years were evaluated. There were significant differences between the two groups in muscle morphology. The athletes' group showed higher values for muscle thickness, cross-sectional area, pennation angle, and fascicle length, and a lower values for muscle echo intensity.
Conclusion: Physical exercise causes changes in muscle morphology and ultrasound is a good method for the musculoskeletal assessment of athletes' performance since it is an imaging modality that allows the carrying out of comparative bilateral studies for athletes' performance follow-up and for preventive strategies to fight sedentarism.
Limitations: The low number of participants.
Ethics committee approval: Participants provided written informed consent. The study conformed to the guidelines of the declaration of Helsinki and was approved by the ethics committee of the Polytechnic Institute of Coimbra.

Dual-energy x-ray absorptiometry patient and staff radiation exposure: an experimental analysis
M. S. D. Nascimento, A. R. Clemente, Ó. M. D. C. Tavares, J. Santos*; Coimbra/PT (marianaimrnascimento@gmail.com)*

Purpose: Dual-energy x-ray absorptiometry (DXA) is broadly used to evaluate mineral bone density and consequently diagnose osteoporosis. DXA technology has evolved throughout time, implying differences in the acquisition mode and radiation exposure levels. This study aims to evaluate the examination and staff dose values in different DXA examinations performed in different technological equipment.
Methods and materials: 2 different DXA scanners, Lunar iDXA and Lunar DPX with narrow fan-beam and pencil-beam systems, respectively, were used in this study. Whole-body, lumbar spine, and left hip DXA acquisitions were performed on a PBU-60 anthropomorphic phantom and six Raysafe I3 dosimeters were placed in different positions in the room, in order to evaluate effective dose values in the possible room positions of the staff.
Results: The highest examination dose values were obtained on the Lunar iDXA scanner. The staff exposures values were higher on hip examinations and no exposure was detected during a whole-body examination.
Conclusion: The lower exposure values in DXA when compared to other medical imaging examinations are not negligible. The narrow fan-beam DXA scanner presented higher exposure values when compared with the pencil-beam technology.
Limitations: It was not possible to compare all DXA technology scanners.
Ethics committee approval: Ethical commmite approval was obtained.
Funding: No funding was received for this work.

Total and regional bone density and body mass in male adolescents: comparison between soccer players and swimmers
J. Pinheiro[1], L. P. Ribeiro[2], M. Coelho-E-Silva[3]; [1]*Sao Bras/PT,* [2]*Faro/PT,* [3]*Coimbra/PT (pedro.alexandrex94@gmail.com)*

Purpose: To compare athletes from sports contrasting in mechanical impact: soccer versus swimming.
Methods and materials: Bone mineral content (BMC) and density (BMD), lean soft tissue, and fat tissue were assessed using dual-energy x-ray absorptiometry. Anthropometric measures such as stature, sitting height, body mass, and 6 skinfolds were also measured. A Shapiro-Wilk test was performed to assess normality distribution. Descriptive statistics consisted of the median, standard deviation, maximum, minimum, frequency, and mode. A comparison between soccer players and swimmers was performed using t-tests for independent samples.
Results: Soccer players (n=40) exhibit higher BMC for the whole body (1,528.4±108.3 vs 1,404.1±50.3) than swimmers (n=36) and for all specific regions of the body, except the upper limbs where swimmers exhibit higher BMC (195.7±35.2 vs 191.8±36.7). Soccer players have higher body mass (53.0±11.7 vs 44.2±9.6) and body mass index percentile for age (61.6±24.9 vs 42.5±27.2). Whole-body DXA shows a higher fat-free mass for soccer players (40.2±6.7 vs 35.5±5.4) and fat mass (20.9±3.5 vs 18.5±2.8).
Conclusion: Physical activity seems to promote and benefit bone mass gains during growth for specific regions of the skeleton. Soccer has a greater impact on specific regions of the pelvis and swimming on the upper limbs.
Limitations: The sample size.
Ethics committee approval: The ethics committee approved the study and written informed consent was obtained.

Funding: No funding was received for this work.

Total and regional bone density and body mass: comparison between normal and overweight male adolescents
J. Pinheiro[1], L. P. Ribeiro[2], M. Coelho-E-Silva[3]; [1]Sao Bras/PT, [2]Faro/PT, [3]Coimbra/PT (pedro.alexandrex94@gmail.com)

Purpose: To compare between normal and overweight/obese male adolescents.
Methods and materials: Bone mineral content (BMC) and density (BMD), lean soft tissue, and fat tissue were assessed using dual-energy x-ray absorptiometry. Anthropometric measures such as stature, sitting height, body mass, and 6 skinfolds were also measured. Descriptive statistics consisted of the median, interquartile range, maximum, and minimum. A comparison between overweight/obese and normal-weight male adolescents was performed using a Mann-Whitney U test.
Results: Overweight/obese (n=12, body mass index ≥85% percentile for age and gender) male adolescents exhibit higher BMD for the whole-body (1.110±0.137 vs 0.967±0.166; p=0.001) and specific regions of the skeleton than normal weight male adolescents (n=27, body mass index <85% percentile for age and gender) except for the upper limbs (0.741±0.160 vs 0.731±0.029; p=0.124) and the femoral shaft (1.122±0.200 vs 1.144±0.090; p=0.315). The mean body mass for overweight/obese subjects was 73.8±10.5 kg and for normal-weight subjects was 46.0± 3.8 kg. Body composition by DXA showed that overweight/obese subjects exhibit higher fat mass (FM) for the whole body (28.2±4.0 vs 17.7±5.3; p<0,001) but shows similar values for the upper limbs (1.9±0.01 vs 1.9±0.01; p=0.411). Overweight/obese subjects also exhibited higher lean soft tissue (LST) for the whole-body (54.2±7.7 vs 33.9±10.1; p<0.001) and specific regions.
Conclusion: Excess body mass may have an osteogenic effect on bone mass gains due to the extra load exerted on the skeleton.
Limitations: The sample size.
Ethics committee approval: The ethics committee approved the study and written informed consent was obtained.
Funding: No funding was received for this work.

Reliability and clinical correlation of different grading scales in the MRI evaluation of endolymphatic hydrops
P. Malmierca Ordoqui[1], A. Paternain Nuin[1], A. Ezponda Casajus[1], M. Calvo Imirizaldu[1], A. C. Igual Rouilleault[1], V. Suárez Vega[2], R. Garcia de Eulate[1], N. Perez[1], P. Dominguez Echavarri[1]; [1]Pamplona/ES, [2]Madrid/ES (pmalmierca@unav.es)

Purpose: To analyse the degree of interobserver agreement in the detection and grading of endolymphatic hydrops (EH) with different scales and to correlate MRI findings with clinical information.
Methods and materials: 75 patients, diagnosed with unilateral definite Meniere's disease (MD), undergoing 3T-MRI of the inner ear were recruited. Cisternography, T2-FLAIR, and REAL IR imaging were performed 4 hours after intravenous contrast administration. Two independent radiologists blinded to clinical data analysed the images. Vestibular EH was evaluated using 4-stage (none/mild/moderate/severe), 3-stage (none/moderate/severe), and 2-stage (none/present) visual scales. Three-point (none/present/severe) and two-point (none/present) scales were employed for cochlear EH assessment. Discrepancies were solved by consensus. Interobserver agreement was evaluated with weighted-kappa (w-K) statistics. The association of pure tone audiometry (PTA) and caloric test with MR findings of EH was analysed with one-way ANOVA (p<0.05).
Results: Out of 75 patients, we identified EH in 90.6% of the clinically affected ear and in 17.3% on the silent side. Substantial or excellent interobserver agreement was found in all cases (mean w-K=0.83; range 0.7-0.91). The agreement was almost perfect with the 4-point vestibular EH scale (0.91±0.1). For cochlear EH, the highest consistency was obtained with the 2-point-scale (0.76±0.1). A statistically significant association was found between PTA and vestibular and cochlear EH, with all the scales. The strongest association was observed with the 2-stage cochlear (49.5±22 vs 25.4±21.5,F=45.1, p<0.001) and vestibular EH (54.8±20.1 vs 27.1±21.2,F=64.9, p<0.001) grading systems. The caloric test was also associated with 2-stage and 4-stage vestibular EH scales (F=4.5, p=0.034 and F=2.9, p=0.035, respectively).
Conclusion: A 4-stage vestibular EH grading system gave the best interobserver consistency. Vestibular and cochlear EH detected by MRI were associated with PTA and caloric tests, especially with the 2-scale grading system.
Limitations: A retrospective, single-institution study.
Ethics committee approval: Ethics committee approval obtained and informed consent waived.
Funding: No funding was received for this work.

Early radiologic manifestations of endolymphatic sac tumours in von Hippel-Lindau disease
J. F. Molto Garcia[1], H. J. Kim[2], P. Chittiboina[2], R. Lonser[2], J. Butman[2]; [1]Washington DC/US, [2]Bethesda/US (josemolto85@gmail.com)

Purpose: To characterise the imaging features of small (<1 cm) endolymphatic sac tumours (ELSTs) in von Hippel-Lindau disease (VHL).
Methods and materials: 19 VHL patients with 22 small ELST (3 with bilateral small ELSTs), 10 males and 9 females with ages between 11 and 74, were enrolled in a longitudinal natural history study of VHL.
High-resolution temporal-bone CT (<1.5 mm) and contrast enhanced MR (<3.0 mm, typically 1.5 thick/0.75 mm spacing T1-weighted) were available in all patients. Endolymphatic hydrops was evaluated in 9 cases using delayed FLAIR obtained 6-12 hours after contrast injection.
Results: Indirect MR findings: endolymphatic hydrops (4/9), intralabyrinthine haemorrhage (7/22), and enhancement within the ipsilateral vestibular aqueduct (13/22).
Direct MRI findings: intratemporal mass around the aqueduct (11/22) and distension/mass involving the extraosseous portion of the endolymphatic sac (10/22).
CT findings: erosion adjacent to the aqueduct (13/22) and asymmetric enlargement of the ipsilateral aqueduct (6/22).
Four cases were CT negative, no case was MRI negative, but 5 cases exhibited only “indirect” signs on MRI. One of these “indirect MRI only” cases were confirmed by erosion on CT.
Of the 4 cases with hydrops, 2 had neither intratemporal mass nor CT findings, and 1 had neither erosion nor intratemporal mass.
Conclusion: As VHL associated ELSTs cause irreversible audiovestibular morbidity independent of tumour size, early diagnosis and surgery have been advocated. ELSTs are locally invasive so that erosion on CT is diagnostic. Direct MRI tumour findings may be present when CT is negative. In some cases, radiologists must rely on indirect findings, e.g. intralabyrinthine haemorrhage or hydrops (requiring delayed FLAIR imaging) to establish the diagnosis of a small ELST.

Localisation evaluation of middle ear cholesteatoma with fusion of turbo spin-echo diffusion-weighted imaging and high-resolution computed tomography

X. Fan, Z. Liu*; Shenyang/CN (18940252031@163.com)*

Purpose: To assess the high-resolution computed tomography (HRCT) and turbo spin-echo diffusion-weighted imaging (TSE-DWI) fusion images in evaluating the anatomical location of cholesteatoma.
Methods and materials: A retrospective collection of 68 patients with clinically suspected middle ear cholesteatoma was performed. These patients underwent a TSE-DWI scan on a Philips Ingenia 3.0T superconductive MRI scanner and an ear HRCT scan on a Siemens Somatom Definition dual-source CT scanner. The fused image was produced using the intelligence space portal workstation to produce TSE-DWI-CT images. Subsequently, all patients underwent surgery within 14 days of the MRI scan. All data was analysed by receiver operating characteristic (ROC) to calculate the diagnostic performance of TSE-DWI-CT fusion images. According to the 2016 revised European Academy of Otolology and Neurootology/Japan Otological Society (EAONO/JOS) Joint Consensus Statements division of ear space (STAM system), Kappa statistical was used to calculate the consistency of TSE-DWI-CT fusion image division and localisation with intraoperative recording division and localisation.
Results: Based on the pathological results, patients were divided into a cholesteatoma group (n=50) and a non-cholesteatoma group (n=18). The use of TSE-DWI-CT fusion had greater diagnosis accuracy (92.65%) than HRCT (80.88%), P<0.05, the sensitivity and specificity of the diagnosis middle ear cholesteatoma were 94.00% and 88.89%. TSE-DWI-CT image fusion also showed increased localisation accuracy (88.82%), which was significantly improved compared with TSE-DWI (76.47%) and HRCT (61.76%).
Conclusion: The TSE-DWI-CT fusion image is a non-invasive, low-cost method for preoperative diagnosis of cholesteatoma and has a high diagnostic value for anatomical location of cholesteatoma, and can guide the choice of surgical planning.
Limitations: A small sample size and less negative patients.

Evaluation of necrotising external otitis on CT and MR: assessment of spreading patterns

L. van der Meer[1], C. Mitea[1], J. Waterval[1], D. Kunst[2], A. Postma[1]; *[1]Maastricht/NL, [2]Nijmegen/NL (liekevandermeer@gmail.com)*

Purpose: Necrotising external otitis (NEO) is a serious complication of the external otitis. NEO can be classified according to anterior, medial, intracranial, and crossed spreading patterns. Currently, there is no consensus on the optimal imaging modality for diagnosis. This study compares NEO spreading patterns and relevant subsites as assessed on MR and HRCT of the temporal bone in order to evaluate diagnostic comparability.
Methods and materials: We retrospectively examined 21 NEO patients who received an HRCT temporal bone and MR within a 3-month interval. Involvement of subsites and subsequent spreading patterns were assessed by a neuroradiologist blinded for the other imaging modality. The prevalence of spreading patterns by CT and MR were calculated and compared.
Results: In all patients, an anterior spreading pattern was noted on both MR and CT. Retrocondylar fat infiltration was the most consistent subsite of the anterior spreading pattern. The medial spreading pattern was seen in 7 patients at MR and in 5 of these 7 patients at CT, with parapharyngeal fat infiltration as the most consistent subsite. The intracranial spreading pattern matched in 1 out of 6 patients. The majority of patients showed a single (62%) and matching anterior spreading pattern at CT and MR.
Conclusion: The most common anterior spreading pattern of NEO can be assessed with CT as well as MR. However, the more complicated medial and intracranial spreading patterns as seen on MR could only be identified on CT in a small number of patients. Diagnosis of NEO at CT should therefore be complemented with additional imaging.
Limitations: The cohort consisted of a small number of included patients. A wide time interval between CT and MR was present, therefore a disease progression/regression between CT and MR is not excluded.

High-definition MRI for the evaluation of labyrinthic disorders

M. A. Esteves Da Cunha, T. Gillanders, M. Perez Akly, L. A. Miquelini, F. M. Olivera Plata, A. B. Granson, J. A. Funes, C. H. Besada*; Ciudad Autonoma De Buenos Aires/AR (maedacunha@gmail.com)*

Purpose: High definition magnetic resonance (HDMR) is the gold standard method in the study of the pathologies of the inner ear, however, there are no precise findings to determine a differential diagnosis between them. We investigated the usefulness of dedicated MR sequences in the characterisation of the intralabyrinthine pathology.
Methods and materials: We included patients evaluated between January 2010 and September 2019. Demographic and imaging data was collected. MRI images included high-resolution T2-weighted (HRT2), pre-enhanced T1-weighted (T1PE) and contrast-enhanced T1-weighted (T1CE). We placed ROIs on both labyrinths and in the fourth ventricle.
Results: MRI scans of 50 patients were analysed. The median age was 63.5 years (IQR 43-73). We found 18 (36%) patients with inflammatory labyrinthitis, 16 (32%) with intra-labyrinthine neurinoma, 9 (18%) with intra-labyrinthine haemorrhage, and 7 (14%) with ossifying labyrinthitis. All patients with intra-labyrinthine neurinoma had a low signal in HRT2, a mild-high signal in T1PE, and contrast enhancement. 14 patients with inflammatory labyrinthitis (77.8%) had low signal intensity in HRT2 and high signal in T1PE, and 13 patients (72.2%) had contrast enhancement. All patients with ossifying labyrinthitis had low signal intensity in HRT2 and 6 patients (87.5%) had high signal intensity in T1PE. All patients with haemorrhage had a high signal in pre-enhanced T1W. When we compared intra-labyrinthine neurinoma with inflammatory labyrinthitis, we found a significant difference in low signal intensity in HRT2 (p 0.001), T1PE (p 0.014), and in T1CE (p 0.003).
Conclusion: There are multiple entities that may alter the labyrinth signal in MR, some with similar radiologic patterns. We found differences in all the sequences studied between inflammatory labyrinthitis and intracochlear neurinoma.
Limitations: A diagnosis based on imaging findings without histopathology.
Ethics committee approval: Approved by an ethics committee.

Superior vestibular neuritis: improved detection using FLAIR sequence with delayed enhancement (1 hour)

A. Venkatasamy, T.-T. Huynh, A. Charpiot, N. Meyer, F. Veillon*; Strasbourg/FR (aina.vnkt@gmail.com)*

Purpose: Vestibular neuritis is a secondary cause of vertigo and new imaging protocols using delayed FLAIR with double-dose of gadolinium are proposed for its diagnosis. Our aim is to demonstrate that a single dose of gadolinium is sufficient.
Methods and materials: 33 patients with unilateral vestibular neuritis were compared to a control group. All patients underwent a FLAIR sequence one hour after intravenous injection of a single-dose of gadolinium at 1.5T. Two radiologists analysed the enhancement intensity of the superior (sup VN) and inferior vestibular nerve (inf VN), and ratios to the signal of the cerebellum were calculated (supVN/C). The statistics were performed using a Bayesian analysis.
Results: A strong enhancement of the sup VN was observed on the pathological side in 85% of patients with vestibular neuritis. The average signal intensity of the pathological sup VN (139 units ± 44) was more than two times the average intensity in the control group (58.5 units ± 5). The average ratios sup VN/C were significantly different between the pathological side in vestibular neuritis (2.43 units ± 0.63) and the control group (1.16 ± 0.14 (Pr(diff > 0) = 1). A delayed enhancement >71.5 units had a sensitivity of 96% and a specificity of 100% for the diagnosis of superior vestibular neuritis.
Conclusion: A delayed FLAIR sequence, acquired one hour after a single-dose of gadolinium injection, is a useful method for the diagnosis of vestibular neuritis. An enhancement of the sup VN >71.5 units was in favour of the diagnosis.
Limitations: A study on more patients should be performed to confirm the findings.
Ethics committee approval: The ethics committee of our institution approved the study (FC/ 2017-29) and it was registered on clinicaltrials.gov (NCT03452410).
Funding: No funding was received for this work.

The length of the organ of Corti in humankind: a meta-analysis study
B. Atalay, M. B. Eser, M. T. Kalcıoğlu, H. Ankaralı*; Istanbul/TR (bilgineser@hotmail.com)*

Purpose: The review question was: what is the length of the Corti organ (OC) in humankind?
Current studies offered that cochlear size might affect implant success in patients with hearing loss.
The hypothesis was: are the covariates (such as gender) affected the OC length?
Methods and materials: This meta-analysis was organised using the PRISMA statement.
The gender, age, country, continent, methods, and materials were determined as covariates, and this data was extracted from the studies.
OC was determined as an outcome. Data was pooled according to a random-effects model.
Meta-regression analysis was performed with Stata software (ver. 14.0) Metareg command. The overall effect was estimated with Metaan command.
Results: The review included 47 studies (n=3,976 material) and found that covariates weren't predictors of outcome.
Estimation of the between-study variance for the OC length (τ^2=0.7692) and the ratio of residual variance resulting from heterogeneity (I^2=0%) was statistically insignificant. Also, the coefficient determination of the model was R^2=19.18% (p=0.356). There wasn't a statistically significant relationship between the OC value and covariates.
The overall effect value for the OC length was 32.742 (CI %95:32.270-33.214) mm.
Conclusion: Evaluating each patient's OC size by imaging prior to cochlear implant surgery is important because of the wide variation.
The fact that there is a difference between spiral coefficient methods with the histological method (the gold standard for measuring the OC) necessitates the development of these methods.
Measurements that are made on images obtained by 3D reconstruction seem to be the future topics of radiology.
Limitations: The review includes only English language papers (except cites). There was no study from South America and Africa.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Role of non-echo-planar diffusion-weighted images in the identification of recurrent cholesteatoma of the temporal bone
A. Guarnera, A. Romano, E. Covelli, G. Butera, M. Barbara, A. Bozzao*; Rome/IT (guarneraalessia@gmail.com)*

Purpose: To verify the specificity of non-EPI DWI-MRI in patients operated on for middle ear cholesteatoma who showed positivity at imaging performed 6 to 9 months after surgery and underwent second-look surgery.
Methods and materials: In a single-centre, a consecutive cohort of patients treated for cholesteatoma and undergoing 1.5T non-EPI DWI-MRI 6 to 9 months after surgery was evaluated. Patients showing a hyperintense signal in the middle ear underwent revision surgery and were included in the study, whilst the others were still under radiological follow-up and were excluded. Two radiologists independently placed an ROI inside the brightest part of the observed signal alteration on coronal HASTE-DWI images. The mean signal intensity (SI) and maximum (SImax) SI values were recorded for each patient. Signal intensity ratios (SIR) were calculated using the inferior temporal cortex (SIRT) and the background noise (SIRN) as references.
Results: 143 subjects (210 ears) were evaluated. 27 subjects (40 ears) showed a high signal lesion inside the middle ear and underwent revision surgery. 36 ears were confirmed to be affected by residual/recurrent cholesteatoma. In 4 ears, inflammatory tissue was found. According to the ROC analysis, SI, SIRT, and SIRTmax showed the best statistical values (AUC=1).
Conclusion: Residual/recurrent cholesteatoma can be accurately detected using quantitative evaluation of non-EPI DWI MRI, which may avoid a revision surgery if negative.
Limitations: The analysed cohort was relatively small. The design of this study excluded patients with normal DWI since false-negative DWI-MRI in post-surgical population is only 3% of cases.
Ethics committee approval: The study was approved by the Institutional Ethics Board and in line with the Declaration of Helsinki. Informed consent was obtained for MR examination.
Funding: No funding was received for this work.

Presence of vascular loop in patients with audio-vestibular symptoms: is it a significant finding? Evaluation with a 3-Tesla MRI 3D constructive interference steady state (CISS) sequence
M. A. Z. Teleb[1], N. Almansour[2]*; [1]Alexandria/EG, [2]Alahsa/SA (mamdouh_zidan@yahoo.com)*

Purpose: To evaluate the association of audio-vestibular symptoms with the presence of vascular loops and vascular contact in the cerebellopontine angle and the internal auditory canal using 3-Tesla magnetic resonance imaging.
Methods and materials: The study included 98 patients (196 ears); 51 females and 47 males, age range 11-73 years, mean 47.6±15 years. The healthy control group with no symptoms in either ear, n=60 (120 ears); 32 females and 28 males, age range 12-69 years, mean 45.3±15.8 years. The non-symptomatic ear in the patients were added to the healthy control group. Patients underwent a neuro-otologic evaluation to exclude an underlying pathologic process. The patients with neuritis or tumours at the CPA were not included in the study. No patients had previous CPA surgery or temporal bone trauma. All MR imaging examinations were performed by using a 3T (Magnetom Verio 3T; Siemens Medical Solutions, Erlangen, Germany). The imaging protocol consisted of axial T2-weighted images of the whole brain and coronal and axial T1-weighted images of the CPA before and after administration of intravenous contrast. 3D constructive interference steady state (CISS) imaging of the CPA was performed. The healthy control group was examined with the 3D CISS sequence in addition to the routine cranial MR imaging protocol.
Results: No statistically significant association was detected between the studied audiovestibular symptoms; tinnitus, deafness or vertigo and vascular loop (grades I-III) or vascular contact (type I-III) (p<0.05).
Conclusion: It was concluded that no possible role of the presence of vascular loop or vascular contact with the 8th cranial nerve in causing tinnitus, deafness or vertigo using 3D-CISS sequence assessment. Therefore, these findings are not certainly considered pathological but possibly to be normal anatomical variants.
Limitations: The sample size.

A critical appraisal of the quality of vertigo practice guidelines using the AGREE II tool: a EuroAIM initiative
F. M. Doniselli[1], M. Zanardo[1], A. Costa[1], V. Cuccarini[1], L. M. M. Sconfienza[1], M. Mazón Momparler[2], A. Rovira Cañellas[3], E. Arana Fernandez de Moya[2]*; [1]Milan/IT, [2]Valencia/ES, [3]Barcelona/ES (fabio.doniselli@gmail.com)*

Purpose: To assess the methodologic quality of guidelines for the management of vertigo and dizziness, and to compare their recommendations.
Methods and materials: In May 2019, a systematic search was performed using MEDLINE, EMBASE, the National Guideline Clearinghouse, and the National Institute for Health and Clinical Excellence to find practice guidelines for the management of vertigo and dizziness. The evaluation of guidelines quality was performed independently by four authors using the AGREE II tool. We excluded from the results those guidelines that were not primarily focused on vertigo and dizziness, such as national/international guidelines in which vertigo and dizziness were briefly mentioned.
Results: Our strategy of literature search identified 162 studies and 16 guidelines were selected for the appraisal. Only four guidelines reached the acceptance level in the overall result (at least 60%), with two of them reaching the highest scores (at least 80%). The highest scores were found in domain 6 “editorial independence” (median value=65%) and domain 4 “clarity of presentation” (median value=61%). The remaining domains showed a low level of quality: domain 2 "stakeholder involvement", domain 3 "rigour of development", and domain 5 “applicability” had median values of 23%, 25%, and

24%, respectively. Comparing with other EuroAIM evaluations, the quality of these guidelines was very low because of low involvement of the multidisciplinary team and no use of the AGREE II guidelines in the writing guidelines recommendations.
Conclusion: Considering all guidelines, only two had a "high" overall score, while 10/16 were rated as "low" quality. Future guidelines might take this into account to improve clinical applicability.
Limitations: Our team of evaluators was composed of three radiologists and an otolaryngologist.
Ethics committee approval: No ethics committee approval was required for this systematic review.
Funding: No funding was received for this work.

Characteristics of small-world connectivity and ninety cortical nodes in bilateral sensorineural hearing loss: a study using graph theoretical analysis
X.-M. Xu, T.-Y. Tang, G.-J. Teng*; Nanjing/CN (xmxu15@163.com)*

Purpose: To explore the topological characteristics of brain connectome following sensorineural hearing loss (SNHL) from the global level and nodal level.
Methods and materials: 36 subjects with long term bilateral SNHL and 37 matched HCs were recruited from the local hospital and community for this study. Every subject underwent pure tone audiometry tests, neuropsychological assessments, and MRI scanning. AAL atlas was employed to divide a brain into 90 cortical and subcortical regions of interest, then investigated the global and nodal properties of “small world” network in SNHL and control groups using a graph-theory analysis. The global characteristics included small worldness, cluster coefficient, characteristic path length, local efficiency, and global efficiency. Node properties included degree centrality, betweenness centrality, nodal efficiency, and a nodal clustering coefficient. Interregional connectivity analysis was also computed among 90 nodes to find alterations in the SNHL group.
Results: The SNHL group had significantly higher hearing thresholds and cognitive impairments as well as disrupted internal connections among 90 nodes. The SNHL group displayed lower AUC of cluster coefficient, path length lambda, but increased global efficiency. The opercular and triangular part of the inferior frontal gyrus, rectus gyrus, parahippocampal gyrus, precuneus, and amygdala showed abnormal local features. Some of these connectome alterations were correlated with duration and cognitive ability.
Conclusion: SNHL changed some topological properties, proving potential imaging biomarkers and treatment targets for future study.
Limitations: Small sample size and various duration of SNHL. Future work needs to recruit more subjects and control confounding factors.
Ethics committee approval: This study was approved by the ethics committee of our hospital and university (2016ZDSYLL031.0). Written informed consent was obtained from each enrollee at the beginning.
Funding: National Natural Science Foundation of China (81520108015).

Influence of injection rate in determining the development of artifact during acquisition of dynamic arterial phase in Gd-EOB-DTPA MRI studies
C. Maino[1], D. Ippolito[2], A. Pecorelli[2], L. Riva[2], C. R. G. L. Talei Franzesi[1], S. Sironi[3]; *[1]Milan/IT, [2]Monza/IT, [3]Bergamo/IT*
(mainocesare@gmail.com)

Purpose: To assess whether modifications of injection rate of Gd-EOB-DTPA contrast media could influence the development of artifacts during arterial phase of liver MRI studies.
Methods and materials: All EOB-MRI studies performed at our institution between 2016 and 2018 were retrospectively evaluated. Each MRI study was acquired on 1.5 T scanner with our liver protocol: T1 in- and out-phase, T2 with and without fat-saturation, DWI, and 3D-T1 pre- and post i.v. injection of contrast media with different flow injection rate (1 mL/sec and 1.5 mL/sec). For each study, a single radiologist recorded the presence or the absence of artifacts during different acquisition phase: 1) all the examination; 2) only during the arterial phase; 3) only during portal venous phase; 4) both arterial and portal venous phase. The reviewer registered the injection flow rate of contrast medium for each examination.
Results: Of 748 MRI studies, 229 were excluded to the presence of artifacts in the entire examination. Of the remaining, 312 were obtained using a flow rate of 1 ml/s and 207 using a flow rate of 1.5 ml/s. Only 14 exams developed artifacts during the arterial phase using a flow rate of 1 ml/min, while a total of 84 when a flow rate of 1.5 ml/s was used (4% vs 40%). Comparing the different groups, the reduction of injection rate (1 ml/sec) statistically reduced the development of artifacts during arterial phase ($p<0.0001$).
Conclusion: Development of artifacts of Gd-EOB-DTPA liver-MR studies can be related to flow injection rate and the reduction of flow (1 mL or less) may help in the better assessment and acquisition of the arterial phase.
Limitations: Single-center study.
Ethics committee approval: Written informed consent.

RPS 1001a-2 11:31
Intrapatient and interobserver image quality analysis in liver MRI study with Gd-EOB-DTPA using two different multiarterial phase techniques
F. Castagnoli[1], V. Ruggeri[2], M. Bertuletti[1], M. Gatti[2], R. Inchingolo[3], R. Faletti[2], L. Grazioli[1]; *[1]Brescia/IT, [2]Turin/IT, [3]Matera/IT*
(francy-cast@hotmail.it)

Purpose: To evaluate intrapatient and interobserver variability in patients who underwent liver MRI with Gd-EOB-DTPA using two different multiarterial phase techniques.
Methods and materials: Two radiologists retrospectively analysed 154 prospectively enrolled patients who underwent liver MRI performed with 1.5T MAGNETOM Aera twice from February 2017 to March 2019, using two different multiarterial algorithms: CAIPIRINHA or TWIST-VIBE (Siemens Healthcare, Erlangen, Germany). For every patient, breath-holding time, BMI, sex, and age were recorded before the second MRI study. The phase without contrast media and every arterial phase (after administration of Gd-EOB-DTPA; dose: 0.025ml/kg; injection rate: 1ml/s) were evaluated using different scores to quantify Gibbs artefacts (present/absent), noise (present/absent), breath artefacts, and general quality of images (score 1-5, 1: “non-diagnostic”, 5: “absence of artefacts”/“optimal exam quality”).
Results: CAIPIRINHA always had better scores for every parameter considered, with the exception of noise score analysis. 37% of patients failed to obtain multiarterial phases: in particular 11% had only one arterial phase, 26% had two. Breath-holding time was the only parameter that influenced the performance of multiarterial techniques. TWIST-VIBE had a worse score for Gibbs and breath artefacts but a better noise score: 23% of patients in the basal phase had noise (vs46% in CAIPIRINHA), 18% in the first arterial phase (vs29%), 18% in the second arterial phase (vs30%), and 17% in the third arterial phase (vs31%).
Conclusion: CAIPIRINHA always allows the obtaining of diagnostic images without multiarterial phase only in 37% of cases. TWIST-VIBE always allows the obtaining of three arterial phases. Breath-holding time is the only parameter which can influence the preliminary choice between CAIPIRINHA and TWIST-

VIBE. TWIST-VIBE is preferable in very compliant patients, otherwise CAIPIRINHA is more appropriate.
Limitations: Limited cohort; non-homogeneous follow-up.
Ethics committee approval: Study approved by ethics committee.
Funding: No funding was received for this work.

Gadoxetate disodium-enhanced MRI: assessment of arterial phase artifacts and hepatobiliary uptake in a large single centre series

N. Vietti Violi[1], P. Agriradi[2], A. Rosen[2], M. Cherny[2], A. Weiss[2], G. Hernandez Meza[2], J. S. Babb[2], S. Kihira[2], B. Taouli[2];
[1]Lausanne/CH, [2]New York, NY/US (nviettivioli@gmail.com)

Purpose: To assess the prevalence of arterial phase artifacts during MRI using gadoxetate disodium and its predictive factors as well as the quality of the hepatobiliary phase (HBP) in a large series.
Methods and materials: This retrospective single centre study included 851 patients (M/F: 537/314, mean age: 63y) with gadoxetate disodium MRI performed in 2017. The MRI protocol included unenhanced, dual arterial (AP1 and AP2), portal venous, transitional and HBP. Three independent radiologists graded dynamic images using a 5-scale score (1: no motion, 5: severe, nondiagnostic). Transient severe motion (TSM) was defined as a score ≥4 during at least one AP with a score ≤3 during other phases. HBP uptake was assessed using a 3-scale score (1: liver hyperintense to portal vein (PV), 2: liver isointense to PV, 3: liver hypointense to PV). The association between demographic, clinical, and acquisition parameters with TSM was tested in uni- and multivariate logistic regression.
Results: TSM related artifacts were observed in 103/851 patients (12.1%): 83 (9.8%) in one AP and 20 (2.3%) in both AP. 87/851 (10.2%) patients demonstrated limited contrast uptake at HBP. 6 patients (0.7%) presented TSM and limited HBP contrast uptake. Presence of TSM was significantly associated with age, presence of liver disease, and cancer on univariate logistical regression, but not in multivariate analysis (p>0.05). No association was found between imaging acquisition parameters and TSM.
Conclusion: TSM was present in 12.1% of gadoxetate disodium-enhanced MRIs and was poorly predicted based on clinical factors. TSM is rarely associated to limited HBP contrast uptake.
Limitations: Single center study.
Ethics committee approval: The institutional review board approved the study and waived informed consent.
Funding: Swiss National Science Foundation, fellowship:P2LAP3_178053.

Relative enhancement of the liver during hepatobiliary phase after Gd-BOPTA administration: correlation with bilirubin levels and renal function

R. Valletta[1], M. Bonatti[2], F. Lombardo[1], G. Zamboni[1], G. Schifferle[2];
[1]Verona/IT, [2]Bozen/IT (riccardo.valletta@studenti.univr.it)

Purpose: To investigate if there is correlation between liver signal intensity during hepatobiliary phase (HBP) after Gd-BOPTA administration and liver/renal function.
Methods and materials: IRB-approved retrospective study, need for informed consent was waived. 75 consecutive patients (44 M, 31 F; mean age 63y) who underwent Gd-BOPTA-enhanced liver MRI (including HBP) on a 1.5T scanner between January 2018 and August 2019 were included. Liver signal intensity on unenhanced and HBP images was measured using round ROIs and normalised to paraspinal muscles. Subsequently, normalised relative enhancement (NRE) between unenhanced phase and HBP was correlated with patients' total bilirubin blood levels and eGFR.
Results: Mean total bilirubin was 1,73 mg/dl (0,27-23,23 mg/dl), while mean eGFR was 69,5 (48-135). There was a significant, weak negative correlation between NRE and total bilirubin (p=0.004; Spearman r=-0.329). No significant correlation was found between NRE and patients' eGFR.
Conclusion: Patients with higher bilirubin levels tend to show lower relative enhancement of the liver during HBP compared to patients with normal liver function. A supplementary dose of Gd-BOPTA could be considered in these patients in order to achieve an optimal quality of the examination, even if further investigations are needed.
Limitations: One limitating factor is the relatively small population.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Visualising liver function by T1 relaxometry based quantification of hepatic concentration of a gadolinium-based liver specific contrast agent

C. Breit, T. Heye, D. J. Winkel, D. Boll*; Basel/CH*

Purpose: To evaluate whole-organ liver function non-invasively, to get spatial information on segmental liver metabolism, and determine a parameter which correlates with fibrotic changes.
Methods and materials: 72 healthy patients (mean 53 yrs, 19-87yrs) without histopathologically proven liver disease, 21 patients with temporary elevated liver enzymes (mean 66 yrs, 34-91 yrs), and 109 patients with biopsy proven liver fibrosis or cirrhosis (mean 61 yrs, 36-86yrs) underwent 1.5T (133) or 3T (69) routine MRI and were included. Fibrosis was classified by using the histopathologicy METAVIR and the clinical Child-Pugh Scores. Gd-concentration was quantitated based on T1 map-based calculations. Gd-concentration mapping was performed by using a look-locker approach prior to intravenous administration of hepatocyte specific contrast agent. Parenchymal fat fraction, R2*, liver volume, laboratory hepatic function parameters, gender, and age were aquired and used for classification based on machine learning algorithms.
Results: Mean Gd-concentration in the liver parenchyma was significant (p<0.0001) higher for healthy patients ([Gd]=0,51mcmol/l) than for those with liver fibrosis or cirrhosis (([Gd]=0.31mcmol/l) and with acute liver disease ([Gd]=0.28mcmol/l), even though there was no significant difference in Gd-concentration between patients with acute liver disease and those with known fibrosis or cirrhosis. There was a significant (p<0.0001) moderate negative correlation for the mean Gd-concentration and the METAVIR score (r=-0.44) as well as for the Child-Pugh stage (r=-0.35). There was a significant strong correlation between the bilirubin concentration and the Gd-concentration (r=-0.61, p<0.0001).
Conclusion: T1-based measuring of contrast agent concentration allows to non-invasively quantify liver function and is a potential predictor even for detection of early fibrotic changes. Furthermore, it is possible to get additional spatial information about liver metabolism by creating concentration maps.
Limitations: Retrospective study design.
Ethics committee approval: Informed consent waived.

Mapping of the liver function: impact of MR field strength on T1 reduction rate

D. Catucci, V. C. Obmann, A. Berzigotti, J. Hrycyk, W. Kajdi, C. Gräni, L. Ebner, A. Christe, A. T. Huber*; Berne/CH (verena.obmann@insel.ch)*

Purpose: To determine whether T1 reduction rate is dependent on field strength in patients with and without liver cirrhosis.
Methods and materials: 85 consecutive Gd-EOB-DTPA liver MRI scans with available T1 mapping pre- and post-contrast administration in equilibrium phase were analysed between September 2018 and January 2019. 44 exams were performed on a 1.5T system and 41 exams on a 3T system. Each of these two groups was then divided into patients with and without liver cirrhosis. T1-reduction rates were calculated as: (native T1 – post contrast T1) / native T1. Groups were compared using a Mann-Whitney-U test.
Results: At 1.5, 23 patients had cirrhosis, while 21 patients had no cirrhosis. At 3T, 17 patients had cirrhosis, while 24 patients had no cirrhosis. At both 3T and 1.5T, T1 reduction rate discriminated between patients with and without cirrhosis (p=0.001 and p>0.001). T1 reduction rates did not differ significantly between 3T

and 1.5T in patients with cirrhosis (median 60% vs. 59%; p=0.991) and without cirrhosis (median 75% vs. 75%; p=0.787).
Conclusion: This study shows that T1 reduction rate is comparable between 3T and 1.5T and may discriminate patients with and without liver cirrhosis as an imaging surrogate to map liver function.
Limitations: We acknowledge limitations to our study, mainly the retrospective study design and limited number of patients included.
Ethics committee approval: This study was approved by the cantonal ethics committee Bern. Written informed consent was given.

RPS 1001a-7 12:01
Precision analysis for dual R2 MRI relaxometry in assessment of liver disease
H. Leao Filho[1], W. Chua-Anusorn[2], P. Clark[3]; [1]Sao Paulo/BR, [2]Camberra/AU, [3]Perth/AU (hiltonmlf@gmail.com)

Purpose: A quantitative MRI method (QMRI) was recently validated using multi-compartmental R2 relaxometry (MCR2R) to map liver fibrosis/inflammation in patients with non-alcoholic steatohepatitis. The study was designed to evaluate this method precision through examinations performed in volunteers on a 3T scanner at different times using the same parameters.
Methods and materials: 30 volunteers were recruited. They underwent exams on a 3T scanner after fasting for 4h. They were re-scanned on the same MRI and protocol less than 1 week apart. The protocols used a multi-spin echo sequence (MSE) to determine water extracellular fraction and R2 maps. We also acquired multi-gradient echo sequences (MGE) to calculate proton density fat fraction. All measures were performed by one radiologist with 13 years of experience using a ROI encompassing the whole liver area in a single slice. The repeatability of the measures was assessed through the within-subject coefficient of variation and repeatability coefficient.
Results: Extracellular water fraction (ECWF) mean values were 12.99% (±1.88) in the first exam and 13.06 (±1.9) in the second, ranging from 9.9 to 16.9%. The repeated scans were not statistically significantly different (T-test). The bias between scans was <0.1% ECWF. The repeatability coefficient between scans was 2.47% (absolute measure of ECWF), comparable to the 2xSD variation of ECWF obtained previously across each fibrosis grade, indicating that approximately 95% of patients would receive the correct fibrosis grade. The within-subject coefficient of variation was 6.86% (as a percentual).
Conclusion: The study showed good precision of the QMRI method for quantifying the extracellular water fraction (as a proxy for degree of fibrosis), with repeatability coefficient of 2.47%.
Limitations: Single institution. Small number of patients. One reader.
Ethics committee approval: Approved by ethics with informed consent.
Funding: No funding was received for this work.

A comparative study of diagnostic value of DWI MRI bewteen mono-exponential, bi-exponential, and non-Gaussian kurtosis models in pancreatic ductal adenocarcinoma
S. Peng; *Sichuan/CN (pengsk1986@126.com)*

Purpose: To investigate the diagnostic value of different DWI models (monoexponential, biexponential models multiple b values diffusion-weighted imaging, and non-Gaussian diffusion-weighted MRI) in poorly differentiated pancreatic ductal adenocarcinoma.
Methods and materials: 52 patients with poorly differentiated pancreatic ductal adenocarcinoma confirmed by surgery were collected. All patients underwent DWI (1.5T, Multi-b values : 0, 50, 100, 150, 200, 500, 800, 1000, 1500, 2000 s/mm2). Mean values of DWI-derived metrics $ADC_{standard}$, ADC_{slow}, ADC_{fast}, f, MK, and DK were calculated from regions of interest in all tumours and non-tumorous parenchyma and compared. ROC was used to evaluate the diagnostic efficiency.
Results: All lesions could be distinguished from non-lesions by three DWI sequences (ADC-DWI, DKI and IVIM). The $ADC_{standard}$, ADC_{fast} , f values, and MK showed significant differences between tumours and non-tumorous parenchyma (both $P < 0.05$). The area under the curve for ADC, D, D*, f, K, and DK were (0.705, 0.665, 0.648, 0.614), respectively. The ROC curve integrated with $ADC_{standard}$ and MD has better diagnostic efficiency (the area under ROC curve is about 0.754).
Conclusion: $ADC_{standard}$, ADC_{fast}, f, and MK could differentiate tumours from non-tumorous parenchyma. The combination of Gaussion distribution model and non-Gaussion distribution model has the potential to increase the diagnostic accuracy of DWI in patients with pancreatic ductal adenocarcinoma.
Limitations: Not enough cases and focused only on poorly differentiated pancreatic cancer.

MRI with diffusion-weighted imaging in the evaluation of abdominal Castleman's disease
W. Mingliang, Z. Mengsu; *Shanghai/CN (wang.mingliang@zs-hospital.sh.cn)*

Purpose: To analyse the MR imaging characteristics and ADC values of abdominal Castleman's disease (CD).
Methods and materials: The MR imaging data of 14 patients with CD were retrospectively reviewed. Image analysis included the location, size, shape, lesion margins, plain signal intensity, and enhancement pattern of the lesions and spleen. ADC values of the CD and spleen were measured on the images of ADC map.
Results: Of the 14 patients with CD, 9 cases were hyaline vessel type, the mean maximum diameter of the lesion was 5.1±2.4 cm, 5 cases were plasma cell type, and the mean maximum diameter of the lesion was 4.5±1.9 cm. All 14 lesions were round or elliptical. The lesions showed an equal or slightly lower signal intensity on T1WI and high or slightly higher signal intensity on T2WI, high signal intensity on DWI. All 14 cases were significantly enhanced in the arterial phase and persisted enhancement in the portal vein phase and in the delayed phase, which was consistent with the spleen. The mean ADC values of CD and spleen in 11 patients without cirrhosis were respectively $(1.12\pm0.18) \times 10^{-3} mm^2/s$ and $(1.13\pm0.15) \times 10^{-3} mm^2/s$, and there was no statistically difference (P=0.836).
Conclusion: The MR characteristics of Castleman's disease have certain characteristics. In particular, the signal characteristics of diffusion-weighted imaging and ADC values of lesions are consistent with the spleen, which is helpful for diagnosis and identification.
Limitations: The number of cases included in this study was small.
Ethics committee approval: The retrospective study was approved by the institutional review board of our hospital. Specific informed consent was not required according to Local Ethics Committee rules for retrospective study design.
Funding: No funding was received for this work.

T1-weighted fat-suppressed sequence: most specific way for time and cost-effective diagnosis of endometriosis with MRI
A. Dumbadze; *Tbilisi/GE (dumbadze.a@yahoo.com)*

Purpose: To determine the accuracy of the high specificity of hyperintensity foci presence on T1-weighted fat-suppressed images in the diagnosis of superficial and deep pelvic endometriosis in everyday practice.
Methods and materials: During 12 months, 40 patients (35.4 ± 7.2 years) referred to our institution with clinically suspected endometriosis underwent 3.0T MRI examination of pelvis without using i.v. contrast. Every examination included T1-weighted fat-sat sequences and was interpreted by two radiologists (with different experience). All patients with T1-W fat-sat hyperintensity foci proceded afterwards to minimally invasive diagnostic procedures as laparoscopy or cystoscopy for confirmation of endometriosis with histopathology.
Results: The two radiologists had an identical sensitivity of 80.3% (95% CI; 57.6-95.2). The specificity was 100% (95% CI; 82.4-100) for the young and 89.5% (95% CI; 66.9-98.7) for the experienced radiologist. The area under the ROC curve was 0.90 (95% CI; 0.81-0.99) for the young and 0.83 (95% CI; 0.70-0.96) for the experienced radiologist. The intraoperator variability was low with almost perfect reproducibility for the overall detection of lesions; k=0.90 (95%

CI; 0.77-1) for the young and k=0.85 (95% CI; 0.70-1) for the experienced radiologist.
Conclusion: Our results show that the characterisation of lesions by MRI, especially with using of T1-W fat sat sequence, is highly specific and moderately sensitive in the diagnosis of endometriosis, with high interoperator reproducibility. Pelvic protocols should always include the T1-W fat-sat sequence. In addition to its accuracy in distinguishing teratomas from endometriomas, it helps to better characterise adhesions and distinguishing from post-surgical scars. In future MRIs, it can be used to diagnose pelvic lesions and the accurate examination may replace the necessity of biopsy.

RPS 1001a-11 12:25
Impaired enhancement of portal vein on portal venous phase with Gd-EOB-DTPA compared to Gd-BOPTA in cirrhosis
F. Vernuccio, V. Greco, C. Gozzo, R. Cannella, M. Midiri, G. Brancatelli; *Palermo/IT (federicavernuccio@gmail.com)*

Purpose: This study compared enhancement of the portal vein with Gd-BOPTA and Gd-EOB-DTPA in cirrhotic patients.
Methods and materials: A total of 84 cirrhotic patients (30 women, 54 men) who underwent both Gd-EOB-DTPA– and Gd-BOPTA–enhanced liver MRI from 2008 to 2018 were retrospectively included. Interval time between Gd-BOPTA and Gd-EOB-DTPA MR studies was 10.7 months. Patients received a weight-dependent dose of Gd-EOB-DTPA (0.025 mmol/kg body) or Gd-BOPTA (0.1 mmol/kg body). Signal intensity of the portal vein, liver-to-portal vein contrast ratio, and image contrast of portal vein were calculated on portal venous phase for each exam and compared per patient through the Wilcoxon signed rank sum test. Statistical significance was set at $p<0.05$.
Results: Compared to Gd-BOPTA MRI, Gd-EOB MRI in the portal venous phase showed significantly lower portal vein signal intensity (1461.72 ± 360.56 vs. 1256.68 ± 327.71, respectively; $p<0.001$) and image contrast of the portal vein (0.27 ± 0.11 vs. 0.35 ± 0.11, respectively, $p<0.001$) and higher liver-to-portal vein contrast ratio (0.72 ± 0.11 vs. 0.64 ± 0.11, $p<0.001$).
Conclusion: At the recommended dose of hepatobiliary contrast agents, Gd-EOB-DTPA yields lower enhancement of the portal vein than Gd-BOPTA in cirrhotic patients. Gd-BOPTA might therefore enable better evaluation of the portal vein in cirrhotic patients.
Limitations: Retrospective design, small sample size and single-centre experience, lack of correlation with laboratory data or contrast dose.
Ethics committee approval: IRB approved, informed consent waived.

A retrospective review of recalled microcalcifications following breast cancer treatment
P. L. Gammack, M. Smith, M. Stewart; *Edinburgh/UK (pauline.gammack1@nhs.net)*

Purpose: This study focused on women with previously treated breast cancer who were recalled for further imaging due to microcalcifications. We aimed to determine our ability to characterise these; which factors increased risk of recurrence, timeframe of recurrence, and results of biopsies.
Methods and materials: Data was collected for patients recalled between June 2013 and February 2019, specifically time interval, original diagnosis, original mammographic appearance, and the outcome of recall.
Results: 194 women were recalled for microcalcifications for further views +/ biopsy. 126 were for ipsilateral to the original cancer, 66 contralateral, and 2 bilateral. 104 (54%) underwent biopsies, the remainder were considered benign. 66% confirmed recurrence/new cancer. 3 microcalcifications were recalled and not biopsied, then subsequently determined to be a recurrence. The time interval for recurrence ranged from 1 to 12 years, with an average of 4.4 years. 74% recurred within 5 years. Of the 40 ipsilateral recurrences, 29 had DCIS with their original cancer and 26 had microcalcifications in their initial cancer.
Conclusion: Our study proved that we perform well in the characterisation of mammographic calcifications in the treated breast. Biopsy rates were appropriate as a large percentage confirmed histological recurrence. Reassuringly, only 3 recurrences were missed (0.02% of all recalls). The presence of DCIS and calcifications in the original cancer increased the risk of recurrence. 25% of recurrences and new cancers were beyond 5 years of follow-up, suggesting that our health board's protocol of following up treated breast cancer for 10 years is appropriate.
Limitations: Data regarding previous mammogram/pathology results were not available for patients who were treated prior to electronic records. The record recalled patients is maintained manually by a mammographer and may not include all patients in the program.

Representative calcifications revisited: how many sequential breast calcifications are adequate for definitive diagnosis?
W. Teh, R. Uzvolk, M. Morgan, J. Rees, R. Felton; *London/UK (william.teh@nhs.net)*

Purpose: The Brevera breast biopsy device provides real-time visualisation of representative calcifications during biopsy potentially, allowing fewer samples, minimising trauma, and ensuring the accuracy of the biopsy. This study examines how many sequential specimens containing calcifications are required for accurate diagnosis.
Methods and materials: A prospective study using tomosynthesis-guided 9 gauge vacuum biopsy (VAB) of screen-detected microcalcifications with realtime imaging of specimen radiograph. A minimum of 12 samples or more until representative calcifications were obtained. Sequential imaging of breast specimens was correlated with the histological assessment for the presence of calcifications and pathology. Final correlation with any lesions undergoing vacuum excision for B3 (high-risk lesions) or surgery.
Results: 157 VABB were performed on 155 patients with calcifications ranging from 2-120 mm (mean 16.3 mm) with pathological calcifications confirmed in 152 (96.8%). 82 (52.2%) were benign, 20 (12.7%) B3 (high risk), 3 suspicious (1.9%), and 47 (29.9%) malignant. 43% of calcifications were obtained on the first specimen. For benign lesions, there was a 85% accuracy on the first positive specimen and 100% by the fourth. For DCIS, the diagnosis was obtained on the first positive specimen in 92% and 100% by the fourth. Three lesions (1 B3 and 1 B4) were upgraded to DCIS on vacuum excision. 10 DCIS were upgraded to the invasive disease at surgery in spite of representative calcifications in 3-7 specimens.
Conclusion: Realtime sequential visualisation of confirmed representative calcifications can reduce the number of samples required during biopsy. Lesions containing calcifications can be confidently diagnosed when 4 specimens containing calcifications are obtained. Careful correlation with direct histological analysis in the multidisciplinary meeting is required. Underestimation of invasive malignancy can still occur.
Limitations: Single institution. Ongoing to accrue numbers.
Ethics committee approval: n/a
Funding: Loan of equipment.

RPS 1002b-3 11:37
Prevalence of papillary lesions in solitary dilated duct visualised by mammography
V. J. Ayres[1], L. Ramalho[2], L. D. M. Pompei[1], E. F. C. Fleury[3]; [1]*Santo André/BR,* [2]*Bg/BR,* [3]*Sao Paulo/BR (ayresve@gmail.com)*

Purpose: To determinate the prevalence, pathological significance, and risk factors associated with papillary lesions when solitary dilated duct is visualised at mammography.
Methods and materials: Prospectively evaluation of consecutive mammography was performed in a specialised breast cancer control centre, in accordance with local ethical approval. Patients that presented solitary dilated duct at mammography were later evaluated with ultrasonography (US). Cases that exhibited intraductal components were submitted to percutaneous biopsy, following anatomopathological correlation.
Results: In the period from March 17, 2016, to March 10, 2017, 9,035 mammographic exams were included, 8,125 (90%) representing screening and 910 (10%) diagnostic exams. The mammographic study identified 135 solitary dilated duct (SDD) cases (1.49%) and 94 (1.04%) of them followed US evaluation. Percutaneous and/or surgical biopsy were performed in all 24 cases with intraductal components and it revealed 8 papilloma lesions: 6 papillomas, one papillary lesion, and one sclerosing papilloma. Association with pathological papilloma findings with statistical significance ($p < 0.05$) using Chi Quadrado were menopause, parity, papillary discharge, breast density category (a) entirely fatty and (b) there are scattered areas of fibroglandular, microcalcifications on mammogram, and mass on ultrasound.
Conclusion: Solitary dilated duct findings without other suspicious signs at mammography benefits from US analysis for intraductal content's evaluation, which often represents benign findings. When associated with intraductal mass, biopsy should be considered and the expected result should be papilloma.
Limitations: The limitation was the 32 cases in which it was not possible to perform a complementary study of US.
Ethics committee approval: This paper had the local ethical committee approval and all participants provided written informed consent.
Funding: No funding was received for this work.

Role of contrast-enhanced imaging in the management of lesions of uncertain malignant potential (B3)
C. Bellini[1], A. Franconeri[2], G. Bicchierai[1], D. de Benedetto[1], F. Di Naro[1], J. Nori[1], V. Miele[1]; [1]*Florence/IT,* [2]*Pavia/IT (1chiarabellini@gmail.com)*

Purpose: To evaluate the role of contrast-enhanced digital mammography (CEDM) and dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) in the management of lesions of uncertain malignant potential (B3).
Methods and materials: We screened 374 women with histological diagnosis of B3 from July 2016 to December 2018, who underwent open excision (OE), vacuum-assisted excision (VAE), or with proof of stability on follow-up. We retrospectively included 252 patients who performed CEDM or DCE-MRI within 30 days before or after a biopsy. Positive predictive values (PPV) and negative predictive values (NPV) of B3 malignancy of the different contrast-enhanced imaging techniques were calculated. Fisher's exact test was used to compare CEDM and DCE-MRI groups. Contrast-enhanced imaging concordance was evaluated for B3 lesions, which underwent both techniques.
Results: 189 (75.0%) patients performed CEDM, 75 (29.8%) DCE-MRI, and 17 (6.7%) both. Out of 123 B3 enhancing on CEDM, 34 (27.6%) resulted in cancers (19 carcinomas in situ, 15 invasive), while out of 53 B3 enhancing onDCE-MRI, 24 (45.3%) resulted in cancers (17 carcinomas in situ, 7 invasive). Sensitivity and NPV of CEDM and DCE-MRI were 100%, specificity was 42.6% vs 43.1%, while accuracy was 52.9% vs 61.3%, respectively. In 11 lesions studied with both techniques, concordance was 100%.
Conclusion: Our results showed that contrast-enhanced imaging is a fundamental tool in B3 management with the high negative predictive value of malignancy since no upgraded B3 lesion showed enhancement. No differences between CEDM and DCE-MRI were found in the group which underwent both techniques.
Limitations: Restrospective study. Not every patient had undergone the two contrast-enhanced imaging techinques. Small sample of study.

Cone-beam breast CT features associated with HER2/neu overexpression in patients with primary breast cancer
Y. Zhu, Y. Zhang, Y. Ma, Z. Ye*; Tianjin/CN (zhuyueqiang1985@126.com)*

Purpose: To identify the relationship between human epidermal growth factor receptor 2 (HER2) status and cone-beam breast CT (CBBCT) characteristics in surgically resected breast cancer.
Methods and materials: Preoperative CBBCT of patients with BI-RADS 4 or 5 lesions identified on mammography or ultrasound and dense or very dense breast tissue were retrospectively evaluated in 181 surgically resected breast cancers (triple-negative excluded) between October 2012 to August 2015. A set of CBBCT descriptors was semiquantitatively assessed by consensus double reading. Multivariate logistic regression analysis using backward elimination method (BEA) was performed to identify independent predictive factors of harbouring HER2/neu. Principle component analysis (PCA) was used to determine characteristics that might differentiate HER2 status. Receiver operating characteristic (ROC) curve analyses were conducted to determine the predictive capability.
Results: HER2 positive was found in 101 (55.8%) of 181 patients. Based on BEA, pathologic grade, maximum dimension, lobulation, ΔCT, and calcification morphology were confirmed as independent predictive factors of HER2/neu overexpression. PCA showed that calcification- and border-related characteristics were the most important for differentiation. ROC curve analyses showed that CBBCT features (AUC = 0.853) were superior to clinicopathologic features (AUC = 0.613, $P < 0.001$) and comparable to combination (AUC = 0.856, $P = 0.866$).
Conclusion: CBBCT features could be used to prognosticate HER2 status independently, which are potentially complementary to histopathologic result and helpful in guiding biopsy.
Limitations: We limited our analyses to non-triple-negative breast cancer, surgically resected, and non-preoperative treated specimens.
Ethics committee approval: The institutional review board approved this study and written informed consent was obtained from all patients.
Funding: National Key R&D Program of China (No. 2017YFC0112600 and 2017YFC0112601). National Natural Science Foundation of China (No. 81571671).

Triple negative and HER2-positive breast cancers found by mammography screening associate with excellent prognosis
J. Alanko[1], R. Vanninen[2], M. Tanner[1], J. Isola[1]; [1]*Tampere/FI,* [2]*Kuopio/FI*

Purpose: To compare clinical and biological features and prognosis of screen detected and clinically detected breast cancers in women aged 50 to 68 years.
Methods and materials: We collected the mammograms and clinical data of 825 patients diagnosed with the invasive breast cancer for the first time in Tampere between 2006 and 2014. Of these, 572 cancers were found by screening mammography (69%), 171 cancers were diagnosed between the screening rounds (21%), and 82 cancers were found in women who had not participated in the screening program (10%).
Results: Of all cancers, 96 were HER2+ (12%) and 47 TN (6%). Majority of HER2+ (59%) and of TN breast cancers (57%) were found by screening.
Screen-detected tumours of HER2+ and TN subtype were smaller and less frequently node positive than those clinically detected. Of HER2+ cancers found by screening, T1 cancers were 79% and N0 81%, and TN cancers were T1 81% and N0 64%. From the screening, these percentages were clearly smaller. During the follow-up (average 7.3 years), distant metastases appeared in screen-detected HER2+ cancers for only 4% of patients and TN cancers for 7% of patients. When in interval and not participation groups, the amounts were evidently larger.

Conclusion: A significant number of HER2+ and TN cancers are found by mammography screening. Despite the fact that HER2+ and TN cancers are considered to be clinically aggressive, the screening showed that their prognosis in this data is very good and clearly better than the cancers found between the screening rounds.
Limitations: The evaluation is based on the results of a single screening unit and the number of cases is not very large.
Ethics committee approval: Approved by the ethics committee.
Funding: Supported by Eka Grant of The Finnish Medical Foundation.

Ultrasonographic features of triple-negative invasive breast carcinomas are associated with mRNA-lncRNA signature and risk of recurrence

J. Li, J. Zhou, Y. Jiang, Y. Liu, Z. Shi, C. Chang, Z. Shao*; Shanghai/CN (jiaweili2006@163.com)*

Purpose: To evaluate the association between mRNA and lncRNA signatures, sonographic features, and risk of recurrence of triple-negative breast cancers (TNBC).
Methods and materials: Data of 114 TNBC patients whose pathological specimens accepted transcriptome analysis were retrospectively reviewed. The risk of recurrence was determined based on the association between transcriptome profiles and recurrence-free survival (RFS). Ultrasound images were assessed according to the breast imaging reporting and data system (BI-RADS). Multivariate logistic regression analysis was used to determine the sonographic features that were associated with the risk of recurrence.
Results: Selected from 183 mRNAs and 195 lncRNAs expressed in tumour tissues and adjacent normal tissues, there were three mRNAs (CHRDL1, FCGR1A, RSAD2) and two lncRNAs (HIF1A-AS2, AK124454) that were closely correlated with the RFS event of TNBCs. Of the three mRNAs, two were upregulated (FCGR1A and RSAD2) and one was downregulated (CHRDL1). Both HIF1A-AS2 and AK124454 were downregulated. We established an integrated mRNA-lncRNA signature for risk score of RFS: risk score= -1.225´CHRDL1+0.74´FCGR1A+0.219´RSAD2+0.482´HIF1A-AS2+0.571´AK124454. An optimum cut-off score of 0.793 was obtained to classify patients into high-risk and low-risk groups. The benign-like features such as regular shape, circumscribed margin, posterior acoustic enhancement, and no calcifications were significantly associated with the upregulated signature of HIF1A-AS2 and a high risk of recurrence ($p<0.05$). The malignant-like features like irregular shapes, uncircumscribed margin, no posterior acoustic enhancement, and calcifications were significantly associated with the downregulated signature of CHRDL1 and a low risk of recurrence ($p<0.05$).
Conclusion: Sonographic features of TNBCs are significantly associated with the risk of recurrence estimated from mRNA-lncRNA signatures.
Limitations: The retrospective review of the ultrasound images.

RPS 1002b-8 12:07

Role of T2-weighted-fs sequences in breast MRI in the evaluation of peritumoural oedema as a predictive marker for breast cancer aggressiveness: results of a retrospective monocentric study

M. Gerboni[1], M. Durando[1], E. Regini[2], G. Bartoli[1], S. A. S. Gentile[1], C. Costanza[1], G. Mariscotti[1], L. Bergamasco[1], P. Fonio[1]; *[1]Turin/IT, [2]Settimo Torinese/IT (mattia.gerboni@gmail.com)*

Purpose: To investigate the predictive role of peritumoural oedema assessed at MRI T2-STIR sequences in patients with invasive breast cancer considering disease free-survival and overall survival time.
Methods and materials: We conducted a retrospective study on 107 patients (mean age: 53 years) with biopsy-proven invasive breast cancers, who underwent preoperative breast MRI on 1.5 T scanner from January 2010 to July 2011. Images were reviewed by two radiologists in consensus, assessing peritumoural oedema on the basis of the degree of the signal intensity surrounding the tumour on T2-STIR images. The MRI protocol included pre-contrast T2-STIR images, DWI, and dynamic GRE T1 images before and after contrast injection, also with the subtraction technique. We categorised patients into two main groups according to the presence or absence of peritumoural oedema on T2-STIR sequences. We retrospectively collected other lesions characteristics, such as size, histology, molecular pattern, absence/presence of positive lymph nodes, and type of surgery. Statistical analysis was performed to assess the disease-free survival and overall survival using the Kaplan-Meier curves.
Results: The median follow-up of patients included in the study was 7.7 ± 1.3 years. Based on MRI findings, peritumoural oedema was found on 52 among 107 lesions (48.9%). In this group, recurrence occurred in 9 patients, while in the second group (absence of peritumoural oedema) in 4 patients. Disease-free survival according to Kaplan-Meier test did not statistically differ between the two groups ($p=0.11$). In the peritumoural oedema group, overall survival time was statistically ($p=0.045$) lower compared to the other group.
Conclusion: The presence of peritumoural oedema detected on MRI T2-STIR sequences could be considered as a valid ancillary feature of predictability of worse survival outcome.
Limitations: Small sample, monocentric study.

Role of ^{18}F-FDG uptake on PET/CT in identifying androgen receptor expression in triple-negative breast cancer and the associated factors

H. Lee[1], H. S. Lim[2], S. Y. Ki[3], H. Park[1]; *[1]Gwang-ju/KR, [2]Jeollanamdo/KR, [3]Hwasun/KR (phm6284@naver.com)*

Purpose: To investigate the relationship between ^{18}F-FDG uptake and androgen receptor (AR) expression in triple-negative breast cancer (TNBC).
Methods and materials: Between July 2013 and April 2017, 163 patients with primary TNBC who underwent ^{18}F-FDG PET/CT were retrospectively categorised into AR-positive (n = 24) and AR-negative (n = 139) groups by immunohistochemical staining. SUV_{max} value and clinicopathologic features were compared between the two groups. The association between prognostic values and SUV_{max} was evaluated by the multiple regression model and the correlation analysis between SUV_{max} and clinicopathologic variables was performed.
Results: Median SUV_{max} was significantly higher in AR-negative group than in AR-positive group ($P = .034$). AR-positive group was significantly older ($P < .001$) and had more DCIS component ($P = .015$), and AR-negative group showed significantly high Ki67 proliferation ($P = .004$) and p53 overexpression ($P = .023$). In multiple regression analysis, tumour size, DCIS component, and histologic grade 1 were significantly associated with SUV_{max}. Tumour size, histologic grade 3, and Ki67 showed positive correlations with SUV_{max} ($P < .001$, Spearman's rho (ρ)= .485; $P = .027$, $\rho = .142$; $P < .001$, $\rho = .291$), while associated DCIS component, androgen receptor, and histologic grade 1 ($P < .001$, $\rho = -.333$; $P = .033$, $\rho = -.167$; $P < .001$, $\rho = -.252$, respectively) showed negative correlation with SUV_{max}.
Conclusion: There was significant difference of ^{18}F-FDG uptake with regard to AR expression in TNBC. SUV_{max} was significantly associated with tumour size, histologic grade, and associated DCIS component in TNBC.
Limitations: Small numbers of study cohorts in a single tertiary centre. Retrospective design - selection bias is inevitable.

Determination of morphological characteristics of primary breast cancer by focus diffusion-weighted MRI: comparison with conventional diffusion-weighted images and dynamic contrast-enhanced MRI

Y. Metin[1], N. Orhan Metin[2], F. Tasci[2], O. Ozdemir[1], S. Kul[3], A. Babatürk[1]; *[1]Ankara/TR, [2]Rize/TR, [3]Trebizond/TR (dr.andelib@gmail.com)*

Purpose: To compare the diagnostic accuracy and effectiveness of focus diffusion-weighted imaging (f-DWI), conventional diffusion-weighted imaging (c-

DWI), and dynamic-contrast enhanced magnetic resonance imaging (DCE-MRI) in determining the morphological characteristics of primary breast cancer.
Methods and materials: c-DWI, f-DWI, and DCE-MRI of newly diagnosed 155 breast cancer patient's images were evaluated retrospectively. Morphological features of the lesions and image quality were compared between all three imaging protocols by two radiologists. Apparent diffusion coefficient (ADC) values of the lesions were compared between f-DWI and c-DWI.
Results: Evaluation by the two readers of all primary breast cancers for the mean ADC values were 82.5 and 88 for f-DWI, and 92.5 and 94.5 for c-DWI, respectively, with the difference being statistically significant (p< 0.001). Both two readers identified that perceived signal to noise ratio (SNR) and sharpness obtained from f-DWI and DCE-MRI was significantly higher than c-DWI (p< 0.001). Distortion was also significantly less encountered at f-DWI than the conventional one. Qualitatively, there was no significant difference between f-DWI and DCE-MRI.
Conclusion: f-DWI allows higher quality images than the conventional one. This allows the morphological features to be identified at a similar accuracy to dynamic contrast-enhanced images with high resolution.
Limitations: In this study, only the morphological features of malignant lesions were compared and no difference was made between focal diffusion and conventional diffusion in the differentiation of benign and malignant lesions. In addition, focus diffusion-weighted imaging is obtained in a slightly longer period than conventional diffusion-weighted imaging.
Ethics committee approval: This retrospective study was approved by the institutional review board in our institution and written informed consent was obtained from all patients.
Funding: No funding was received for this work.

Application of delayed contrast-enhanced MRI for improved accuracy in the evaluation of breast lesions
D. Daniels, N. Nissan, D. Last, S. Sharabi, Y. Mardor, M. Sklair-Levy; *Ramat Gan/IL (Dianne.Daniels@sheba.health.gov.il)*

Purpose: Contrast-enhanced MRI of the breast provides high sensitivity but variable specificity and may lead to excessive benign biopsies. Based on previous success with the application of delayed contrast MRI (DCM) in differentiating tumour/non-tumoural regions in brain tumours, we aim to study the feasibility of applying DCM to breast cancer patients in order to potentially reduce the number of benign unnecessary biopsies.
Methods and materials: 52 women undergoing breast MRI were scanned by standard DCE-MRI, as well as with DCM acquired 20 minutes post-contrast. Image analysis was provided via in-house developed software, affording colour-coded maps reflecting contrast accumulation/clearance (depicted red/blue in the maps) at the delayed time point. DCM maps were retrospectively compared with the results of the conventionally obtained diagnostic workup.
Results: A total of 69 lesions were evaluated. All 19 malignant and high-risk lesions correctly appeared blue in the DCM maps, while 42 of the benign lesions appeared red. Another eight lesions appeared mixed or blue. No false-negative cases were obtained. False-positive cases (blue for benign) were mainly due to haemangiomas, fat necrosis, and fibroadenomas with myxoid components. Standard DCE resulted in 100%/52%/44%/100% sensitivity/specificity/PPV/NPV to breast cancer, while DCM resulted in 100%/84%/70%/100%, respectively. Further comparison of DCM maps with histology specimens suggested that high vessel-density with vessel compression appeared blue in the maps while low vessel-density with dilated lumens appeared red.
Conclusion: DCM may provide improved specificity for the diagnosis of breast cancer. Further application aimed at the optimisation of biopsy planning is now underway.
Limitations: A pilot study with a limited number of participants. Future aims include protocol optimisation and the scanning of larger cohort.
Ethics committee approval: Approved by IRB committee. Written informed consent was waived.
Funding: Israel Science Foundation.

Epidural pulsed radiofrequency (EPR) with access via sacral hiatus: therapeutic indications
F. Castelli[1], C. Di Lorenzo[2], A. M. Ragusa[3], B. Varsallona[2], A. Scavone[2], G. Scavone[2], M. V. V. Raciti[4], P. Aliffi[2], G. Galvano[2]; *[1]Verona/IT, [2]Catania/IT, [3]Biancavilla/IT, [4]Pavia/IT (fedicastelli@gmail.com)*

Purpose: To evaluate the effectiveness of EPR with access via sacral hiatus in patients affected by chronic lumbosciatalgia resistant to conservative treatment
Methods and materials: In this retrospective study, 120 patients were included (72 women and 48 men) who were affected by chronic lumbosciatalgia caused by discal protrusions or hernias for which no surgical or percutaneous treatment was provided; Pfirrmann's grade of discal degeneration 4 or 5 and discal calcifications. Pain symptoms were evaluated using the visual analogue scale (VAS) and the numeric pain rating scale (NPRS), including patients scoring above 7. After local anaesthesia, the sacral hiatus was located via AP and lateral fluoroscopically guided x-ray. By using a cannula, a catheter was introduced with a bipolar electrode at its distal extremity which was directed to the nerve roots requiring treatment. The catheter was introduced into the epidural space; once the target root was reached, a neurophysiological study was run to confirm the correct root via bioelectrical impedance and sensory and motor stimulation. Having ensured the correct positioning of the electrode, pulsed radiofrequency begun for 240 seconds. Then, a mix of steroids and local anaesthetic were injected via the same catheter.
Results: There was a significant reduction in pain in 75% of cases (90/120). VAS/NPRS scores were evaluated after treatment and after 2 weeks, 1, 3, 6, and 12 months, showing a significant improvement. VAS/NPRS pre-treatment average scores were 7.6 (+-0.3), after 1 month they had decreased to 2.3 (+-0.3), and after 12 months they were 2.8 (+-0.1). There were no peri and post-procedural complications.
Conclusion: In accordance with scientific literature evidence, this treatment proved effective in patients with chronic lumbosciatalgia with discopathy for which there are no surgical or percutaneous treatment indications.

CT-guided screw fixation by interventional radiologists in traumatic injuries of the pelvic ring: screw accuracy placement and clinical outcome
F. Torre[1], C. Dekimpe[1], L. J. Pavan[1], O. Andreani[1], S. Guinebert[2], A. Prestat[1], N. Stacoffe[3], D. S. Palominos Pose[4], N. Amoretti[1]; *[1]Nice/FR, [2]Paris/FR, [3]Lyons/FR, [4]Santiago de Chile/CL*

Purpose: To report our clinical experience of CT-guidance fixation of pelvic ring traumatic fractures, evaluating screw placement accuracy, safety, complications, and clinical outcome.
Methods and materials: All consecutive patients who beneficiated from a CT-guided fixation of a sacroiliac or acetabular fracture in our radiology department after a high energy trauma from 11/2016-11/2018 were included. All procedures were realised under general anaesthesia with dual CT and fluoroscopic guidance by two experienced interventional radiologists. Treated fractures, unstable reduced posterior pelvic ring disruptions, with or without sacroiliac disjunction (TILE B or C), and minimally displaced acetabular fractures were minimally displaced. The primary outcome was screw placement accuracy. Secondary endpoints were patient radiation exposure, procedure time,

complications, clinical functional score (MAJEED score), and pain scale evaluation (VAS) during a follow-up period from 4-30 months.
Results: 32 patients were included (mean age 46 years) and 62 screws were placed. Screw placement was correct in 28/31 patients (87.5%, missing data of one patient). 2 patients presented with persistent pain after fixation due to a screw conflict. In both cases, screws were removed by an interventional radiologist after fracture consolidation, resolving the pain. The mean procedure time was 67 minutes and the mean patient radiation exposure was 965mGy cm. No major complications occurred. The mean follow up was 13 months. The mean postoperative MAJEED score was 84/100 and the mean pain score was 1.6/10.
Conclusion: This technique is an effective and safe procedure in undisplaced or minimally displaced pelvic fractures, allowing both accurate fixation and minimally invasiveness. The possibility of percutaneous removal allows resolution of any eventual unsatisfying screw positioning in a minimally invasive way.
Limitations: The retrospective design.
Ethics committee approval: Informed consent was obtained.
Funding: No funding was received for this work.

Percutaneous ozone nucleolysis for low back pain: any issues for spine biomechanics? 6 years of MRI imaging follow-up

E. Tommasino, P. Palumbo, F. Bruno, M. Varrassi, M. V. M. Micelli, F. Arrigoni, A. Splendiani, C. Masciocchi*; L'Aquila/IT (emanuele.tommasino@gmail.com)*

Purpose: To explore how O2-O3 chemiodiscolysis affects the biomechanics of the spine and the functional spinal unit and whether it accelerates lumbar spine degeneration.
Methods and materials: A total of 100 patients treated with an O2-O3 mixture, either periganglionic or intradiscal, 6 years before our study underwent MRI examination. An evaluation of the success rate was performed on both groups on the basis of the modifications of lumbar spine biomechanics, using well-defined markers of spine degeneration. Comparisons were made between the patients treated with the percutaneous O2-O3 intradiscal injection and the paraganglionic O2-O3 injection was used as a control group.
Results: Both treatments showed a significant reduction of disc height ($p<0.05$), although only the intradiscal injection obtained the decrease of disc area and protrusion ($p<0.05$). Similarly, in the periganglionic injection, the Pfirrman and Modic score markers of lumbar spine degeneration increased ($p<0.05$), whereas in the intradiscal injection they remained stable ($p>0.05$).
Conclusion: Biomechanical properties of the spine are not affected after the intradiscal injection of O2-O3. This study demonstrates that chemiodiscolysis, restoring the natural loads along the FSU, does not exacerbate lumbar spine degeneration.
Conversely, periganglionic injection, acting as a symptomatic treatment, does not delay lumbar spine degeneration.
Limitations: Although in the paraganglionic injection, we did not directly obtain any shrinkage of the disc, a protruded disc naturally reduces its own extrusion due to the dehydration of the NP.
Ethics committee approval: Approval of our medical ethical committee and informed consent was obtained.
Funding: No funding was received for this work.

Systematic evaluation of low-dose MDCT for planning purposes of lumbosacral periradicular infiltrations

N. Sollmann, K. Mei, S. Schön, I. Riederer, F. K. Kopp, C. Zimmer, J. S. Kirschke, P. B. Noel, T. Baum*; Munich/DE (nico.sollmann@tum.de)*

Purpose: To evaluate image quality and confidence for planning of periradicular infiltrations using virtually lowered tube currents and in-house developed statistical iterative reconstruction (IR) for multi-detector computed tomography (MDCT).
Methods and materials: 20 patients (54.9±13.1 years) underwent MDCT for planning purposes of periradicular infiltrations at the lumbosacral spine (120 kVp/100 mAs). Planning scans were simulated as if they were performed at 50% (D50), 10% (D10), 5% (D5), and 1% (D1) of the tube current of original scanning. Image reconstruction was achieved with two levels of IR (A: similar in appearance to clinical reconstructions and B: ten times stronger noise reduction). Two readers (R1/R2) performed image evaluation including confidence for intervention planning (scoring: 1-high, 2-intermediate, and 3-low confidence).
Results: Level A of IR was favourable regarding overall image quality, artefacts, image contrast, and nerve root depiction, with preserved good scores down to D10 scans. The confidence for planning was not significantly different ($p>0.05$) between scans with tube currents virtually lowered down to 10% and original-dose scans when using level A of IR (R1: 1.2 ± 0.4, R2: 1.1 ± 0.3). Inter-reader agreement for planning confidence was good (Cohen's kappa: 0.62-1.00).
Conclusion: MDCT for lumbosacral periradicular infiltrations may be conducted with tube currents lowered down to 10% of the standard dose (equal to 10 mAs) without limitations in planning confidence.
Limitations: Evaluations were performed for procedure planning only and not for the sequential scans acquired during the intervention. The time needed for image reconstructions using IR can be long, hampering direct implementation into the clinical setting.
Ethics committee approval: This retrospective study was approved by the IRB.

The predictive role of the lumbar disc FA (fractional anisotropy) map in diffusion tensor imaging (DTI) to select patients with low back pain who may benefit from intradiscal oxygen-ozone injections

E. Tommasino[1], M. Varrassi[1], M. Perri[2], A. Splendiani[1], F. Bruno[1], C. Masciocchi[1], A. Barile[1], E. Di Cesare[1]*; [1]L'Aquila/IT, [2]San Giovanni Rotondo/IT (emanuele.tommasino@gmail.com)*

Purpose: To assess annular fibers anisotropy through the intervertebral disc FA map to select patients suffering from low back pain of lumbar disc origin and who may benefit from intradiscal oxygen-ozone injection.
Methods and materials: A total of 75 patients suffering from low back pain were selected. Before treatment, they underwent MR examination on a 3T, with a standard protocol of conventional sequences (T2, T2 fat-sat, and T1 FSE) and one additional DTI sequence for assessing respectively lumbar disc pathology and the fractional anisotropy (FA) map of the involved intervertebral disc. Discography of the involved disc was also obtained under CT guidance in order to confirm MRI reports. Patients were randomly assigned into two groups. One control group (20 men, 16 women) underwent intraforaminal injection of steroids and anaesthetics. The remaining 39 patients in the study group (18 men, 21 women) underwent the same treatment with the addition of an intradiscal oxygen-ozone (O2-O3) injection. An ODI questionnaire was administered before and after the treatment. Results were compared with a $\chi 2$, t-test, and regression analysis.
Results: In cases of annular fissure without herniation or disc extrusion, O2-O3 intradiscal injection therapy was successful in 41% of the study group patients compared to 27.5% of the control group patients ($P<0.01$). The ODI questionnaire showed a significant improvement of symptoms in both groups ($P<0.01$). FA disc map values positively correlated with the annular fissuration and the positive outcome.
Conclusion: An FA disc map congruous with a rupture of annular fibres could be considered as a predictive sign of a response to oxygen-ozone lumbar intradiscal injection and should be included in the preoperative study.
Limitations: n/a
Ethics committee approval: Ethical approval was obtained by our medical committee.

RPS 1009b-6 11:45

The association between osteoarthritis features on MRI and the clinical outcome of transcatheter arterial embolisation therapy for knee osteoarthritis

T. A. van Zadelhoff[1], Y. Okuno[2], S. M. A. Bierma-Zeinstra[3], A. Moelker[4], E. Oei[3]; [1]Amsterdam/NL, [2]Tokyo/JP, [3]Rotterdam/NL, [4]Bergschenhoek/NL (tijmenvanzadelhoff@gmail.com)

Purpose: To explore the association between baseline MRI features related to knee osteoarthritis and the clinical outcome of patients undergoing transcatheter arterial embolisation (TAE) of neoangiogenesis around the knee for the treatment of pain caused by osteoarthritis.
Methods and materials: Baseline knee MR images of patients who underwent TAE were assessed semi-quantitatively using the MRI osteoarthritis knee score (MOAKS). Items scored included effusion and Hoffa synovitis, cartilage defects, bone marrow lesions (BMLs), and osteophytes. Absolute pain reduction was calculated from the Western Ontario and McMaster Universities osteoarthritis index (WOMAC) questionnaire pain subscore at baseline and at 6 months. Linear regression analysis adjusted for age, sex, and a baseline WOMAC pain score was used to measure the association between MRI signs at baseline and clinical outcome.
Results: 52 patients were analysed. The mean baseline pain score was 61.11 (SD=9.04) and the mean pain reduction was 35.46 (SD=20.97). Effusion-synovitis (MOAKS score 2-3) at baseline showed a negative association with WOMAC pain reduction (β: -.30; P<0.05). Hoffa synovitis showed a positive but not statistically significant association (β: .18; p>0.05). The amount and severity of cartilage full-thickness defects, BMLs, and osteophytes all had a negative association with pain reduction (β: -.42, β: -.38, and β: -.38, respectively; all p<0.05).
Conclusion: The presence of effusion-synovitis at baseline is associated with decreased pain reduction after TAE treatment. In general, the presence of more and a higher-grade of osteoarthritis-related MRI signs at baseline is associated with less reduction in the WOMAC pain score after TAE. This information could be useful when selecting patients for TAE treatment.
Limitations: Synovitis was assessed using non-contrast-enhanced MRI instead of contrast-enhanced MRI. This could potentially have caused underdiagnosis of synovitis.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Symptomatic low-grade lumbar isthmic lysis: trans-isthmic pars interarticularis screwing under CT and fluoroscopic guidance

L. J. Pavan[1], F. Torre[1], A. Kastler[2], P. Kugelstadt[1], N. Stacoffe[3], A. Prestat[4], A. Rudel[1], C. Dekimpe[1], N. Amoretti[1]; [1]Nice/FR, [2]Grenoble/FR, [3]Lyons/FR, [4]Nancy/FR

Purpose: To assess the accuracy of trans-isthmic percutaneous screwing under CT and fluoroscopic guidance in patients with symptomatic low-grade isthmic spondylolisthesis.
Methods and materials: 50 consecutive patients treated for trans-isthmic screwing at our centre were retrospectively included. Treatment indications were low-grade lumbar isthmic lysis and persisting low back pain (visual analog scale VAS>6) refractory to medical treatment and local infiltrations. Exclusion criteria were a neurological deficit, spinal posture impairment, lumbar surgery, refusal to undergo the procedure, high-grade spondylolisthesis, and coagulopathies. The procedure was carried out under local anaesthesia with CT and fluoroscopic guidance by an experienced interventional radiologist. The primary outcome was a technical success, assessed on postoperative CT using the same success criteria as surgical screw placement. The secondary outcome was pain decrease assessed with a VAS pain score preprocedural and at 1 year.
Results: 99 screws were positioned in 50 patients (28 females, 22 males, mean age 50±19 years [17-80y], bilateral screwing in 49 patients, unilateral in one patient). The average screw length was 27 mm [24-32 mm] and the mean procedure duration was 50 minutes [45-60 min]. Postoperative CT assessment showed satisfactory placement in 96/99 screws (technical success rate of 96.9%). No complications occurred intra or postoperatively.
The mean VAS pain score decreased from 7.8±1.6 [5-10] to 2.9±2.1 [0-7] at 1 year.
Conclusion: Percutaneous trans-isthmic screwing under CT and fluoroscopic guidance allows an accurate and safe pars-isthmic fixation in patients with symptomatic low-grade spondylolisthesis, with satisfying pain reduction following the procedure.
Limitations: A retrospective design.

Percutaneous treatment of vertebral body fractures in patients with vertebral metastases by using expandable SpineJack® intravertebral implants: the initial experience of 21 consecutive patients

C. Pusceddu, N. Ballicu, L. Melis; Cagliari/IT (clapusceddu@gmail.com)

Purpose: To evaluate the feasibility and effectiveness of the SpineJack® intravertebral implant in the treatment of pathological vertebral fractures in cancer patients. The primary aim of the treatment was pain palliation and recovery of the height of the vertebral body.
Methods and materials: 21 patients (10 men and 11 women, median age 62) with fractures of 24 vertebral metastases underwent CT fluoroscopy-guided percutaneous vertebral augmentation by bi-peduncular expandable SpineJack® insertion followed by vertebroplasty. 7 patients underwent MW ablation immediately before the osteosynthesis. We analysed the feasibility and complications of the procedure, the decrease in pain using a visual analogue scale (VAS), and the restoration of the anterior and middle height of the vertebral body, before and 1 week after the procedures. Patients were followed up for 14 months (range from 3-25 months).
Results: The procedure was technically successful in all treated vertebrae. Bone cement leakage occurred in 12 cases, but no symptoms were reported. No signs of root irritation or neurological deficit were observed. VAS score decreased from 7.1 (range, 4-8.7) to 1.2 (range, 0-3). The anterior and middle height of the vertebral body reduced in all patients with a deformity reduction and improvement of column stability.
Conclusion: This preliminary result suggests that the SpineJack ® procedure in vertebral pathological fractures is safe and effective, provides immediate benefits in terms of pain relief, functional recovery, and vertebral height restoration, with a rapid return to self-sufficiency.
Limitations: The small sample of patients and the short follow-up don't permit establishing the exact role of this approach in the treatment of patients with vertebral fractures of spinal metastases.
Ethics committee approval: n/a
Funding: No funding was received for this work.

A 7-year experience of magnetic resonance-guided focused ultrasound surgery (MRgFUS) ablation of bone lesions: results from an MSK interventional centre

F. Arrigoni, C. de Cataldo, P. Palumbo, M. Ruschioni, F. Formiconi, L. Zugaro, A. Barile, C. Masciocchi; L'Aquila/IT (arrigoni.francesco@gmail.com)

Purpose: To retrospectively evaluate clinical and radiological results of ablative procedures of focal benign bone lesions performed with a magnetic resonance-guided focused ultrasound surgery (MRgFUS) equipment.
Methods and materials: We retrospectively evaluated patients who underwent MRgFUS treatment on painful and symptomatic benign bone lesions from February 2012-October 2019. Patients were considered eligible for the procedure if the lesion was on the bone surface, i.e. accessible from the ultrasound beam, and if there were no contraindications to MRI. We evaluated

the success rate in terms of clinical and imaging results, complications, and relapse rates.
Results: Our population included 71 patients (40 males, 31 females, mean age at the time of treatment 29±16). In the last few years, since 2012, we successfully treated 66 lesions (success rate 93.5%): 51 osteoid osteomas and 15 epiphyseal lesions (6 intraarticular osteoblastomas, 4 fibroangiomas, 1 subperiosteal chondroma, 1 mixofibroma, 2 chondroblastomas, and 1 GCT recurrence). Pain control was obtained in all cases with a fast and definitive relief. No complication from the percutaneous approach was recorded (complication rate 0%). The advantage in HIFU treatment was also shown by the imaging follow-up (up to over 2 years), with significant bone densification and no pathologic fracture after thermal ablation. In 5 patients, we reported clinical and radiological relapse (relapse rate 6.5%): 1 tug lesion, 3 osteoid osteomas, and 1 osteoblastoma. All the disease relapse cases occurred before 2017, probably related to limited technical experience.
Conclusion: Our results confirm the validity of MRgFUS as the treatment of choice for benign superficial bone lesions because of its minimally invasive approach, high-profile of safety, and excellent effectiveness.
Limitations: A limited number of patients and an operator with progressively increasing experience.

Intravertebral cleft in percutaneous vertebroplasty: what else?

F. Torre[1], L. J. Pavan[1], A. Prestat[1], H. Vasseur[1], C. Ibba[1], N. Stacoffe[2], A. Kastler[3], P. Foti[1], N. Amoretti[1]; [1]*Nice/FR,* [2]*Lyons/FR,* [3]*Grenoble/FR*

Purpose: To compare the clinical outcome of CT and fluoroscopy-guided percutaneous vertebroplasty (PVP) in vertebral fractures with and without an intravertebral cleft.
Methods and materials: All patients treated at our centre with PVP from 11/2014-11/2015 under CT and fluoroscopic guidance were reviewed. Inclusion criteria were the presence of painful thoracolumbar osteoporotic vertebral fractures (VAS>5 under antalgic medication) with MRI confirmation, graded type II or III according to Genant's classification. Patients were divided into two groups according to the presence (group 2) of an intravertebral cleft (Kümmel disease) or not (group 1). Exclusion criteria were medullary compression, acute infection, active haemorrhage, and malignant vertebral fractures. Follow-up was done at day 1, months 1, 3, 6, and 1 year with a visual analogue scale (VAS) score for pain.
Results: 90 patients were included (mean age 79 years [70-92 years], 27 males and 63 females, 61 thoracic and 39 lumbar vertebral fractures). 50 patients (group 1) didn't have an intravertebral cleft before PVP, while 40 patients did (group 2). Vertebral fractures with a cleft were significantly more painful at preoperatory ($p<0.05$). Both groups demonstrated significant improvement in VAS results at follow-up after PVP ($p<0.05$). Group 2 (cleft) presented a larger decrease in pain compared to group 1 (no cleft). Cement leakage into an intervertebral disc was observed in 25/90 cases (27.7%), significantly more frequent in patients without a cleft (20/50, 40%) than in patients with a cleft (5/40, 12.5%)($p<0.0006$).
Conclusion: Fractures with an intravertebral cleft are more painful that those without a cleft and receive greater clinical benefit from PVP, with a larger VAS decrease and less intervertebral disc cement leakage in comparison to the group of osteoporotic fractures without a cleft.
Limitations: The retrospective design.
Ethics committee approval: IRB approval and informed consent was obtained.

Complications of image-guided thermal ablation of bone metastasis: a single-centre experience

G. Bianchi, F. Arrigoni, A. Izzo, C. de Cataldo, P. Palumbo, M. V. M. Micelli, L. Zugaro, A. Barile, C. Masciocchi; *L'Aquila/IT*

Purpose: To review complications following thermal ablation and cryoablation of painful bone metastasis and discuss the risks and clinical presentation of each complication, as well as how to treat and potentially avoid complications.
Methods and materials: We retrospectively evaluated 50 advanced cancer patients with painful bone metastasis (BM) treated by CT-guided percutaneous thermal ablation techniques (RFA, CA, or MWA) with palliative or curative intent in the last 4 years in our department. Curative treatment was performed to selected oligometastatic patients presenting with limited bone disease (<3 potentially treatable BM, each ≤3 cm in size). Patients with a painful bone metastasis (≥4/10 on a 0-10 VAS scale over the 24h) or higher risk of pathological fracture underwent palliative treatments.
Results: Axial bones were involved in 21 patients (42%). CA was performed in 31 cases (62%), RFA in 11 patients (22%), and MW ablation in 8 cases (16%). Complications were observed in 4 patients out of 50 (8%). An intramuscular haematoma was detected in 1 lesion located in the sacral wing. In 1 patient, an abscess developed after CA of an acetabular lesion. A lumbar artery pseudoaneurysm was observed following CA of an L2 secondary lesion. In 1 case, subcutaneous emphysema after CA of an ischiatic lesion was detected. In all the patients, the complications were successfully managed.
Conclusion: Percutaneous thermal ablation techniques are minimally invasive and a safe option in the management of BM. In our study, the low rate of complications observed is related to an appropriate patient selection made by a multidisciplinary team with 10-years experience in this field.
Limitations: A small sample size.

Ablation, vertebroplasty, and radiotherapy in treating symptomatic spinal metastases: can a combined treatment ensure stability and disease control in a medium-long term follow-up?

C. de Cataldo, A. Izzo, G. Bianchi, M. Ruschioni, F. Formiconi, F. Arrigoni, L. Zugaro, A. Barile, C. Masciocchi; *L'Aquila/IT*
(camilladeca@hotmail.it)

Purpose: To assess the efficacy of the combined approach through ablation, vertebroplasty, and postoperative radiotherapy in the management of painful and lytic bone metastases in vertebral fractures or in vertebrae with increased fracture risk.
Methods and materials: We retrospectively evaluated clinical and radiological outcomes of 17 patients who consecutively underwent ablation, vertebroplasty, and radiotherapy. Treated patients had a life expectancy of at least 1 year and required analgesic therapies because of disabling back pain. 20 painful vertebral body metastases were treated, including vertebral fractures and impending vertebral fractures. Ablation and vertebral cementation were performed in a single session under TC guidance, with the purpose being the most radical removal of the metastasis and the injection of the least quantity of cement. The postoperative single session radiotherapy treatment was performed no longer than 10-days after the procedure. VAS and ECOG-PS were evaluated before and after treatment, as well as imaging lesion features.
Results: Patients showed an immediate, rapid, and persistent regression of the symptomatology. Clinical follow-up (mean 18±6 months) showed a decreased need for opioid pain medication and significantly decreased functional disabilities (mean improvement VAS score 2.5 points, mean improvement ECOG-PS 1.8 points). The radiological follow-up (mean 16±7 months) did not show local metastatic recurrence in terms of vertebral height and morphology variations or marginal osteolysis progression.
Conclusion: We strongly support the evidence of combining ablation, vertebroplasty, and radiotherapy as a promising option for the treatment of spinal metastatic lesions, both with a palliative and, in selected cases, curative purpose.
Limitations: A limited study population size.

Ethics committee approval: In accordance with the Helsinki declaration.
Funding: No funding was received for this work.

Investigating the use of CT colonographs in patients too frail for optical colonoscopy and their management outcome
S. C. Chin[1], G. Duncan[2]; *[1]Dundee/UK, [2]Perth/UK (sookcheng@doctors.org.uk)*

Purpose: CT colonographs (CTCs) are often used as an alternative investigation for colorectal malignancies (CRCs) for patients who are deemed too frail for colonoscopy. We hope to investigate if CTCs performed for this cohort of patients changes their management outcome.
Methods and materials: All CTCs performed from 01/06/14 to 30/06/18 with the keywords 'frail', 'unfit', or 'dementia', and patients coming from nursing homes, were identified. Patients where colonoscopy was attempted previously were excluded. As a control group (non-frail), 100 random CTCs were selected from 01/01/18 to 30/06/18. The CTC quality and findings were collected and categorised. For patients with suspected CRC or polyps, subsequent management and colonoscopy, surgical and pathology report (if applicable) were analysed. The correlation of CTC findings was recorded and any complications from subsequent intervention were also recorded. The Chi-square test was used to test for significance of differences between the groups.
Results: 57 patients met the inclusion criteria. The population group median age was 83 years old vs 67 years old. 46.6% of the study group's examinations were suboptimal quality ($p<0.005$). None of the suspected CRC and polyps <6mm in the study group had a subsequent intervention. Patients with polyps >6mm, 33.3% from the study group versus 83.3%, had an intervention. There was statistical significance in the number of CRC, polyps >6mm, and intervention rate of patients with suspected CRC.
Conclusion: For patients too frail to undergo colonoscopy, CTCs rarely changes their management outcome and a contrast-enhanced abdominopelvic CT examination may be sufficient to identify CRCs and facilitate potential future palliative intervention.
Limitations: Reliance on the accuracy of the provided clinical history to identify the study population and subjective assessment of the clinician to assess the patient's frailty.

The evaluation of the redundant sigmoid colon on computed tomography images
N. Hürsoy[1], O. Aydemir[2], S. Ünal[3], E. Anamurluoğlu[4], H. E. Akkaya[5], M. Kul[4]; *[1]Rize/TR, [2]Konya/TR, [3]Trebizond/TR, [4]Ankara/TR, [5]Karaman/TR (nurhursoy@gmail.com)*

Purpose: To investigate the frequency of the redundant sigmoid colon on computed tomography images by using Kantor's criteria and to compare the results with the literature. We also aimed to emphasise the clinical importance of redundancy and to increase the awareness of radiologists for this condition.
Methods and materials: This retrospective study was performed with 500 patients who underwent CT scans in Turhal State Hospital from August to October 2017. Axial views were evaluated to detect the presence of the redundant sigmoid colon. The thickness of the rectus abdominis muscle, psoas muscle, subcutaneous fat, anteroposterior diameter of abdomen, and the transverse diameter between each anterior superior iliac spinae were measured. The presence of colonic diverticulae was also noted.
Results: The redundant sigmoid colon was detected in 93 patients with a frequency of 18.6%. Age and sex were not significantly different between both groups. The transverse diameter between each anterior superior iliac spinae was significantly shorter in patients with a redundant sigmoid colon.
Conclusion: Kantor's criteria is a useful method for evaluating the redundancy of the sigmoid colon on axial CT images. The frequency of the redundant sigmoid colon is nearly 20% and this condition is important since it is a major risk factor for volvulus, it causes incomplete optic colonoscopies, and is associated with irritable bowel syndrome.
Limitations: Limitations of design and number of patients.

Dedicated MR imaging for staging of peritoneal metastases in colorectal cancer patients considered for CRS-HIPEC: the DISCO randomised multicentre trial
M. P. Engbersen[1], A. G. J. Aalbers[1], D. M. J. Lambregts[1], J. Nederend[2], I. de Hingh[2], R. G. H. Beets-Tan[1], N. F. M. Kok[1], M. J. Lahaye[1]; *[1]Amsterdam/NL, [2]Eindhoven/NL (m.engbersen@nki.nl)*

Purpose: To determine the value of dedicated MRI as a non-invasive staging method to evaluate whether complete CRS can be achieved via a randomised controlled trial.
Methods and materials: The study is set-up as a multicentre randomised controlled trial. Patients are eligible when they are considered for CRS-HIPEC after conventional CT staging. The participant will be randomly assigned to either the experimental arm A or the control arm B. Patients in arm A will undergo an MRI scan dedicated to PM, which includes diffusion-weighted, T2 weighted, and post contrast-enhanced T1 weighted imaging of the chest, abdomen, and pelvis. MRI assessment will determine whether the patient can directly proceed for CRS-HIPEC, or whether patients are not eligible for CRS-HIPEC. In borderline cases, a diagnostic laparoscopy (DLS) will be advised. Arm B patients will receive a standard of care, namely proceed to CRS-HIPEC and DLS if deemed necessary at MDT meeting. The primary outcome is the proportion of preventable surgical staging procedures. A preventable surgical procedure is defined as an exploratory laparotomy of a patient with clearly unresectable disease and a DLS or exploratory laparotomy of a patient with clearly resectable disease.
Results: The 270 patients are yet to be included.
Conclusion: If MRI staging can help surgeons in selecting patients who might benefit from CRS-HIPEC, it will spare curative patients unnecessary surgical staging and less open-close procedures in palliative patients. In addition, MRI will provide a clear overview of the abdominal disease for the surgeons to use for their preoperative planning.
Limitations: Need for pathological proof might need DLS.
Ethics committee approval: METC approval has been received.

Clinical impact of dedicated whole-body MR imaging in patients with advanced colorectal cancer
E. Nerad[1], M. P. Engbersen[1], D. M. J. Lambregts[1], E. M. Godfrey[2], N. F. M. Kok[1], A. G. J. Aalbers[1], R. G. H. Beets-Tan[1], M. J. Lahaye[1]; *[1]Amsterdam/NL, [2]Cambridge/UK*

Purpose: To evaluate the clinical impact of dedicated whole-body MRI (WB-MRI) in patients with stage IV colorectal cancer (CRC) on CT.
Methods and materials: This was a retrospective study of 42 patients with CRC referred to our specialist oncologic centre with suspicion of liver and/or peritoneal metastasis. All patients underwent an additional 3T WB-MRI at our institution, including pre/postcontrast T1, T2, and diffusion-weighted imaging (DWI). Multidisciplinary team (MDT) meeting notes were evaluated and if the result of WB-MRI changed the original treatment plan (based on the CT result), it was regarded as a significant clinical impact.
Results: All metastases detected on CT images were also detected with WB-MRI. WB-MRI changed the treatment strategy in 13 patients (31%). WB-MRI diagnosed additional liver and peritoneal metastases in 3 (7%) and 1 (2%) patients, respectively. WB-MRI confirmed or ruled out liver and peritoneal metastases in indeterminate CT studies in 1 (2%) and 6 (14%) patients, respectively. In one patient (2%), WB-MRI confirmed pulmonary metastasis in a lesion that was indeterminate with CT and in another patient (2%) WB-MRI detected an additional metastatic lesion in the anterior abdominal wall and potential renal malignancy.
Conclusion: Dedicated WB-MRI changed the treatment plan in almost one third (31%) of patients with stage IV CRC on CT. WB-MRI should be considered in this patient group to prevent undertreatment.
Limitations: Number of patients included.

Low-volume reduced bowel preparation for CT colonography: a randomised controlled trial
N. Panvini[1], D. M. Bellini[1], M. Rengo[1], S. Vicini[2], I. Carbone[3], A. Laghi[3]; *[1]Latina/IT, [2]Sora/IT, [3]Rome/IT (npanvini88@gmail.com)*

Purpose: To investigate feasibility and patient tolerance of a reduced bowel preparation for CT colonography (CTC).
Methods and materials: Asymptomatic and symptomatic patients were enrolled in this multicentric randomised trial. All patients were randomly assigned (1:1 ratio, blocks of ten) to receive a reduced (52.5 g of Macrogol dissolved in 500 mL of water, RBP) or full (105 g of Macrogol in 1000 mL, FBP) bowel preparation and faecal tagging. Five readers performed a blinded subjective image analysis by means of 4-point Likert-scales from 0 (highest score) to 3 (worst score). Endpoints were the quality of large bowel cleansing and tolerance to the assigned bowel preparation regimen.
Results: 78 patients were randomly allocated to treatments (44 in FBP-group, 34 in RBP-group). Both groups resulted in optimal colon cleansing. Homogeneity of fluid tagging (median score 0 vs 0, p=0.075), volume of residual stools (median score 0 vs 0, p=0.082), and colonic distension (median score 0 vs 0, p=0.073) were similar for both groups. RBP resulted in better patient tolerance.
Conclusion: Reduced bowel preparation may provide better tolerance for patients undergoing CTC without affecting colon cleansing and image quality.
Limitations: The main limitation of our study is that the diagnostic accuracy has not been evaluated.
Ethics committee approval: The study protocol was approved by the Institutional Review Board of our Institution and written informed consent was obtained from all patients.
Funding: No funding was received for this work.

Evaluation accuracy of US compared to CT for the diagnosis of colonic diverticulitis: prospective single-centre study
S. E. Gabrieli, M. Dahan, N. Granat, H. Neiman,, T. Gurvitz, E. Atar, G. Bachar; *Petah Tikva/IL (nadavgranat@gmail.com)*

Purpose: Diverticulitis is commonly diagnosed using CT. The major drawback of a CT scan is exposure to ionising radiation that increases the risk of malignancy. Our aim was to determine the diagnostic accuracy of US compared with CT for patients suspected for diverticulitis and to examine the possibility of using US as a primary tool in emergency department for the diagnosis of diverticulitis.
Methods and materials: A double-blind prospective analysis was conducted between 2015-2019 on 170 consecutive patients who were admitted to the emergency department suspected clinically for diverticulitis. Their medical history, clinical signs, and laboratory exams were reviewed. All patients underwent first US examination followed by an abdominal CT scan.
Results: 122 patients were identified with colonic diverticulitis as the final diagnosis by CT compared to 125 by US. Sensitivity and specificity of US examination were 93.6% (95% CI 87.37% - 97.0%) and 88.9% (95%CI 75.1%-95.8%), respectively.
The positive and negative predictive values for the diagnosis of simple diverticulitis by US were 95.9% and 83.3%, respectively. 19 patients were identified with complicated diverticulitis by CT compared to 17 patients by US (89.5%). In those two cases, a small tiny perforation was missed by US.
Conclusion: Our study shows that US has high sensitivity and specificity in the evaluation of patients with suspected diverticulitis and can replace CT examination as a primary tool in diagnosing simple colonic diverticulitis. CT examination can be reserved as a second tool in cases of suspected complicated diverticulitis.
Limitations: Single-centre study.
Ethics committee approval: The study was approved by our IRB committee.
Funding: No funding was received for this work.

The impact of mismatch repair status to the preoperative staging of local colon cancer
E. Erbs, S. R. Rafaelsen, J. Lindebjerg, L. H. Jensen, T. F. Hansen; *Vejle/DK (s.rafaelsen@dadlnet.dk)*

Purpose: Computed tomography (CT) scan is standard in preoperative local staging of colon cancer. Tumours with a deficient mismatch repair (dMMR) system are characterised by unique clinical and pathophysiologic aspects that may impact on the accuracy of the preoperative CT staging.
Methods and materials: Data from the Danish Colorectal Cancer Group national clinical database addressing a cohort of patients operated for stage I-III colon cancer in 2010-15 was analysed. The analyses of MMR status had been conducted consecutively through means of immunohistochemistry. All CT scans were blindly assessed by a certified radiologist.
Results: Data from 590 patients, operated at a specialised cancer centre were available for analyses. 135 (22.9%) of the patients had tumours demonstrating dMMR. The overall correlation of the clinical and pathological T-category was significant for both groups. There was inferior correlation between clinical (cN) and pathological (pN) N-category (p>0.05) in pMMR cancers with a higher degree of over-staging assessed by CT-scan compared to a significant correlation between cN and pN stage in pMMR cancers (p<0.01). Of the 91 dMMR tumours assessed node-positive by the preoperative CT scan, 59 (64.8%) showed no sign of metastatic involvement at the postoperative assessment.

Conclusion: The accuracy of preoperative lymph node staging in colon cancer by CT scan seems to differ depending on MMR status and may impact the clinical management including the neoadjuvant setting.
Limitations: This study is based on data from a national database and by that suffers from limitations related to this kind of research such as incomplete data registration.
Ethics committee approval: n/a

RPS 1001b-8 12:07

Effect of iterative model reconstruction algorithm on radiologists' performance in CT colonography

Y. Lian[1], J. Dong[1], W. Cao[2], J. Gao[1]; [1]*Zhengzhou/CN*, [2]*Guangzhou/CN (lybang0507@126.com)*

Purpose: To assess radiation dose and image quality of CT colonography (CTC) at 100 kVp with iterative model reconstruction algorithm (IMR) at 20 mAs compared with filtered back projection (FBP) at 50 mAs.
Methods and materials: 32 patients suspected with colon adenomatous polyp or adenocarcinoma were enrolled. All patients underwent CTC examination at 50mAs in a supine position and 20mAs in a prone position, with the same tube voltage at 100 kVp about two hours before fibro-colonoscope. Images were reconstructed using FBP and IMR. Two radiologists independently evaluated image quality. Qualitative image quality was assessed with a five-score scale. Image noise, signal-to-noise ratio, contrast-to-noise ratio, and effective radiation dose were recorded and calculated. Qualitative and quatitative values were analysed using the Wilcoxon signed rank test and the paired t test, respectively.
Results: 38 colon polyps or adenocarcinomas were detected in fibro-colonoscope examination. For 20 mAs with IMR (A group) and 50 mAs with FBP (B group), there is no statistically significant difference in lesion detection (reader 1: 35/38 vs 36/38, and reader 2: 31/38 vs. 33/38, p>0.05). However, qualitative image quality scores (3.9 vs 2.5), image noise ([12.77± 0.91] HU vs. [50.04±5.45] HU), SNRs (3.13±0.28 vs. 1.02±0.20), and CNRs (81.42±6.11 vs. 19.93±1.46) were significantly superior of 20 mAs with IMR, respectively (p<0.05). Compared with group B, the radiation dose of A group decreased significantly (0.42±0.03 mSv vs. 1.07±0.12mSv).
Conclusion: Image quality of CTC using 20 mAs with IMR reconstruction could be comparable to 50 mAs with FBP at the same tube voltage with no significant detection of polyp and radiation dose of the former was only 0.42 mSv, which was reduced by about 39.3%.
Limitations: Lacking data of patients with BMI>24.
Ethics committee approval: n/a
Funding: No funding was received for this work.

RPS 1001b-9 12:13

Extra-peritoneal findings on dedicated DW-MRI for colorectal cancer patients considered for CRS/HIPEC

I. van 't Sant, M. P. Engbersen, C. Gispen, D. M. J. Lambregts, N. F. M. Kok, A. G. J. Aalbers, R. G. H. Beets-Tan, M. J. Lahaye*; Amsterdam/NL*

Purpose: To examine the added value of preoperative DW-MRI in colorectal cancer patients considered for cytoreductive surgery and hyperthermic intraperitoneal chemotherapy (CRS-HIPEC) regarding extra-peritoneal findings over the standard diagnostic work-up.
Methods and materials: Between February 2016 and January 2019, all colorectal cancer patients with suspected peritoneal metastases (PM) who were considered for CRS-HIPEC and who underwent a preoperative DW-MRI in addition to standard diagnostic work-up (CT thorax/abdomen ± PET-scan) were included. The added value of DW-MRI was determined by scoring the number of extra-peritoneal findings that had not emerged in previous imaging, the number of previously uncertain findings that could be rejected or confirmed, and the number of findings that could be qualified as more or less likely. The reference standard was surgical results or follow-up imaging in patients that did not undergo surgery.
Results: Of the 153 included patients (M/F=83/70), 40 had a PET scan in addition to CT and DW-MRI scans. Mean delay between CT (±PET) and DW-MRI was 17 days (IQR:4-31). DW-MRI was scored as of added value in 39% (59/153) of cases. New extra-peritoneal findings were found in 14% (22/153), the majority being metastases in the abdominal wall (10), liver (5), and adnexa (4). 32 lesions previously characterised as possibly malignant could be refuted based on DW-MRI findings. In 85%, this concerned liver lesions. 8 malignant lesions were left unmentioned on imaging altogether, 5 of which were port-site metastases.
Conclusion: DW-MR imaging in colorectal cancer patients considered for CRS-HIPEC has an added value in detecting and clarifying extraperitoneal findings that are occult or indistinct on standard work-up imaging methods. These findings are important as they may form contraindications to otherwise futile CRS-HIPEC procedures.
Limitations: Retrospective nature.

RPS 1001b-10 12:19

Neural network-based diagnosis algorithm of appendicitis in patients with acute abdominal pain presenting to emergency department

J. J. Park, K. A. Kim, Y. Nam*; Seoul/KR*

Purpose: To investigate the feasibility of a neural network-based diagnosis algorithm of appendicitis by using CT for patients with acute abdominal pain visiting an emergency room (ER).
Methods and materials: For this retrospective study, a neural network-based diagnostic algorithm of appendicitis was developed using CT data of patients who visited ER with abdominal pain and underwent abdominopelvic CT between December 2018 and May 2019. For training, 3D isotropic cubes ($4\times4\times4cm^3$) including appendix were manually segmented and labelled as appendicitis or normal appendix. A 3D convolutional neural network was trained to perform binary classification for input 3D images. In the training process, cross-entropy loss was used and kernel size was 3. To reduce overfitting, data augmentation processes such as shifting, flipping, and adding random noises were adopted. 8-fold cross-validation was used. For each model, 64 subjects were used to train the network and the remaining 16 subjects were tested using the trained network algorithm. Diagnostic performance was assessed.
Results: 667 patients were involved, with 215 patients with acute appendicitis and 452 patients with normal appendix (331 men and 336 women; mean age, 45.6 years old). Accuracy of a neural network-based classification algorithm for diagnosis of appendicitis was 91.60 %. Sensitivity, specificity, positive predictive value, and negative predictive value were 90.65 %, 92.05 %, 84.35 %, and 95.42 %, respectively.
Conclusion: A neural network-based diagnosis algorithm was feasible with high diagnostic performance for acute appendicitis on CT of patients visiting ER with acute abdominal pain.
Limitations: We only included CT image in patients with normal and inflamed appendix. External validation was not performed. We manually extracted appendix. Automatic detection algorithm is under development.
Ethics committee approval: The institutional review board approved this study. Informed consent was waived due to the retrospective nature.
Funding: No funding was received for this work.

Role of abdominal helical computed tomography in the diagnosis of adult intussception

D. Vo Tan, P. M. N. Do*; Ho Chi Minh/VN (duc.vt@ump.edu.vn)*

Purpose: To describe imaging characteristics of adult intussception (AI) on CT and to identify diagnostic values of them.
Methods and materials: Case series report including patients: defined AI on CT, over 18 years of age, having had surgery, with/without histo-pathology. Patients were divided into two groups: those with enteroenteric intussusception (EI) and those with intussusceptions involving colon (IC), including enterocolic and colocolic lesions.
Results: From 01/2014 to 01/2017 at University Medical Center, HCMC, there were 53 intussusceptions of 52 patients on CT (EI: 14_26%, IC: 39_74%). 33 of those had intussusception on surgery (EI: 10_3%, IC: 23_70%). Mean length of intussusceptions of both groups was 7,6±4,0cm (2,4-19,6). Mean diameter of intussusceptions was 4,7±1,1cm (2,2-7). Mean interposed fat thickness was 1±0,6cm (0,1-2,6). CT and surgery characteristics of patients in EI group were

of minor differences. The ratio of AI on CT with obstruction and with ischemia necrosis were both 3,8%. The outcome of diagnosing complications by CT and by surgery was comparable. Characteristics capable of predicting presence of intussusception on surgery were in EI group: lead point, length > 6cm, interposed fat thickness > 0,5 cm; in IC group: length > 5.65 cm, interposed fat thickness > 0,75 cm.
Conclusion: Characteristics capable of predicting the presence of intussusception on surgery are lead point, length, and interposed fat thickness.
Limitations: Retrospective and cross-sectional study.
Ethics committee approval: University of Medicine and Pharmacy at Ho Chi Minh City, Vietnam.

Cardiac deformation parameters measured by cardiac magnetic resonance in a cohort of highly-trained endurance athletes
B. Domenech Ximenos[1], M. Sanz-de la Garza[2], D. Lorenzatti[2], A. Sepulveda[3], F. Crispi[2], R. J. Perea[2], S. Prat Gonzalez[2], M. Sitges[2]; *[1]Girona/ES, [2]Barcelona/ES, [3]Santiago de Chile/CL (bl.domenech@gmail.com)*

Purpose: There is evolving evidence that the cumulative effects of intensive endurance exercise may induce a broad spectrum of cardiac adaptation/remodelling patterns. Even if the common features of the athlete's heart are well-known, whether changes in cardiac strain parameters occur in response to training is less well-studied. We aimed at understanding and characterising these changes in CMR derived-strain parameters in highly trained endurance athletes.
Methods and materials: 93 highly trained endurance athletes (>12 hours training/week at least during the last 5 years) and 72 age and gender-matched controls (52% male, mean age 35±5.1 years) underwent a resting-CMR. Biatrial and biventricular dimensions and function were assessed, as well as the presence of myocardial fibrosis by LGE. We evaluated radial, circumferential, and longitudinal strain of both ventricles and left atrium from feature tracking (FT) of cine images.
Results: High endurance training load was associated with larger bi-ventricular and bi-atrial sizes, mildly reduced the systolic function of both ventricles, as compared to controls (P < 0,05). LGE was significantly more prevalent in athletes (n=33, 35.4% vs 4,2%; P<0,001), with a constant pattern in the right ventricle (RV) insertion points. Left ventricle circumferential and radial strain, RV circumferential, radial and longitudinal strain, and left atrium strain were all lower in athletes than in controls; p<0.05.
Conclusion: The strain values from FT in our group of highly-trained endurance athletes were lower than in the control group. This was observed together with harmonic biventricular dilation and with the presence of LGE confined to the RV insertion point. The clinical impact of these strain values is currently uncertain and still warrants further investigation.
Limitations: No long-term follow-up available.
Ethics committee approval: Institutional review-board approval was obtained. Subjects provided written informed consent.

Non-invasive MRI evaluation of adjuvant chemotherapy effects on heart in breast cancer patients: 1-year follow-up in a single centre
C. de Cataldo[1], E. Cannizzaro[1], P. Palumbo[1], S. Torlone[1], M. C. de Donato[1], M. Latessa[2], S. Necozione[1], E. Di Cesare[1], C. Masciocchi[1]; *[1]L'Aquila/IT, [2]Sienna/IT (camilladeca@hotmail.it)*

Purpose: To evaluate the accuracy of a non-invasive MRI follow-up through strain analysis in the detection of anthracycline-induced left ventricular systolic dysfunction.
Methods and materials: We prospectively evaluated 36 breast cancer patients (mean age 53,4, range 39-67) undergoing anthracycline-based chemotherapy, between February 2018 and February 2019. All the patients underwent a non-enhanced cardiac magnetic resonance (CMR) before (Time 0), at 3-6 months (Time 1), and after 1 year (Time 2) from the beginning of chemotherapy. Global radial (GRS), circumferential (GCS), and longitudinal (GLS) strain values were assessed for each patient on each CMR examination through a dedicated software (Cvi42). Statistical analysis through Friedman's test and Post-hoc Test according to Conover was performed.
Results: We found statistically significant difference among strain values at Time 0, Time 1, and Time 2, respectively. [GLS median: 18,26±2,2 vs -15,09±1,6 vs -13,51±1,7(p<0,0001), GCS median: 18,51±2,9 vs -18,11± 1,7 vs -17,03±1,8(p<0,00001), and GRS: 29,56±3,9 vs 26,94±3,6 vs 24,86±3,4(p<0,00001)]. Median FE was 60±4% at Time 0, 56±5% at Time 1, and 53±2% at Time 2 (p<0,00001). 18 patients showed a GLS decrease with a compensatory GRS and GCS increase at Time 1, followed by a consensual decrease of all the values at Time 2. 11 patients showed a gradual decrease in all strain values from Time 0 to Time 2. 7 patients demonstrated no significant variation between strain values at Time 0 and 1, with a significant decrease at Time 2.
Conclusion: We support the validity of a non–enhanced CMR follow-up in breast cancer patients undergoing anthracyclines treatment in the detection of early myocardial impairment through strain analysis. It is a reliable post-processing tool deserving a definitive clinical validation.
Limitations: Small study specimen size.
Ethics committee approval: In accordance with the Helsinki Declaration.

Decreased myocardial deformation in athletes correlates with the degree of LV hypertrophy
J. Stáreková, C. Behzadi, G. K. Lund, G. H. Welsch, B. P. Schoennagel, K. Muellerleile, G. Adam, M. Regier, E. Tahir*; Hamburg/DE (j.starekova@uke.de)*

Purpose: To assess ventricular morphology and parameters of diastolic function between professional soccer players and competitive triathletes compared to sedentary controls using cine feature-tracking CMR.
Methods and materials: 23 soccer players (22±4 years), 19 triathletes (28±6 years), and 16 controls (26±3 years) underwent CMR. Chambers volume and left ventricular mass were determined and correlated with global myocardial strain. Peak systolic longitudinal (LS), circumferential (CS), and radial (RS) strains were analysed on cine CMR images using feature-tracking software.
Results: Athletes displayed higher myocardial mass (P<0.001) compared to the controls. The longitudinal ventricular strain was significantly reduced in athletes in comparison to the controls (P<0.01 for the right ventricle (RV) and P<0.05 for LV) as well as radial LV strain (P<0.05). Both athletic groups were characterised by eccentric hypertrophy. However, in comparison to triathletes, soccer players revealed higher LV mass (87±15 vs. 75±13 g/m2, P<0.05). Furthermore, soccer players experienced a greater decrease in the longitudinal strain of LV (-16±2 vs. -17±2%, P<0.05) and RV (-18±2 vs. -20±3%, P<0.05), as well as in radial LV strain (38±8 vs. 43±7%, P<0.05). An increase in LV mass correlated with a

decrease in the longitudinal strain (r=0.47, P<0.001) and radial strain (r=-0.28, P<0.05).
Conclusion: Reduction of global myocardial strain in athletes correlates with the level of LV hypertrophy. Detrimental effects on myocardial mechanics due to an increased level of sport-induced hypertrophy pronounced in soccer players cannot be excluded.
Limitations: The presence of myocardial fibrosis and its potential influence on LV strain cannot be excluded.
Ethics committee approval: Ethics comitee aproval (Ärztekammer Hamburg). Written informed consent was obtained.

Coronary atherosclerosis in apparently healthy master athletes discovered during pre-participation screening: role of coronary CT-angiography (CCTA)

G. Rovere, R. Marano, B. Merlino, L. Natale, G. Savino, R. Manfredi*; Rome/IT*

Purpose: To assess the role of coronary CT-angiography (CCTA) and non-invasive detection of coronary atherosclerosis (cATS) in the assessment and clinical management of master athletes (MA) during the pre-participation screening (PPS).
Methods and materials: We retrospectively examined 167 MA who underwent CCTA in our hospital since 2006, analysing symptoms, stress-test ECG, cardiovascular risk profiles (SCORE), and CCTA findings.
Results: Among the whole enrolled population, 153 (91.6%) MA underwent CCTA for equivocal/positive stress-test ECG with/without symptoms, 13 (7.8%) just for clinical symptoms, and 1 (0.6%) due to family history. The CCTA showed the presence of cATS in 69 MA (41.3%), congenital coronary anomalies (anomalous origin or deep myocardial bridge) in 8 (4.8%), and both in 7 (4.2%). A negative CCTA was observed in 83 MA (49.7%). The risk-SCORE (age, hypertension, hypercholesterolemia, and smoking) was a good indicator for the presence of moderate/severe cATS on CCTA. However, mild/moderate cATS was present in 17.8% of MA clinically stratified at a low risk-SCORE.
Conclusion: CCTA may be helpful in the PPS of MA with an abnormal stress test ECG and/or clinical symptoms engaged in competitive sports with high cardiovascular involvement, while the invasive coronary angiography is more indicated in athletes with positive stress-test ECG and high clinical risk. Age, gender, presence of symptoms, and clinical risk-SCORE assessment may help sports-physicians/cardiologists to decide whether to request a CCTA or not.

Instant impact of a competitive event on ventricular strain by feature tracking cardiac magnetic resonance imaging and changes in cardiac biomarkers in triathletes

M. L. Warncke, J. Stáreková, C. Jahnke, B. Scherz, K. Müllerleile, U. Radunski, G. Adam, G. Lund, E. Tahir*; Hamburg/DE*
(m.warncke@uke.de)

Purpose: To analyse the impact of an endurance competition on left (LV) and right ventricular (RV) function by feature-tracking strain analysis by cine cardiac magnetic resonance imaging (CMR) in competitive male and female triathletes.
Methods and materials: 50 asymptomatic triathletes (45 ±10 years, 20% female) with more than 10 weekly training hours were studied by CMR performed on a 1.5T system with a 5-channel cardiac coil before and after an endurance competition (1.3 ±0.5 km of swimming, 59.9 ±72.5 km of cycling, and 15.9 ±11.5 km of running). Functional and morphological LV parameters were determined using CVi42 (circle cardiovascular imaging). Global peak systolic longitudinal, radial, and circumferential myocardial strains were analysed using Segment (Medviso, Sweden). Blood tests were performed before the competition and at the time of the CMR.
Results: Troponin T (6 ±4 pg/ml vs. 51 ±77 pg/ml, P<0.0001), NT-proBNP (45 ±73 pg/ml vs. 116 ±99 pg/ml, P<0.0001), and creatine kinase isoenzyme MB (10 ±14 U/l vs. 32 ±19 U/l, P<0.0001) increased significantly after the competition. Radial and circumferential LV strain increased from baseline to post-competition with 39 ±11% vs. 44 ±11% (P<0.05) and -16 ±4% vs. -18 ±3% (P<0.05). LV longitudinal strain showed a trend for decrease (-17 ±2% vs. -17 ±2%, P=0.054). Circumferential RV strain increased significantly post-competition (-6 ±3% vs. -7 ±2%, P<0.01), whereas RV longitudinal strain remained constant (-9 ±3% vs. -9 ±4%, P=0.668). LV ejection fraction did not change (63 ±7% vs. 62 ±6%, P=0.607).
Conclusion: Cardiac biomarkers are markedly elevated following strenuous endurance exercise in healthy male and female triathletes with normal LV ejection fraction. LV radial, circumferential, and RV circumferential strain increases. LV longitudinal strain decreases post-competition.
Limitations: Different competition formats.

RPS 1003a-6 11:55

Coronary CT-angiography in the clinical workflow of athletes with malignant anomalous origin of coronary arteries

F. Paciolla, R. Marano, G. Savino, L. Natale, B. Merlino, R. Manfredi*; Rome/IT*

Purpose: To assess the CCTA, added to clinical-profiles, in the diagnosis, management, and follow-up of athletes with anomalous-origin of left- (AOLCA) and right-coronary-artery (AORCA) from the wrong-sinus.
Methods and materials: Subjects with suspected AOLCA/AORCA at the trans-thoracic-echocardiography (TTE) or with inconclusive-TTE underwent CCTA to rule out/confirm and characterise the anatomical findings: partial- (pINT) or full-(INT) inter-arterial-course, high-take-off (HTO), acute-take-off-angle (ATO), slit-like-origin (SLIT), intramural-course (IM), intraarterial-course-length (LEN), and lumen-reduction/hypoplasia (HYPO).
Results: CCTA identified 28 athletes: 6-AOLCA (3-males, 20.3±11.0years), 22-AORCA (18 males, 29.1±16.5years); 26/28 (92.9%) suspected at TTE. Clinical symptoms were present only in 13 athletes (46.4%; 10-AORCA). Four subjects (3-AORCA) had abnormal rest ECG and 11 (40.7%) (9-AORCA) abnormal stress ECG. INT course was observed in 15 athletes (53.6%): 6/6-AOLCA and 9/22-AORCA (40.9%). HTO/ATO occurred in 1 and 3/6 AOLCA-patients, HTO in 12/22 (54.5%) and ATO in 21/22 (95.5%) in AORCA. Slit-like-origin was never recorded in AOLCA and present in 7/22 AORCA (31.8%). Suspected IM resulted in 3-AOLCA (50%), always with HYPO/ATO and in one case HTO, whereas IM was suspected in 6/22 AORCA (27.3%), in all cases with HYPO, observed in 12/22 AORCA (54.5%). No statistically significant differences resulted between asymptomatic/symptomatic subjects regarding the prevalence of pINT/INT-courses, HTO/ATO, and slitlike-ostium. A slight significant relationship between suspected proximal IM (r=0.47,p<0.05) and proximal HYPO of anomalous-vessel (r=0.65,p<0.01) resulted in AORCA and confirmed on AOLCA/AORCA pooled analysis (r=0.58,p<0.01 for HYPO). All AOLCA/AORCA athletes were disqualified from competitive sports and warned to avoid vigorous physical efforts. Surgery was recommended to all AOLCA athletes and to 13 AORCA (3-asymptomatic), but only 6 underwent surgery. No MACE/ischemic symptoms/signs occurred during a mean-follow-up of 49.6±39.5 months.
Conclusion: CCTA is an accurate/mandatory diagnostic technique for the detection of anomalous-coronary-anatomy and risk-stratification, providing essential information for safe/effective clinical management of athletes, with important prognostic and sport-activity implications.

Assessment of myocardial deformation in elite male weightlifters using cardiovascular magnetic resonance feature tracking technique

G. Ge, W. Xiaohua*; Beijing/CN (guogeegg@sina.com)*

Purpose: To assess the myocardial deformation in elite male weightlifters with cardiovascular magnetic resonance imaging (CMR) feature tracking technique.
Methods and materials: 14 elite Chinese male weightlifters and an age-, sex-matched cohort of 14 sedentary volunteers were enrolled. All participants underwent CMR scans at 3.0T and feature tracking technique was used to obtain global and regional left (LV) and right ventricular (RV) strain parameters.
Results: The LV global longitudinal (LV-GLS), circumferential (LV-GCS), radial strains (LV-GRS), and RV-GLS were significantly lower in weightlifters (-11.19±1.19%, -14.02±1.19%, 21.31±2.35% and -14.89±4.25%) than in volunteers (-14.50±1.84%, -16.62±1.24%, 27.01±3.18% and -18.75±3.54%, P<0.001). The LV peak systolic longitudinal, circumferential, radial-strain rate, and peak diastolic radial-strain rate were lower in weightlifters (-0.73±0.18, -0.88±0.13, 1.27±0.22 and -1.27±0.24) than in volunteers (-0.90±0.15, -0.98±0.12, 1.55±0.25 and -1.62±0.34, P<0.05). Differences in torsion, torsion rate, LV peak diastolic longitudinal and circumferential strain rate, RV-GRS, RV peak systolic and diastolic longitudinal or radial strain rates were non-significant (P>0.05). For segmental analysis, the basal anterior wall and mid-cavity to apical inferior walls of athletes had significantly lower LV GLS (P<0.05), while the inferior walls, inferolateral walls, and apical slice had significantly lower LV GCS and LV GRS compared with control volunteers (P<0.05).
Conclusion: Using CMR feature tracking technique, elite weightlifters demonstrated lower LV GLS, LV GCS, LV GRS, RV GLS, and segmental hypokinesis when compared to volunteers, which could be considered as a physiological adaptation to intensive training.
Limitations: There was a small number of participants. A direct comparison to athletes of other disciplines was not performed. All measurements were invariably acquired at rest.
Ethics committee approval: The Peking University Third Hospital Ethics Committee approved the study. Written informed consent was obtained from all subjects
Funding: No funding was received for this work.

Cardiac MRI texture analysis with semi-automatic segmentation: comparison between segmentation techniques and reproducibility

M. Orlando, N. Di Meo, G. M. Agazzi, M. Ravanelli, D. Farina*; Brescia/IT (matteo.orland@gmail.com)*

Purpose: To compare cardiac MR (CMR) texture analysis (TA) features extracted from the whole left ventricle (wLV-ROI) with those obtained on a representative single short-axis section with a circumferential ROI (c-ROI) or with a ROI on the interventricular septum (s-ROI).
Methods and materials: Retrospective single-centre study in 85 patients submitted to CMR from Jan 17 to Feb 18 with a negative report (i.e. no late gadolinium enhancement, no contractile dysfunction, normal LVEF, and volumes). MRI was performed with a 1.5-T system with cardiac coil; b-SSFP sequences in the short-axis at end-diastole were analysed using a freeware software (3DSlicer). wLV-ROI and c-ROI segmentation was performed semi-automatically with a brush tool on an intensity threshold-based mask; s-ROI was segmented manually. 107 TA features for segmentation were extracted with the pyRadiomics library. Interobserver and intraobserver agreement tests were performed in a subset of 20 patients after a 4-week pause. The intraclass correlation coefficient (ICC) was used to compare TA data from wLV-ROI, c-ROI, and s-ROI, and to measure inter and intraobserver agreement.
Results: The comparison between wLV-ROI and c-ROI, and between wLV-ROI and s-ROI, obtained ICC>0,8 for 5 first-order features: Median, RootMeanSquared, 90Percentile, 10Percentile, Mean. Additionally, 2 shape features had ICC>0,8 for c-ROI: Maximum2DDiameterSlice and MinorAxisLength. We observed good inter and intraobserver agreement for 76 features (ICC>0,8).
Conclusion: The agreement between TA features obtained with wLV-ROI and smaller samples is limited to first-order radiomic metrics suggesting the need for whole-ventricle analysis for diffuse myocardial disease. No superior order feature, except for 2 of shape, can be reliably obtained unless segmenting the whole LV. The reproducibility is good (ICC>0,8 for >70% of the features).
Limitations: Single-centre, retrospective, small sample.
Ethics committee approval: All patients gave written consent to CMR.
Funding: No funding was received for this work.

Native T1 mapping early detects the cardiotoxicity caused by daunorubicin: verified by histological

R. Xu, H. Liu, Y. Guo, L. Chen*; Chengdu/CN (Xrongdoctor@163.com)*

Purpose: Daunorubicin (DNR) serves as the backbone of many anti-cancer treatment strategies, but DNR-induced cardiotoxicity was rarely reported compared with doxorubicin (DOX).
Methods and materials: 38 adult male New Zealand white rabbits weighing 2 to 4 kg were included in this study. There were divided into 3 groups including control subjects and the DNR subjects with 3 or 4 mg/kg respectively. The CMR imaging included the function, native T1 mapping, and LGE. The time points were 2 weeks and 4 weeks. Some subjects were sacrificed for histological evaluation at the end of CMR scan.
Results: In the group of controls rabbits and DNR rabbits, the EF was decreased from 2 weeks to 4 weeks (controls 62.32±7.95% vs. 2 weeks 56.29±5.64% vs. 4 weeks 52.41±11.35%). For the T1 mapping analysis, the global native T1 values in rabbits with 4mg/kg weekly at 2 and 4 weeks were significantly higher than the controls (P <0.05) and all modelling rabbit had higher T1 values than controls. Most of the DNR rabbits (94.68%) were without the presence of LGE and a few of the subjects (5.32%) showed the LGE positive in subendocardial or the free wall. The Masson stain showed diffuse extracellular collagen deposition in the LV myocardium.
Conclusion: Native T1 mapping could detect diffuse myocardial injury in 4 weeks caused by daunorubicin. The higher cumulative dose and longer time may result in a more severe myocardium injury.
Limitations: This is preliminary research and short of follow-up in the protection of the cardiotoxicity. And we will do further research for the comprehensive assessment of the myocardial injury.
Ethics committee approval: Our research was approved by the animal ethic institution.
Funding: This work is supported by the clinical research funding (K1519) in our institution.

Identifying early stages of doxorubicin-induced cardiotoxicity in rat model using 7.0 tesla cardiac magnetic resonance and creatine kinase isoenzymes

S. Wang, F. Gao*; Chengdu/CN*

Purpose: To identify early stages of doxorubicin (DOX)-induced cardiotoxicity in a rat model using 7.0-tesla cardiac magnetic resonance (CMR) combining creatine kinase isoenzymes (CKMB).
Methods and materials: 34 rats were included. 28 of these rats were injected with DOX (2.5mg/kg) through vena caudalis weekly and were divided into 4 subgroups. The first subgroup received DOX for four weeks and underwent CMR examination after 4 weeks. The other groups received DOX for six weeks and underwent CMR examination after 6, 8, and 10 weeks, respectively. 2 rats injected with physiological saline (2.5ml/kg) also performed CMR examination at the same time as each experimental subgroup. All these rats were sacrificed after CMR examination and venous blood was collected to detect CKMB. Ejection fraction (EF) for the left ventricle (LV) was quantified from all CMR images. Global radial (GRS), circumferential (GCS), and longitudinal strain (GLS) parameters of LV were also obtained by CMR tissue tracking (CMR-TT). All these parameters were compared between treatment groups and controls.
Results: The earliest DOX-induced cardiotoxicity CMR parameter was GLS（-17.84±2.50 vs -21.79±5.80, P=0.007）decreasing at week 6. EF, GCS, CLS, and GRS were declined at week 8 and week 10. For CKMB, it was significantly increased at week 4 (869.14±210.69u/L vs 417.50±9.20u/L, P=0.001) and all CMR parameters were not affected at this time. CKMB continued to rise at week 6 and week 8, however, it showed no significant difference between treatment groups and controls at week 10 (376.29±65.29u/L vs 443.50±16.26u/L, P=0.210).
Conclusion: CKMB and CMR-TT are an effective method to evaluate DOX-induced cardiotoxicity at an early stage.

Limitations: Small sample size.
Ethics committee approval: This study was approved by Institutional Animal Research Committee of our local institute.

Assessment of myocardial extracellular volume on routine body computed tomography in a cohort of breast cancer patients treated with anthracyclines
D. Capra, C. B. Monti, T. Bosetti, E. de Benedictis, A. Luporini, M. Alì, F. Sardanelli, F. Secchi*; Milan/IT (davide.capra@unimi.it)*

Purpose: To evaluate the feasibility of estimating myocardial extracellular volume (ECV) on routine thoracic contrast-enhanced CT in breast cancer patients, and, if feasible, to assess if a rise in ECV is associated with anthracyclines administration even in the absence of clinical symptoms or echocardiographic changes.
Methods and materials: Female patients with breast cancer who had undergone routine CT examinations at our institution before and shortly after the end of chemotherapy including anthracyclines were retrospectively evaluated. Patients without available haematocrit, with CT images with artefacts, or who had undergone radiation therapy of the left breast were excluded. Follow-up CT examinations were also analysed, when available. ECV was calculated on scans obtained at about 1, 3, and 7 min after contrast injection.
Results: 32 female patients (aged 57±13 years, mean±standard deviation) with pre-treatment haematocrit 38±4% and ejection fraction 64±6% were analysed. Pre-treatment ECV was 27.0±2.9% at 1 min, 27.4±3.8% at 3 min, and 26.4±3.8% at 7 min, similar to normal values reported for normal subjects in the literature. Post-treatment ECV (median interval: 89 days after treatment) was 31.1±4.9%, 32.5±5.0% and 30.0±5.1%, respectively. The values were significantly higher than pre-treatment values at all times ($p < 0.005$). ECV at follow-up (median interval: 135 days after post-treatment CT) was 31.0±4.5%, 30.0±3.4%, and 27.7±3.7%, respectively, without significant differences ($p > 0.548$) when compared to post-treatment values.
Conclusion: After anthracyclines treatment, ECV was significantly higher than pre-treatment values. In the follow-up, ECV remains higher than pre-treatment values.
Limitations: This study is limited by its small sample size and its retrospective, monocentric nature.
Ethics committee approval: Ethics Committee approval was obtained. Written informed consent was waived.
Funding: No funding was received for this work.

Automated deep learning-based meningioma segmentation in multiparametric MRI
K. R. Laukamp, L. Pennig, F. Thiele, R. P. Reimer, L. Goertz, D. Zopfs, M. Timmer, M. Perkuhn, J. Borggrefe*; Cologne/DE (kai.laukamp@uk-koeln.de)*

Purpose: Volumetric assessment of meningiomas represents a valuable tool for treatment planning and the evaluation of tumour growth as it allows for a more precise assessment of tumour size than conventional diameter methods. Segmentation data can be used for consecutive quantitative or radiomics analysis allowing for improved tumour characterisation. However, manual segmentations are time-consuming and therefore usually not performed. In this study, we established a dedicated meningioma deep learning model based on routine MRI-data and evaluated its performance for automated segmentation.
Methods and materials: MRI datasets (T1-/T2-weighted, T1-weighted contrast-enhanced [T1CE], and FLAIR) of 126 patients with intracranial meningiomas (grade I: 97, grade II: 29) were included. Preprocessing of imaging data included registration, skull-stripping, resampling, and normalisation. Target volumes for manual and automated segmentations included contrast-enhancing tumour volume in T1CE and the total lesion volume (union of lesion volume in T1CE and FLAIR [including solid tumour parts and surrounding oedema]). For automated segmentation, an established deep learning model architecture (3D-Deep-Convolutional-Neural-Network, DeepMedic, BioMedIA) operating on all four MR-sequences was trained using manual segmentations of two independent readers from 70 patients (training-group). The trained deep learning model was then validated on the 56 remaining patients (validation-group) by comparing automated to ground-truth manual segmentations, which were performed by two additional readers in consensus.
Results: In the validation-group, comparison of the deep learning model and manual segmentations revealed average Dice coefficients of 0.91±0.08 for the contrast-enhancing tumour volume and 0.82±0.12 for the total lesion volume. In the training-group, inter-reader variabilities of the two manual readers were 0.92±0.07 for the contrast-enhancing tumour volume and 0.88±0.05 for the total lesion volume.
Conclusion: Deep learning-based automated segmentation yielded high segmentation accuracy, comparable to manual inter-reader variabilities.
Limitations: Due to the retrospective study design, no evaluation of the actual clinical benefit could be applied.
Ethics committee approval: The study was approved by the institutional review board.
Funding: No funding was received for this work.

Radiomics analysis in predicting the grade of meningiomas using monoexponential, biexponential, and stretched-exponential diffusion models
L. Lin, X. Chen, Y. Xue, Q. Duan*; Fuzhou/CN (84088100@qq.com)*

Purpose: Grading meningiomas before surgeries is particularly essential for therapeutic decisions and prognosis. The purpose of this study was to establish a radiomic model based on monoexponential, biexponential, and stretched-exponential diffusion models for non-invasively predicting the grade of meningiomas.
Methods and materials: Consecutive 107 patients who underwent MRI including multi-b values were histopathologically confirmed as having meningiomas. Apparent diffusion coefficient (ADC), true diffusion coefficient (D), pseudo diffusion coefficient (D*), perfusion fraction (f), distributed diffusion coefficient (DDC), and intravoxel water diffusion heterogeneity radiomics features were obtained based on solid components of the entire tumour. Optimal feature subsets were selected as using the support vector machine with a recursive feature elimination algorithm (SVM-RFE). Receiver operating characteristic curve (ROC) analysis was employed to assess the efficiency for grading the tumours.
Results: 7 radiomic features were selected in the training set, based on which radiomics model yielded area under the curve (AUC) values of 0.730 and 0.785 for the training and test sets. The accuracies/sensitivity/specificity of predicting the grade of meningiomas were 75.00%/70.37%/100.00%.
Conclusion: It is feasible to grade meningiomas by using a radiomics model built from monoexponential, biexponential, and stretched-exponential diffusion imaging.
Limitations: The number of high-grade meningiomas was relatively small. The acquisition times of the IVIM sequence were relatively long in this study.
Ethics committee approval: Written informed consent was obtained from all subjects in this study. Institutional review board approval was obtained.

Radiomics analysis of enhancing residual tumours better predicts survival in post-surgery MRI patients with brain glioblastomas
A. Garcia-Ruiz[1], P. Naval Baudín[2], M. Ligero[1], A. Pons Escoda[1], N. Calvo[2], M. Cos Domingo[1], C. Majós Torró[1], R. Perez Lopez[1]; [1]*Barcelona/ES,* [2]*L'Hospitalet de Llobregat/ES*

Purpose: To extract radiomics first-order distribution and texture features from post-surgical enhancing tumours and explore their prognostic value in patients with brain glioblastomas.
Methods and materials: We retrospectively analysed 160 consecutive patients with glioblastoma multiforme treated with surgery and radiotherapy plus concomitant and adjuvant temozolomide from 2009-2017. Censored patients and those with images acquired later than 7 days from surgery were excluded. Subtraction of the T1-weighted and contrast-enhanced T1-weighted MRI was performed to obtain the enhancement map; the area of residual enhancement was semi-automatically segmented to obtain the enhancing mask. 96 radiomics features were extracted from the contrast-enhanced T1-weighted images (texture and first-order statistics). The population was split into training (80%) and test (20%) subpopulations. Feature selection was performed by minimum-redundancy-maximum-relevance and stepwise regression on the training set. Logistic regression and ROC curve analyses were performed to evaluate the prognosis into high/low survival (threshold at median survival of 16 months).
Results: 124 patients were included in the final analysis. A total of 10 radiomics features, including minimum intensity, contrast grey-level co-occurrence matrix, and inverse difference grey-level co-occurrence matrix features were selected. These features predicted short and long survival with an AUC=0.72 (95% CI 0.62-0.82, p<0.001) in the training and 0.71 (95% CI 0.49-0.92, p=0.044) in the test subpopulation.
Conclusion: The selected radiomics features quantifying tumour intensity and heterogeneity are able to predict longer or shorter patient survival in both the training and test subpopulations with similar/fair accuracy.
Limitations: In this retrospective study, the variability of image acquisition parameters was unavoidable. Manual segmentations might present interobserver variability. An external validation may confirm the applicability of the proposed method.
Ethics committee approval: Informed consent was waived by the Bellvitge University Hospital research ethics committee.
Funding: RPL is supported by La-Caixa-Foundation and Prostate-Cancer-Foundation.

MR textural features (radiomics) for assessing the response to treatment in patients with intracranial tuberculomas: a retrospective review
S. Khan, M. Awais, M. Wasay, M. Azeemuddin*; Karachi/PK (shahmeer.khan@aku.edu)*

Purpose: To study whether MR-based radiomic features can be used to assess the response to antituberculous treatment.
Methods and materials: We included 24 patients with intracranial tuberculomas diagnosed by either culture or histopathology who had a pre- and post-treatment brain MRI with contrast performed at our institute from July 2009-July 2019. Patients with coexisting demyelination, tumour, or history of surgery were excluded. 16 patients showed a treatment response while 8 showed no response. A textural analysis was performed using Lifex and 44 textural parameters were extracted. The region of interest (ROI) was manually drawn on post-contrast FLAIR images. An independent Sample's t-test was employed to study statistically different parameters in both groups. Logistic regression was performed to develop a model for predicting the response to treatment on the basis of MR radiomic features in differentiating patients with intracranial tuberculoma.
Results: MR radiomic parameters, histogram skewness and GLCM correlation, showed a statistically significant difference in patients who showed improvement versus those who did not ($\chi2=11.517$, p=0.003). The model explained 52.9% (Nagelkerke R2) of variance in predicting the response to treatment and correctly classified 83.3% of cases. ROC curve analysis for histogram skewness showed an area under the curve of 0.766 (p=0.037 and 95% CI =0.577-0.954).
Conclusion: MR textural parameters including histogram skewness and GLCM correlation can be used as imaging biomarkers to differentiate patients with intracranial tuberculomas who responded to treatment versus resistant cases.
Limitations: The small sample size and retrospective analyses.
Ethics committee approval: Ethics committee approval obtained.
Funding: No funding was received for this work.

Between and within rater agreement in white matter hyperintensity segmentation from manual rating and a supervised automated classifier (FSL-BIANCA)
L. Griffanti[1], I. Mattioli[2], V. Bordin[3], I. Bertani[3], S. Suri[1], E. Zsoldos[1], K. Ebmeier[1], C. Mackay[1], G. Zamboni[2]; [1]*Oxford/UK,* [2]*Modena/IT,* [3]*Milan/IT (ludovica.griffanti@ndcn.ox.ac.uk)*

Purpose: Volumetric quantification of white matter hyperintensities (WMH) is well established in research and is starting to be adopted clinically for structured reports.
Automated tools using machine learning should avoid time-consuming manual segmentation and give more objective results. However, supervised tools require segmentation examples to train the algorithm and the tools' performance is usually evaluated by comparing the output to manual masks, which suffer from between and within rater variability.
We aimed to evaluate whether our tool, FSL-BIANCA, can overcome the variability present in the manual training set and increase the consistency of automatic results.
Methods and materials: We used 24 MRI scans from the Whitehall II imaging sub-study.
Manual WMH segmentation was performed by two raters (R1, R2) and repeated by the second rater a year later (R2a, R2b).
The manual masks were used to train BIANCA and the automated WMH masks were generated using a leave-one-out approach.
Between and within rater agreement on manually and automatically segmented masks were calculated using a Dice index and results were compared with paired t-tests.
Results: The agreement between BIANCA outputs generated with masks from different raters is similar to the manual between rater agreement. BIANCA outputs trained with masks from R2 (a,b) are more consistent than the within rater agreement of manual masks.
Conclusion: Our results suggest that if the examples provided to BIANCA are sufficiently in agreement, the automated tool improves the consistency of the output. This also highlights the need to standardise the definition of WMH, especially if automated tools are planned to be used in multicentre studies.
Limitations: The limited amount of scans, raters (with different expertise), and re-tests.
Ethics committee approval: Ethics approval and consent from all participants were obtained.
Funding: MRC (G1001354), MRC-DPUK, and Parkinson's UK.

A comparison of different radiomics models in the prediction of haematoma expansion in patients with intracerebral haemorrhages
H. Xie, S. Ma, X. Zhang, X. Wang*; Beijing/CN (xiehuihui1030@163.com)*

Purpose: To compare the predictive performance of different models in predicting haematoma expansion (HE) in patients with intracerebral haemorrhages (ICH).

Methods and materials: 251 patients with ICH who underwent computed tomography (CT) shortly after symptom onset and follow-up CT within 24 hours were retrospectively recruited. Haematoma expansion was defined as a volume growth exceeding 6 mL or 33% from the baseline volume. Patients were randomly allocated into a training cohort (177: with HE, 74; without HE, 103) and a validation cohort (74: with HE, 34; without HE, 40). Baseline images were analysed. The radiological model was constructed based on conventional radiological features (shape, volume, etc.). Radiomics features were extracted and a radiomics signature was calculated for each patient. Combined models were constructed with both conventional radiological features and a radiomics signature using 5 different methods: a logistic regression model, decision tree, random forest, AdaBoost, and support vector machine model (SVM). The predictive performance of models was assessed with a receiver operating characteristic curve (ROC) analysis.
Results: The radiological model reached an AUC of 0.869 in the training cohort and 0.811 in the validation cohort. Combined models built with 5 different methods achieved high AUCs in both cohorts. Among them, the combined model using AdaBoost reached the highest AUC of 0.959 in the training cohort. The combined model using logistic regression reached the highest AUC of 0.924 in the validation cohort.
Conclusion: Combined models based on radiologic features and a radiomics signature yield high predictive performance in predicting HE in both cohorts.
Limitations: A retrospective study, limited sample size, and the study was performed in only one institution.
Ethics committee approval: This study was approved by local institutional review board and informed consent was waived.
Funding: No funding was received for this work.

Automated MRI brain volumetry: a software comparison
P. Kousis, P. Toulas, E. Lamprou*; Athens/GR (p_koussis@yahoo.gr)*

Purpose: The automated brain volumetry from MRI images is a modern tool to quantify brain anatomy in patients with conditions related to brain atrophy. There is much software available in the market. We choose Neuroquant (NQ) and Volbrain (VB) in order to investigate any differences between their volumetric measurements and how these differences affect their atrophy estimation.
Methods and materials: 26 patients with multiple sclerosis visited the MRI lab at Bioiatriki SA (Athens) with the query of brain volumetry. They scanned in GE Discovery 750 3.0T MR system and the exam protocol included a 3D T1 sequence without contrast enhancement. The parameters in 3DT1 were in accordance with NQ's directions. These same images were processed both with NQ and VB. Measurements from different brain structures were compared. The unpaired t-test was the statistical method used for data analysis. In patients with an atrophy result from NQ, the possible agreement with VB was checked.
Results: Whole-brain, hippocampus, cerebellum, and white matter measurements had or had not quite significant differences ($p>0.05$).
Intracranial cavity measurements had very significant differences.
Amygdale, putamen, and thalamus had extremely significant differences with a deviation from the bibliography average of 167.7% for NQ and 17.7% for VB, 35.9% for NQ and 3.3% for VB, and 0.7% for NQ and 29.3% for VB, respectively.
Conclusion: There are important differences in the measurements of some brain structures, with significant deviation from the bibliography average for both NQ and VB.
Although the initially unexpected differences, NQ and VB are both able to determine atrophy.
VB has smaller deviations from average values and, for the time, is free (10/d).
Limitations: The 3DT1 parameters should be constant during the study.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Deep learning AI technology matches lumbar spine MRI image quality at about 1/3 the scan time
L. N. Tanenbaum[1], W. Gibbs[2], S. Bash[3], L. Wang[4], H. Gandhi[4], P. Gulaka[4], A. Shankaranarayanan[5], T. Zhang[6]; *[1]Riverside, CT/US, [2]Pasadena/US, [3]Los Angeles/US, [4]Palo Alto/US, [5]Waukesha, WI/US, [6]Menlo Park, CA/US (nuromri@gmail.com)*

Purpose: To evaluate the performance of deep learning AI (DLAI) to match routine lumbar spine MRI image quality at highly reduced scan times.
Methods and materials: 27 consecutive patients (49+/-16 years old; 17 male) underwent standard of care (SOC) lumbar spine MRI exams on 1 of 3 different clinical 1.5T scanners. All subjects underwent an additional accelerated 2D sagittal T2 series processed by an FDA cleared convolutional neural network-based deep learning AI application trained on multivendor MR platforms (SubtleMR™). The sagittal T2 scan times averaged 2:12 (SOC) and 0:49 (DLAI=2.7x acceleration). 54 image series (27 SOC and DLAI) were randomised and independently rated by two board-certified neuroradiologists for perceived SNR, anatomy/pathology conspicuity, motion artefacts, and overall image quality on a 5-point Likert scale (1: non-diagnostic, 2: poor, 3: diagnostic, 4: good, and 5: excellent). A two-sided paired t-test was performed with $P<0.05$ considered as statistically significant.
Results: The average scores for perceived SNR, anatomy/pathology conspicuity, motion artefacts, and overall image quality (SOC/DLAI) were 5.0/4.9, 5.0/4.9, 4.9/4.8, and 5.0/4.9, respectively, for reader 1, and 4.4/4.3, 4.8/4.5, 4.7/4.7, and 4.4/4.2 for reader 2. No statistically significant difference between DL-accelerated scans and standard scans were present for all criteria and both readers.
Conclusion: Deep learning AI technology can match routine lumbar spine MR image quality at approximately 1/3 of the scan time.
Limitations: The limited number of subjects (27).
Ethics committee approval: IRB approved with written informed consent.
Funding: No funding was received for this work.

Automated expert level localisation of perivascular spaces in the centrum semiovale and the basal ganglia
K. M. H. van Wijnen, F. Dubost, P. Yilmaz, M. P. D. M. A. Ikram, W. J. Niessen, H. H. H. Adams, M. W. Vernooij, M. de Bruijne*; Rotterdam/NL (k.vanwijnen@erasmusmc.nl)*

Purpose: Enlarged perivascular spaces (PVS) are a neuroimaging marker for cerebral small vessel disease. Manual annotation of PVS is challenging, time-consuming, and subject to observer bias. We developed and evaluated an automated method for the localisation of PVS in the two most clinically relevant regions: the centrum semiovale (CSO) and the basal ganglia (BG).
Methods and materials: We used T2-weighted 1.5T MRI scans from 2,202 subjects enrolled in the population-based Rotterdam scan study, 1,202 for method development, and 1,000 for evaluation. An expert rater annotated one predefined slice per brain region with a single dot per PVS. A separate set of 40 MRI scans was annotated twice to estimate intra-rater agreement, which was computed by considering both sets once as ground truth and computing the average sensitivity and false-positives per image (FPPI).
We trained a regression convolutional neural network to predict the intensity-based distance to the nearest PVS for each voxel. Subsequently, the predicted distance maps were thresholded to detect PVS.
Results: The intra-rater agreement showed an average sensitivity of 55.7% with 4.43 FPPI in the CSO and in the BG this was 73.2% and 2.09, respectively. Our method had similar performance with, for the same number of FPPI, an average sensitivity of 55.6% in the CSO and 75.3% in the BG.
Conclusion: Even for an expert rater, this is a challenging problem as shown by the intra-rater agreement. Our proposed method can annotate PVS fully automatically as well as an expert rater. This method could replace the time-consuming manual assessment of PVS in neurological studies.
Limitations: The single scanner, single protocol dataset; 1 slice per brain region annotated.
Ethics committee approval: Rotterdam scan study approved by the medical ethics committee of Erasmus MC.

The added diagnostic value of a model-based reconstruction algorithm in detecting acute trauma-related lesions in brain CT examinations in an emergency setting

C. Maino[1], D. Ippolito[1], S. Lombardi[1], L. Riva[1], C. R. G. L. Talei Franzesi[2], S. Sironi[3]; [1]Monza/IT, [2]Milan/IT, [3]Bergamo/IT (mainocesare@gmail.com)

Purpose: To evaluate the added value of a model-based reconstruction algorithm (IMR) in the assessment of traumatic and acute findings in emergency non-enhanced computed tomography (NECT) cranial scans in comparison to the standard hybrid iterative reconstruction approach (iDose).
Methods and materials: We evaluated 150 patients who underwent a 256-row NECT scan at the emergency department for head trauma. Images of the volumetric acquisition of the brain scan were reconstructed with iDose and IMR (2mm thickness), then were randomly evaluated by two radiologists who recorded the presence, nature, number, and location of the acute findings. Image quality evaluation was also performed using a 4-point scale (1: unacceptable, 4: more than average).
Results: IMR showed a higher detection rate of acute lesions in comparison to iDose (IMR identified 55 vs 15 subdural haemorrhages, 97 vs 44 subarachnoid haemorrhages, 11 vs 11 intraventricular haemorrhages, 42 vs 21 parenchymal haemorrhages, 48 vs 36 contusive lesions, and 62 vs 7 diffuse axonal injuries). We obtained significant intraobserver difference when comparing the two different reconstruction protocols ($p<0.05$), while no significant difference between the observers was found when evaluating each reconstruction protocol ($p<0.05$), obtaining high interobserver agreement ($k= 0.87$). IMR offered a higher image quality rating (3.32 vs 2.53), CNR (3.18 vs 2.1), and SNR (15.67 vs 8.53), and a lower noise index (2.13 vs 4.3) than iDose.
Conclusion: IMR, by offering high diagnostic image quality at a thinner slice, identifies a higher number of acute traumatic lesions than iDose with a significant reduction of noise and partial volume artefacts, thus representing a very useful diagnostic tool in assessing brain lesions of trauma patients.
Limitations: A single-centre study.
Ethics committee approval: Written informed consent was obtained from each patient.
Funding: No funding was received for this work.

An advanced deep learning approach to automatically detect and segment intracranial aneurysms in patients with subarachnoid haemorrhages on CTA

R. Shahzad[1], L. Pennig[1], L. Goertz[2], F. Thiele[3], M. Perkuhn[1], J. Borggrefe[1]; [1]Cologne/DE, [2]Mannheim/DE, [3]Aachen/DE (rahilshahzad@gmail.com)

Purpose: To develop a deep learning model (DLM) for fully automated detection and segmentation of intracranial aneurysm in patients with subarachnoid haemorrhages (SAH) on CT-angiography (CTA).
Methods and materials: This retrospective single-centre study included 295 confirmed aneurysms from 253 patients with SAH (2010-2017). All patients from 2016-2017 (68 patients/79 aneurysms) provided the training-set, whereas subjects from 2010-2016 (185 patients/216 aneurysms) served as a test-set. Ground truth was established by independent manual segmentations of the aneurysms by a radiologist and neurosurgeon in a voxel-wise manner. CTA source images acquired using a standard clinical protocol for head/neck (n=222) and head (n=29) were pre-processed by extracting the brain mask and enhancing the blood vasculature. A 3D convolutional neural network (CNN) architecture based on DeepMedic was used for training 3 different DLMs using a different combination of vessel-enhanced input images as multiple-channels, as well as modifying the CNN parameters. An ensembling strategy was then used to generate the final DLM, optimised by using 5-fold-cross-validation.
Results: In the training-set, DLM achieved an aneurysm detection rate of 0.72, average false-positives (FP's)/scan of 0.21, a Dice coefficient of 0.74, and a volume correlation (r) of 0.97. Comparing the performance of the individual DLMs to the ensemble approach, we observed an increase of 37% (0.54 vs 0.74) with respect to Dice and a decrease of 90% with respect to FP's/scan (2.10 vs 0.21). On the independent test-set, sensitivity was 0.82 with an average of 0.81 FP's/scan, a Dice of 0.75, and r of 0.9.
Conclusion: The proposed DLM is robust in detecting and segmenting aneurysms in patients with SAH on routine CTA images. We also demonstrated a significant increase of performance by using an ensemble of different DLMs.
Limitations: n/a

RPS 1011b-12 12:21

Morphometry: a way to facilitate the diagnosis of dementia?

P. Malmierca Ordoqui, A. Paternain Nuin, M. Calvo Imirizaldu, A. C. Igual Rouilleault, B. Echeveste, M. Riverol, P. Dominguez Echavarri, M. A. Fernandez Seara, R. Garcia de Eulate; Pamplona/ES (pmalmierca@unav.es)

Purpose: To evaluate the reproducibility of morphometry MRI to assess atrophy in patients with a mild cognitive impairment (MCI).
Methods and materials: We retrospectively analysed MR images of 114 patients with MCI. One radiologist rated atrophy in 6 key brain regions bilaterally in T1-MPRAGE sequences using established visual rating scales.
Afterwards, atrophy was rated with a morphometry function (MorphoBox algorithm, Siemens prototype) which automatically estimates the volume of different brain regions and compares them with normative adjusted ranges. Maps with the different brain regions colour-coded indicated the degree of deviation (no deviations=green, mild=yellow, moderate=orange, and large=red). Using Fisher's tests, we evaluated the association between classifications (visual and morphometric) and between each classification and the actual clinical diagnosis, including all patients and including only those classified as normal or MCI/Alzheimer's disease (AD) by all methods.
Results: When all patients were included, there was no association between visual and morphometric classifications ($p=0.44$). However, if only normal or MCI/AD patients were considered, the association was close to significance ($p=0.073$). When all patients were included there was a significant association between the visual classification and clinical diagnosis ($p=0.006$), but no association between morphometry and clinical diagnosis ($p=0.29$). However, when only normal or MCI/AD patients were considered, the association between clinical diagnosis and visual classification was not significant ($p=0.43$), while the association between clinical diagnosis and morphometry was closer to significance ($p=0.0920$).
Conclusion: The morphometry function has a tendency to be significant when it comes to differentiating normal patients from MCI/AD. Nevertheless, it doesn't classify other dementias as well as visual classification.
Morphometry may represent a facilitating tool in the clinical assessment of MCI/AD, although further investigations are required.
Limitations: The small sample size.

Differentiating head and neck paraganglioma versus schwannoma using texture analysis: a preliminary analysis

A. Ghosh, S. R. Malla, A. S. Bhalla, S. Manchanda, D. Kandasamy; New Delhi/IN (soumyaranjan_aiims@yahoo.com)

Purpose: To investigate the value of T2-weighted based radiomics in the differentiation of head and neck paragangliomas and schwannomas.
Methods and materials: This retrospective study included patients presenting with neck masses who were imaged under our institutional protocol in 3T MRI scanner between January 2016 and March 2019. A total of 46 patients (36 paragangliomas and 16 schwannomas) were identified using a composite gold standard of histopathology, cytology, and DOTANOC PET CT. Fat-suppressed T2-DIXON axial images with TR-2500-3500msec, TE-90msec, 4 mm slice thickness and 190x190 mm-FOV were used for analysis.
First- and second-order texture-parameters were calculated from original and filtered images. Feature selection using F-statistics and collinearity analysis provided 10 texture parameters for further analysis. A Mann-Whitney-U test was used to compare the two groups and p-values were adjusted for multiple comparisons. AUC for the significant features was obtained.
Results: A total of 7 texture parameters were found to be significantly different between paragangliomas and schwannomas (adjusted $p < .05$). Laplacian of Gaussian intermediate, first-order kurtosis, wavelet HLL, grey-level co-occurrence matrix (glcm) correlation, and wavelet LHH glcm correlation each achieved a specificity of 93.5% in differentiating paraganglioma and schwannoma with AUC of 0.738, 0.819, and 0.689, respectively. A logistic regression model combined the 7 significant texture parameters to differentiate between paragangliomas and schwannomas, which obtained a sensitivity of 97.2% and specificity of 75%, with an AUC of 0.97 (0.87 to 0.99).
Conclusion: T2-weighted based radiomics could serve as a useful adjunct to conventional MRI in distinguishing head and neck paragangliomas from schwannomas, which may influence triage contrast administration or nuclear medicine based DOTANOC studies.
Limitations: These results are preliminary and thus require validation on a larger and independent data set to assess reproducibility for the potential for clinical translation.

Radiomics-based approach for the diagnosis of osteoporosis using hip radiographs

K. Sang Wook, J. Lee, S.-J. Ye, H. D. Chae*; Seoul/KR*

Purpose: To evaluate the performance of a radiomics-model for the diagnosis of osteoporosis using hip radiographs.
Methods and materials: For the development dataset, 6,995 hip anteroposterior radiographs with dual-energy x-ray absorptiometry (DXA) were collected between 2010 and 2018. Both hip joints were automatically segmented using U-net, except for joints with fractures or metal prostheses. A total of 11,243 joints (normal 9,170, osteoporosis 2,073) were used for the development dataset and a temporally-separated validation dataset was comprised of 553 joints (normal 459, osteoporosis 74) from 300 hip anteroposterior radiographs between 2008 and 2009. T-scores on hip DXA were used as reference standards. Three clinical (age, sex, and weight) and 293 radiomics features were used to train the random forest and gradient boosting classifiers. Two radiologists assessed the possibility of osteoporosis using a 5-point scale and the performance of the radiologist was compared with the radiomics-model. Receiver-operating characteristic curve analysis was used to assess diagnostic performance.
Results: The diagnostic performance was AUC 0.809 (95% CI 0.774-0.842) for board-certified radiologists and AUC 0.760 (95% CI 0.721-0.796) for the radiology resident. The performance of the radiomics-model was AUC 0.830 (95% CI 0.796-0.861), sensitivity 74.3%, and specificity 79.5%, with an optimal cut-off probability of 0.318. The performance of the radiomics-model was significantly higher than the radiology resident ($P = 0.038$).
Conclusion: The radiomics-model for the diagnosis of osteoporosis using hip radiographs showed comparable diagnostic performance to those of the radiologists and may help in the automatic screening of osteoporosis in plain radiographs.
Limitations: Additional external validation is needed to assess the generalisability of the model.
Ethics committee approval: All datasets were collected under IRB approval in SNUH.
Funding: This work was supported by the National Research Foundation of Korea grant funded by the Korean government (No. NRF-2017M2A2A6A01071214).

Quantitative ultrasound texture analysis of the foetal lung versus foetal pulmonary artery Doppler as a non-invasive predictor of neonatal respiratory distress syndrome (RDS)

N. Osman*; Minia/EG (nasrosman_7@yahoo.com)*

Purpose: To make a comparison between quantitative ultrasound texture analysis of the foetal lung (QuantusFLM) and pulmonary artery acceleration time/ejection time ratio (AT/ET) for the evaluation of foetal lung maturity.
Methods and materials: The prospective cohort study was conducted on 65 pregnant women selected from cases referred to the obstetrics and gynaecology department at Minia University Hospital from May 2018 to March 2019. All patients underwent ultrasound examination for foetal pulmonary artery acceleration time/ejection time ratio (AT/ET) as well as a grey-scale axial ultrasound image of the foetal lungs, which were analysed using the Quantus-FLM software online application. 25 patients were excluded from the study due to a foetal birth more than 48 hours after the ultrasound examination, corticosteroid administration in between the examination and delivery, congenitally malformed foetuses, neonatal sepsis, or respiratory distress due to causes other than neonatal RDS. After delivery, the neonates were grouped according to diagnosis of RDS as positive or negative.
Results: From the 40 eligible foetuses, 9 (22%) developed neonatal RDS. Both AT/ET and Quantus FLM results were significantly correlated with the development of neonatal RDS. AT/ET were significantly lower in feotuses developed RDS. A cutoff value of 0.305 for AT/ET predicted the development of RDS (sensitivity: 77.78%, specificity: 87.1%) while Quantus FLM predicted neonatal RDS with 88.9% sensitivity and 90.32% specificity.
Conclusion: Both AT/ET and Quantus-FLM may provide a noninvasive means of detecting the development of neonatal RDS with acceptable levels of sensitivity and specificity.
Limitations: Small numbers of patient study.
Ethics committee approval: This study is approved by our university ethics committee.
Funding: No funding was received for this work.

Can MRI texture analysis of the pancreas predict postoperative pancreatic fistulas?

S. M. Skawran, P. Kambakamba, B. Baessler, M. Kupka, D. Eshmuminov, H. Petrowsky, C. S. Reiner*; Zurich/CH (stephan.skawran@usz.ch)*

Purpose: To evaluate whether a magnetic resonance imaging (MRI) texture analysis (TA)-based machine learning (ML) classifier can predict postoperative pancreatic fistulas (POPF) after pancreaticoduodenectomy (PD).
Methods and materials: 70 patients who underwent MRI before PD between 2010 and 2018 were retrospectively analysed. POPF was graded according to the international study group of pancreatic fistula and split into clinically relevant versus non-relevant or no POPF. On T1- and T2-weighted images, two regions of interest were placed in the pancreatic corpus and cauda. 1,350 radiomic features were extracted after standardised image processing using the open-source pyRadiomics library. The dataset was split into training and test sets. After feature reduction, a non-linear support vector machine (SVM) was trained on the 3 most important features. Logistic regression analyses were performed using these features and mean T1 and T2 signal intensity values (SImean). Diagnostic accuracy of the models was compared using areas under the receiver operating characteristics curve (AUCs).
Results: One T1 and two T2 higher-order texture features were identified as the most important variables for classification. All 3 variables showed significant differences between the two groups (all $p<0.02$). The trained SVM achieved an AUC of 0.68 when applied on the test dataset. In contrast, logistic regression models using only SImean from T1- and T2-weighted images resulted in an AUC of 0.51 [T1mean], 0.60 [T2mean], and 0.59 [combined] (all $p<0.001$).
Conclusion: MRI-texture analysis based on routine sequences provides a promising prediction of clinically relevant POPF.
Limitations: Studies were limited to one vendor. Cross-vendor-transferability remains to be elucidated. Image analysis was done by one reader. Reproducibility will be subject to further research.
Ethics committee approval: The local ethics committee approved this retrospective study and all patients gave written informed consent.
Funding: No funding was received for this work.

The influence of different levels of adaptive statistical iterative reconstruction (ASIR) regarding computed tomography texture features
T. Polidori, D. Caruso, E. Muscogiuri, D. de Santis, A. Laghi*; Rome/IT (tiziano.polidori13@gmail.com)*

Purpose: To evaluate the influence of different levels of ASIR on computed tomography texture features.
Methods and materials: We analysed 10 patients who underwent unenhanced computed tomography (CT) scans of the abdomen with the same scanner (Revolution Evo, GE Healthcare, USA). Subsequently, we reconstructed raw data with 11 levels of ASIR (from 0 to 10), thus obtaining datasets with different percentages of blending between filtered back projection and iterative reconstruction. Two radiologists analysed the texture features of the liver, kidney, spleen, and muscle tissues using four different regions of interest (ROIs) that were cloned for all 11 different iteration levels datasets. Data was then elaborated with TexRad medical imaging software. 5 different radiomic features (mean, standard deviation, entropy, skewness, and kurtosis) were compared among the different reconstruction algorithms and spatial scaling factor (SSF) by using ANOVA test with Bonferroni correction.
Results: Different iteration levels significantly affect ($p<0.05$) standard deviation (SD) and entropy values for SSF 0, with a decrease of these parameters from 0 to 10 ASIR (e.g. statistically significant decrease of entropy between level 10 and 0-7). The influence of different ASIR levels on these parameters gradually faded with an increase in the SSF, thus no significant differences between all the radiomic values have been obtained from SSF 5 to 6. We did not find statistically significant differences between the values of mean, skewness, and kurtosis, regardless of the SSF value and the tissue.
Conclusion: We demonstrated that different ASIR levels moderately affect standard deviation and entropy with a declining trend from SSF 0 to SSF 5-6. Mean, skewness, and kurtosis are not significantly affected by different ASIR levels.
Limitations: A small study population.

RPS 1005a-6 11:45
Correlation between CT texture parameters and clinicopathological properties of regional lymph nodes in patients with colon cancer
D. Wen[1], J. Y. Sun[2]*; [1]Chengdu/CN, [2]Cheng Du/CN (snow88416@163.com)*

Purpose: To investigate the correlation between CT texture features and regional metastasis of regional lymph nodes in colon cancer patients.
Methods and materials: We collected 69 patients with colon cancer from January 2018 to March 2019. A CT-enhanced scan informed consent was signed one week before surgery and a full-abdominal enhanced CT scan was performed. A radiologist was responsible for marking the enlarged lymph nodes in the area. A gastrointestinal surgeon was responsible for the location of the lymph nodes of the ex vivo specimens. The image of the venous phase was exported to the CK texture analysis software platform, the largest cross-section of the matching lymph nodes was selected, and the contour was manually drawn, extracting a total of 41 texture parameters of labelled lymph nodes. The marker-matched lymph nodes were divided into LNM (-) group and LNM (+) group by labelling the lymph node metastasis (LNM) as a standard. The texture characteristic parameters of the two groups were analysed and the ROC and AUC were used for performance evaluation.
Results: A total of 69 patients with colon cancer were collected, the markers matched 101 lymph nodes, of which 15 were metastatic lymph nodes and 86 non-metastatic lymph nodes. After statistical analysis, the texture parameter inertia had a correlation with lymph node metastasis ($P<0.05$, AUC=0.671). The other 40 texture parameters had no obvious correlation with lymph node metastasis.
Conclusion: Some texture parameters of single lymph nodes in colon cancer patients have a correlation with their metastasis.
Limitations: The sample size was small and the research period not long enough.
Ethics committee approval: Approved by the Bioethics Committee of West China Hospital of Sichuan University.

RPS 1005a-7 11:51
Classification of non-enhancing glioma tumours by diffusion MRI with B-tensor encoding: an explorative study of tumour heterogeneity
J. Brabec, F. Durmo, F. Szczepankiewicz, B. Lampinen, L. Knutsson, P. Sundgren, M. Nilsson*; Lund/SE (jan.brabec@med.lu.se)*

Purpose: To classify gliomas based on the anisotropic and isotropic diffusional kurtosis obtained from dMRI with B-tensor encoding.
Methods and materials: 25 patients with glioma tumours were examined on a 3T scanner (MAGNETOM Prisma, Siemens Healthcare, Erlangen, Germany). A prototype spin-echo B-tensor encoding sequence was used with TR/TE=5300/80 ms/ms, resolution=2.3×2.3×2.3mm^3, two B-tensor shapes (linear and spherical), and four b-values between 0.1 and 2.0ms/μm^2. The mean diffusivity, anisotropic kurtosis, and isotropic kurtoses were obtained. The tumours were delineated on post-Gd T1w images. All five non-enhancing glioblastomas (WHO IV) and all four non-enhancing oligodendrogliomas (WHO II) were selected for analysis, where mean and standard-deviations were compared with a U-test.
Results: The anisotropic and isotropic kurtoses for a glioblastoma together with a post-Gd T1w image and a mean diffusivity map was mapped. In this example, the necrotic core was associated with lower anisotropic kurtosis. It also demonstrated higher isotropic kurtosis, with a contrast stronger than that of the mean diffusivity. Two non-enhancing tumours without a necrotic core (glioblastoma and oligodendroglioma) that appear similar on the T1w images were compared. Within the glioblastoma, the isotropic kurtosis showed a lower variability, whereas the oligodendroglioma showed higher variability, possibly due to higher tumour heterogeneity. This finding was corroborated, showing that the standard deviation of the isotropic kurtosis differs significantly between non-enhancing glioblastomas and oligodendrogliomas ($p=0.032$).
Conclusion: Non-enhancing glioblastomas and non-enhancing oligodendrogliomas had a significantly different standard deviation in isotropic kurtosis, which indicates that it can be used to distinguish them.
Limitations: Conclusions are based on a small sample size and will therefore be validated in a larger cohort.
Ethics committee approval: Informed written consent was obtained from all subjects. Approvals 2016/6 and 2017/866.

RPS 1005a-8 11:57
Whole-tumour histogram analysis of diffusion kurtosis imaging as a predictive biomarker of tumour response in locally advanced rectal cancer treated with neoadjuvant chemoradiation
Y. Sun, T. T. Tong, G. Yajia, C. Fu*; Shanghai/CN (12211230032@fudan.edu.cn)*

Purpose: To explore the predictive value of whole-tumour histogram analysis in diffusion kurtosis imaging to assess tumour response to neoadjuvant chemoradiation therapy in locally advanced rectal cancer.
Methods and materials: 43 enrolled patients were examined using MRI at two time points: 1-7 days before NCRT (pre-MRI) and within 1-7 days of NCRT completed (post-MRI). Pretreatment T stage, N stage, MRF, EMVI, tumour location and length, pretreatment CEA, and CA19-9 levels were recorded. According to tumour response, we classified the patients into pCR and non-pCR groups. Whole tumour volume of interest (VOI) was obtained by a semi-automatic segmentation method in both pre- and post-MRI. Then, ADC, K, and D histograms and corresponding parameters, difference histograms value between pre-MRI and post-MRI, were calculated. Histograms metrics of ADC,

K, and D, tumour characteristics, and their relationship with tumour response were evaluated by using logistics regression.
Results: Pre-K_{ske}, post-tumour volume, and ADC_{sd} (pre-post) were correlated with tumour response by using a Lasso regression model and then a radiological signature score was built. Pretreatment EMVI(+) (OR=9.231,p=0.048), MRF(+) (OR=5.317, p=0.030), higher rectal cancer (OR=4.110,p=0.021), CEA≥5ng/ml (OR=9.231, p=0.048), and a low radiological signature score (OR=14.428, p=0.011) could be associated with non-pCR in univariate analysis. Multivariate analysis identified that the pretreatment CEA≥5ng/ml (OR=42.311, p=0.044) and low radiological signature score (OR=1.312, p=0.007) would be independent factors to indicate a patient with non-pCR.
Conclusion: Whole-tumour histogram analysis of DKI is a valuable and easily available tool to predict tumour response. It will be helpful to stratify patients who are sensitive to NCRT in locally advanced rectal cancer.
Limitations: This study is not a large-scale randomised trial and comprises data from only one centre.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Quantitative comparison of a novel visualisation technique (gradient-intensity projection, GIP) with an average projection for ultra-low-dose CTs of the chest
S. Carey[1], B. E. Hoppel[2], W. Hamilton[1], S. Kandel[3], P. Rogalla[1]; [1]*Toronto, ON/CA,* [2]*Vernon Hills, WI/US,* [3]*Berlin/CA (sean.carey@uhn.ca)*

Purpose: To develop a thick-slab presentation technique (gradient-intensity projection) which can effectively mitigate the increased noise inherent in ultra-low-dose CT (ULDCT) while demonstrating superior image contrast as compared to average projection.
Methods and materials: The value of a voxel in the thick-slab output slice is computed as a weighted average of the voxels contained in each contributing slice of the input image at the same position in the slice. The weight of each contributing voxel is determined by computing the difference in HU value of that voxel with its neighbours in a 3x3 area in the input image. This creates a weighting matrix of the same size as the input image, where a higher weight reflects a higher intensity gradient at the position in the image (GIP). A moving average low-pass filter is applied to the weight matrix to provide local consistency and to reduce the contribution of speckle-noise while leaving the contribution of larger structures. Both projection techniques were applied to a thoracic ULDCT image (0.16 mSv) reconstructed using deep-learning reconstruction. The noise level was assessed by comparing the standard deviation of regions in the liver and in the air and contrasted by computing a GLCM on a circular ROI drawn over the lung vasculature. The entropy in the lung ROI was also assessed.
Results: The standard deviation of the ROIs in the liver for average/GIP was 8.89/9.89, in air 10.614/11.919, respectively (n.s.). The contrast of the lung vasculature (GLCM) was 2347.41/14353.05, the entropy 7.19/8.165, respectively, both p< 0.001.
Conclusion: Gradient-intensity projection offers significantly increased contrast of fine structures without a significant increase of image noise over average projection.
Limitations: Not yet clinically validated.
Ethics committee approval: n/a
Funding: No funding was received for this work.

RPS 1005a-10 12:09
Phantomless assessment of volumetric bone mineral density using virtual non-contrast images from spectral detector computed tomography
C. E. S. Zaeske[1], D. Zopfs[1], S. Lennartz[1], K. R. Laukamp[1], M. Merkt[2], R. P. Reimer[1], D. Maintz[3], J. Borggrefe[1], N. Grosse Hokamp[1]; [1]*Cologne/DE,* [2]*Coblenz/DE,* [3]*Münster/DE*

Purpose: To evaluate a phantomless assessment of volumetric bone mineral density (vBMD) based on virtual non-contrast images of arterial (VNC_a) and venous phase (VNC_v) derived from spectral detector CT (SDCT) as compared to true non-contrast images (TNC) and adjusted venous phase conventional images ($CI_{V(adjusted)}$).
Methods and materials: Retrospective inclusion of 104 patients with triphasic SDCT between January 2018 to April 2019 with subsequent reconstruction of TNC, VNC_a, VNC_v, and venous phase images (CI_V). Assessment of vBMD by two radiologists usnig an FDA/CE-cleared software, which determined average vBMD of the first 3 lumbar vertebrae in each reconstruction. CI_V was adjusted for contrast enhancement using earlier suggested formulae.
Results: No significant difference was found comparing vBMD values obtained from $CI_{V(adjusted)}$ and TNC images (91.79 ± 36.52 mg/cm^3 vs. 90.16 ± 41.71 mg/cm^3, p=1.00), whilst vBMD values obtained from VNC_a and VNC_v (42.20 ± 22.50 mg/cm^3 and 41.98 ± 23.3 mg/cm^3) were significantly lower as compared to TNC and $CI_{V(adjusted)}$ (all p≤0.01).
Conclusion: vBMD values obtained from adjusted venous phase images did not show significant differences to vBMD values derived from TNC images, and thus may be utilised for an opportunistic BMD screening in CT examinations. SDCT-derived virtual non-contrast images appear to systematically underestimate vBMD, hence appropriate adjustments are required prior to a possible clinical implementation.
Limitations: No correlation to the reference standard areal BMD measurements by DEXA was performed. No cross-vendor comparison was performed.

Supervised machine learning predictive modelling for primary versus secondary lung malignancy in CT-guided transthoracic biopsies
E. J. M. Barbosa Jr., D. Lindsay, N. Sachs, J. Gee; *Philadelphia, PA/US*

Purpose: CT-guided transthoracic biopsy (CTTB) is a minimally invasive method for the diagnostic evaluation of a variety of thoracic diseases. We leveraged a large cohort of CTTB patients to assess how well supervised machine learning models utilising clinical and imaging variables can predict pathology diagnosis in primary versus secondary lung malignancy.
Methods and materials: 588 patients were retrospectively identified, comprising of biopsies performed at our institution. Our model included variables such as age, race, sex, smoking history, smoking pack-years, history of prior cancer, immune status, nodule location, nodule size, nodule margin, and nodule shape. These variables were extracted from radiology reports and electronic medical records. Ground-truth was CTTB pathology diagnosis, classified as primary (60.5%) versus secondary (39.5%). We compared 3 supervised machine learning classifiers: random forest (RF), logistic regression (LR), and decision tree (DT), utilising a 75%/25% training/validation ratio for the CTTB cohort (10-fold cross-validation).
Results: The RF model produced AUC (area under the curve) of ROC (receiver operating characteristic) of 0.87 and accuracy of 0.81, the LR model produced AUC of ROC of 0.89 and accuracy of 0.81, whereas the DT model produced AUC of ROC of 0.79 and accuracy of 0.71.
Conclusion: CTTB, while accurate for pathologic diagnosis of thoracic lesions, can be costly and may entail significant risks. LR and RF models achieved up to 81% diagnostic accuracy, potentially allowing non-invasive prediction of primary versus secondary lung malignancy, a crucial distinction for patient management.
Limitations: A retrospective design.
Ethics committee approval: IRB approved, waiver of informed consent.
Funding: Funded by the NIH (USA).

RPS 1005a-12 12:21
Dominant language hemisphere detection by using a ML model informed by structural and functional connectivity
S. Pascual-Diaz, J. C. Pariente, E. Muñoz-Moreno, C. Garrido, E. Conde, N. Bargallo I Alabart; *Barcelona/ES (PARIENTE@CLINIC.CAT)*

Purpose: To develop a method to determine the language dominant hemisphere (LDH) by using structural, diffusion, and resting-state MRI.

Methods and materials: This study was performed on structural and functional neuroimaging data from 15 subjects. We define the LDH goal standard using MRI functional data with language and comprehension tasks.
For the structural analyses, whole-brain tractography reconstructions were performed using multi-shell, multi-tissue, constrained spherical deconvolution. We obtained the language-related tracts using a pre-trained convolutional neural network (Tractseg) and used them to obtain language connectivity matrices.
We obtained different indices from the volumetric acquisition (e.g. cortical thickness), diffusion-based parameters (e.g. FA), and graph theoretical indices derived from structural and functional language connectivity matrices. We performed a parametric statistical analysis for each of the metrics and used the significant indices to obtain single-subject laterality differences by training a ML-based classification algorithm.
Additionally, we compared the results obtained with our methodology using the standard laterality index approach.
Results: We found statistically significant differences for the cortical thickness in the superior temporal gyrus and in the MD for the uncinated tract. The ML model had an accuracy of 0.90 +/- 0.19 with a confusion matrix.
We did not find differences using the LI analysis.
Conclusion: Our results suggest that we can use this methodology to predict the LDH by using a ML classification model based on resting-state and diffusion from MRI data.
Limitations: The sample is not big enough for a ML-based study. This abstract is a proof of concept and we are now acquiring new subjects to validate the new methodology.
Ethics committee approval: n/a

Long-term evolution of hepatocellular adenomas at MR imaging follow-up
F. Vernuccio[1], R. Maxime[2], M. Dioguardi Burgio[2], F. Cauchy[3], S. Dokmak[2], D. Valla[2], J. Zucman-Rossi[3], V. Paradis[2], V. Vilgrain[2]; [1]Palermo/IT, [2]Clichy/FR, [3]Paris/FR (federicavernuccio@gmail.com)*

Purpose: Hepatocellular adenomas (HCAs) are rare benign liver tumours. Guidelines recommend continued surveillance for patients diagnosed with HCAs, but these recommendations are mainly based on small series or experts' opinion. The aims of this study were to analyse the long-term evolution of HCAs, including solitary and multiple lesions, and to identify predictive features of progression.
Methods and materials: In a retrospective cohort study, we included 118 patients (mean age 40±10 years old) with pathology-proven HCAs: 41 had solitary HCAs and 77 patients multiple HCAs. ß-catenin mutated HCAs and HCAs with foci of malignancy were defined at-risk of progression. MR exams were analysed and tumour evolution was evaluated using RECISTv1.1.
Results: In a median follow-up of 5.0 years, 37/41 (90%) patients with solitary HCAs and 55/77 (71%) patients with multiple HCAs showed stable or regressive disease. After resection of solitary HCAs, new lesions appeared only in 2/29 (7%) patients, both with HCAs at-risk of progression. Among patients with multiple HCAs, HNF-1α inactivated HCAs showed a higher rate of progression compared to inflammatory HCAs (11/26[42.3%] vs. 7/37[18.9%], p=0.043), and lower use and lesser duration of oral contraceptives intake (28/32 [87.5%] vs. 45/45 (100%), p=0.027, and mean 12.0±7.5 years vs. 19.2±9.2 years, p= 0.001, respectively).
Conclusion: 78% of HCAs showed long-term stability or regression. After resection of solitary HCAs, new lesions occurred only in HCAs at-risk of progression. Patients with multiple HCAs were more likely to show progressive disease, with HNF-1 α inactivated HCAs being the most common subtype showing progression.
Limitations: Retrospective design. A low number of unclassified, sonic hedgehog, or ß-catenin mutated in exon 7-8 HCAs. A lack of serial MRI exams. An adoption of RECIST 1.1 may have underestimated size changes.
Ethics committee approval: IRB approved; waiver of informed consent obtained.
Funding: No funding was received for this work.

Prediction of histopathological growth patterns by radiomics and CT-imaging in patients with operable colorectal liver metastases: a proof-of-concept study
M. P. A. Starmans[1], F. E. Buisman[1], F. Willemssen[1], S. R. van der Voort[1], D. J. Grünhagen[1], P. B. Vermeulen[2], C. Verhoef[1], S. Klein[1], J. J. Visser[1]; [1]Rotterdam/NL, [2]Antwerp/BE (m.starmans@erasmusmc.nl)*

Purpose: The histopathological growth pattern (HGP) is a prognostic factor in patients with colorectal liver metastases (CRLM). Currently, HGPs can only be obtained postoperatively through resection. We present a non-invasive, preoperative alternative using CT and radiomics.
Methods and materials: As a proof-of-concept, we aimed to distinguish two extrema: pure (i.e. 100%) desmoplastic HGP (dHGP) and pure replacement HGP (rHGP). The dataset consisted of CT scans from 76 patients with 93 CRLM (45 dHGP; 48 rHGP). Three clinicians manually delineated the lesions; one repeated process. Observer segmentation variability was determined using the dice similarity coefficient (DSC). From each segmentation, 410 radiomics features were extracted. Decision models were created for the segmentations of each observer separately and by training and testing on different observers. The models were created through an automated search amongst a variety of machine learning algorithms to find the combination that maximizes performance. The evaluation was implemented through a 100x random-split cross-validation, using 80% for training and model optimisation and 20% for testing.
Results: The mean inter-rater DSC was 0.69, indicating poor observer agreement. The single-observer radiomics models resulted in mean area under the curves (mAUCs) of 0.67, 0.61, and 0.70. The multiobserver radiomics models, trained on two observers and tested on the third, resulted in mAUCs of 0.72, 0.70, and 0.64. Thus, no substantial model differences were found among the segmentations of the observers.
Conclusion: Our radiomics model is able to associate quantitative CT imaging features with pure HGPs and generalises well to segmentations of an unseen observer. Pending further optimisation and validation, radiomics based on CT imaging may have potential as a non-invasive, preoperative surrogate for postoperative HGP assessment.
Limitations: Relatively small dataset.
Ethics committee approval: Erasmus MC IRB (MEC-2017-479).

MRI of atypical liver haemangioma: significant imaging features to differentiate accurately from cholangiocarcinoma
R. Boxhoorn, R. S. Dwarkasing, F. Willemssen, G. P. Krestin; Rotterdam/NL (rboxhoorn@gmail.com)*

Purpose: The purpose of this study was to evaluate liver lesions that were initially suspected of CCA on MRI and proved haemangioma on histopathology evaluation. Are there features of MRI that can reliably differentiate atypical haemangioma from CCA?

Methods and materials: Retrospectively we identified 16 consecutive patients with PA proven haemangiomas that were initially suspected of CCA on MRI. We compared these lesions with a group of 20 PA proven CCAs from the same search period. Two observers evaluated lesions qualitatively and quantitatively on morphologic features, signal intensity, DWI/ADC values, and contrast enhancement patterns.
Results: 16 patients with atypical haemangiomas were included: lesion size mean 6.3 cm; range 2.2 cm-11.2 cm. The control group consists of 20 CCA with size mean 6.9 cm; range 2.8 cm-13.5 cm. All lesions in both groups had heterogeneous signal intensities in T1W and T2W and, although progressive contrast enhancement was seen in both groups, haemangiomas demonstrated more intense enhancement in the early arterial phase. Perilesional arterial enhancement with iso-intensity in the portal-venous phase was observed in the majority (n=11) of haemangiomas, significantly more (p<0.001) than CCAs (n=1).
The average ADC mean of haemangiomas was 2.40±0.57 x 10^{-3} mm^2/s (range 1.55-3.55), significantly higher (p<0.0001) than for CCAs: 1.36±0.18 x 10^{-3} mm^2/s (range 0.95-1.62).
Conclusion: Atypical liver haemangiomas demonstrate significant higher ADC value and perilesional arterial enhancement than CCA and can be used to suggest the right diagnosis.
Limitations: Usual limitations and potential sources of bias associated with retrospective study design.
Ethics committee approval: n/a

New IVIM parameter PDR (perfusion/diffusion ratio) in discrimination of benign and malignant focal liver lesions

J. Podgorska, P. Kus, B. Gołębiewski, K. Pasicz, J. Jasieniak, A. Rogowska, W. Skrzyński, P. Kukołowicz, A. Cieszanowski*; Warsaw/PL*
(jpodgo@gmail.com)

Purpose: Intra-voxel incoherent motion (IVIM) imaging allows simultaneous assessment of the diffusion of water in the extracellular space and the microcirculation of blood in capillaries. The aim of the study was to assess the usefulness of IVIM parameters: true diffusion (D), pseudo-diffusion (D*), perfusion fraction (f,) and the author's own parameter, PDR (perfusion/diffusion ratio; the ratio of the speed of signal b loss as a result of IVIM, to the speed drop of signal b due to diffusion), in the differentiation of benign and malignant focal liver lesions (FLLs).
Methods and materials: We evaluated prospectively 50 patients (age: 25-80 years, mean 60) with 83 FLLs (24 benign and 59 malignant) examined on 3T MRI, including the IVIM (10 b values: 0-900 s/mm^2). Malignant lesions were confirmed histopathologically, benign lesions were verified by follow-up studies.
Results: Significant differences (p<0.05) between benign and malignant lesions were obtained for D parameter (median ± standard deviation: benign: 1.40±0.66x10^{-3} mm^2/s; malignant: 0.97±0.38x10^{-3} mm^2/s) and for the PDR (10.6±11.0; 4.0±20.6). No significant differences were found for f and D*. The analysis of ROC curves for D with a cut-off value of 1.05x10^{-3} mm^2/s showed 71% sensitivity, 72% specificity, 71% accuracy, and for the PDR with a cut-off of 5.18, 65%, 75%, 68%, respectively.
Conclusion: The study showed the usefulness of IVIM parameters: D and the PDR in differentiation of FLLs.
Limitations: There is a predominance of malignant over benign lesions in the study group.
Ethics committee approval: The research protocol was approved by the local ethics committee and written consent was obtained from all patients prior to the study.
Funding: No funding was received for this work.

RPS 1001c-5 11:39

Hepatic uptake index in the hepatobiliary phase of Gd-EOB-DTPA-enhanced magnetic resonance imaging estimates functional liver reserve and predicts posthepatectomy liver failure

M. Donadon[1], E. Lanza[1], B. Branciforte[2], R. Muglia[2], C. Lisi[2], V. Pedicini[1], D. Poretti[1], L. Balzarini[1], G. Torzilli[1];
[1]Rozzano/IT, [2]Pieve Emanuele/IT
(riccardo.muglia@humanitas.it)

Purpose: Recent evidence suggests that gadolinium-ethoxybenzyl-diethylenetriamine penta-acetic acid-enhanced magnetic resonance imaging (Gd-EOB-DTPA MRI) may be used to evaluate liver function. We assessed whether the signal intensity of Gd-EOB-DTPA MRI might correlate with common use liver disease clinical score systems and posthepatectomy liver failure (PHLF) in patients undergoing hepatectomy for liver tumours.
Methods and materials: We retrospectively analysed 137 preoperative Gd-EOB-DTPA MRIs of patients undergoing hepatectomy from November 1st, 2015, and July 31st, 2018.
Mean signal intensity of liver (L_{20}) and spleen (S_{20}) were measured on T1-weighted single-breath-hold 3D fat-saturated gradient-echo sequences acquired 20 minutes after Gd-EOB-DTPA administration.
The hepatocellular uptake index (HUI) of liver volume (V_L) was calculated with the following formula $V_L[(L_{20}/S_{20})\text{-}1]$ and was tested with several clinical score systems for liver disease and to the occurrence of PHLF.
Results: Patients with unhealthy livers had significantly lower values of HUI in comparison with those with normal function. This was found for MELD score ≤9 vs. >9 (p=0.0488), BILCHE score ≤2 vs. >2 (p=0.0208), ALBI grades (p=0.0357), and Humanitas score ≤6 vs. >6 (p=0.0311). HUI was significantly lower in those patients with PHLF (p=0.001). Receiver operating characteristics curve analysis revealed valuable HUI ability in predicting PHLF (AUC=0.84; 95%CI=0.71-0.92; p<0.001), with a cutoff value of 574.33 (98% sensitivity; 83% specificity).
Conclusion: HUI measured on preoperative Gd-EOB-DTPA MRI identifies patients with unhealthy liver and predicts PHLF. This index could be used to discriminate those patients at higher risk of complications after hepatectomy.
Limitations: Patients with severely diseased liver were not included since they weren't considered candidates for hepatectomy. Other proposed methods of Gd-EOB-DTPA MRI signal intensity measurements weren't analysed for our cohort.
Ethics committee approval: Informed consent was obtained from each considered patient.
Funding: No funding was received for this work.

RPS 1001c-6 11:45

Improved display of hepatic arteries with multiple arterial phases using differential sub-sampling with cartesian ordering: comparison with single arterial phase and computed tomographic angiography

Z. Ye, Y. Wei, H. Tang, B. Song*; Chengdu/CN (948080771@qq.com)*

Purpose: To evaluate whether multiple arterial phases (MAP) using DISCO acquisition would improve the display of hepatic arteries when comparing to single arterial phase (SAP) and computed tomographic angiography (CTA).
Methods and materials: A total of 130 patients were enrolled. In part I of the study, 50 patients underwent MRI with MAP image and 50 patients with SAP images. In part II of the study, 30 patients underwent both MRI with MAP and CTA. Two readers independently assessed the hepatic arterial display on a four-point scale in terms of image quality and visualisation of hepatic arterial branches. The kappa test was used to evaluate the agreement between the two readers. Kruskal-Wallis test was used to compare the difference of arterial display and Bonferroni correction was used for further multiple comparisons of arteries.
Results: Moderate to excellent interobserver agreement was obtained for the arterial phase timing and degree of motion artifact (all kappa value > 0.65). For part I, the mean arterial display score obtained with MAP was higher than SAP imaging in the common hepatic artery (CHA, 3.68±0.47vs3.14±0.5), proper hepatic artery (PHA, 3.40±0.50vs2.88±0.44), left hepatic artery (LHA, 2.78±0.42vs2.40±0.57), right hepatic artery (RHA, 3.04±0.45vs2.72±0.54), left gastric artery (LGA, 3.10±0.42vs2.62±0.67), and gastroduodenal artery (GDA, 2.80±0.61vs2.42±0.76) (all p<0.01). For part II, MAP and CTA acquisition showed comparable image quality and arterial display score in CHA (3.50±0.51vs3.47±0.51, p=0.798), PHA (3.30±0.47vs3.30±0.53, p=0.935), LHA

(2.83±0.59vs3.03±0.41, p=0.122), RHA (3.10±0.48vs3.13±0.35, p=0.809), LGA (3.03±0.32vs3.00±0.37, p=0.710), and GDA(2.80±0.61vs2.80±0.48, p=0.659).
Conclusion: MAP using DISCO acquisition is superior than SAP and is comparable with CTA in the display of hepatic arteries.
Limitations: The diagnostic performance of these imaging methods in lesion detection and conspicuity was not evaluated.
Ethics committee approval: Local IRB approved this study and written informed consent were obtained.
Funding: No funding was received for this work.

CT texture analysis and liver regeneration: preliminary data on associating liver partition and portal vein ligation for staged hepatectomy (ALPPS) in liver malignancies
A. Borgheresi, A. Agostini, A. Mari, L. Ottaviani, D. Nicolini, M. Vivarelli, S. Maggi, A. Giovagnoni*; Ancona/IT (alessandra.borgheresi@gmail.com)*

Purpose: ALPPS is a two-stage liver resection: the splitting in-situ and portal vein ligation in the 1st step allow for rapid liver hypertrophy and completion of resection after 7-15 days (2nd step). Accurate patient selection is mandatory to avoid periprocedural liver failure.
The aim of this work is to evaluate the correlation of preoperative CT textural features with liver hypertrophy on virtual resection on CT after ALPPS 1st step.
Methods and materials: All ALPPS performed between January 2013 and January 2015 were retrospectively included. All patients were <70 yo with no-known cirrhosis or severe steatosis.
All CT were obtained with a 64-row CT (LighSpeed VCT, GE Healthcare) and performed at baseline and at 7th postoperative day after ALPPS 1st step with a tri-phasic CT protocol. The remnant liver volume (mL) was calculated with liver analysis on Syngo.via (Siemens Healthineers). The liver regeneration index (RI) was calculated as: $[(RLV_{7day}-RLV_{baseline})/RLV_{baseline}]\times100$. The texture analysis was performed on baseline CT with radiomics prototype (Syngo.via Frontier, Siemens Healthineers) on the segmented RLV at baseline. The correlation between RI>70% and texture features were calculated with univariate and multivariate analysis.
Results: 14 patients were included (10 F/4M) with a median age of 47 (25-75p: 41-62 yo) with a RI of 69% (25-75p: 52%-81%). Among texture parameters, gray level co-occurrence matrix (GLCM) contrast was an independent predictor of RI>70%.
Conclusion: The preliminary data on CT texture analysis in patients undergoing ALPPS show potential for prediction of liver hypertrophy after ALPPS 1st Step.
Limitations: This is a single-center study with a limited number of patients.
Ethics committee approval: n/a

Liver size estimation revisited: why we should replace distance measurements in midclavicular line by automated volumetry
T. J. Weikert, D. J. Winkel, H.-C. Breit, L. Noordtzij, T. Heye, D. Boll*; Basel/CH (thomas.weikert@usb.ch)*

Purpose: To investigate the inter-rater reliability and validity of distance measurements in the mid-clavicular line (MCL) that are frequently reported as an estimate of liver size in cross-sectional imaging on a large dataset.
Methods and materials: We identified 275 consecutive abdominal CT examinations acquired at our institution in December 2018. The corresponding reports contain measurements of liver height in MCL. Firstly, to investigate inter-rater reliability, MCL distance measurements were performed independently by three radiology residents on a subset of 55 exams (coronal plane). ICC and the corresponding 95% confidence interval (CI) were calculated (absolute-agreement, two-way-random-effects model). Secondly, to assess validity, we calculated the Pearson correlation coefficient for actual liver volumes and the MCL distance measurements extracted from the corresponding clinically-approved reports. Liver volumes of all 275 datasets were determined by an AI-based organ volumetry software (NeuronX, Siemens Healthineers), whose validity had been previously proven. All measurements were performed on the portal-venous phase series (slice-thickness: 5 mm).
Results: Mean liver volume was 1775 ml (95% CI: 1693 ml–1856 ml). ICC for the MCL measurements of the three raters was 0.56 (95% CI: 0.39-0.70). The Pearson correlation coefficient for distance measurements in MCL and liver volumes was 0.58 (p<0.001).
Conclusion: The poor to moderate inter-rater reliability of MCL distance measurements of the liver as well as its only moderate correlation with actual liver volumes suggest that we should stop using them as an estimate for liver size. Instead, we should promote the integration of reliable automated liver volumetric measurements into our workflows.
Limitations: Only three readers. Measurement of liver volumes only in the coronal plane.
Ethics committee approval: Written informed consent was waived by the local ethics committee.
Funding: No funding was received for this work.

Can CT textural analysis reliably differentiate peritoneal tuberculosis from peritoneal carcinomatosis?
N. Khan, M. Awais*; Karachi/PK (awais_aku@yahoo.com)*

Purpose: To determine whether quantitative CT texture parameters can reliably differentiate peritoneal tuberculosis (PT) from peritoneal carcinomatosis (PC).
Methods and materials: Patients with a biopsy confirmed diagnosis of PT or PC from 2010-2018 were enrolled. Textural analysis was performed using LIFEx software and 42 textural parameters were calculated. Student t-test was used to compare the individual textural parameters between the two groups. Logistic regression analysis was used to study the significant textural parameters for differentiating between study groups. Area under the receiver operating curve (ROC) for the significant textural parameters was calculated to determine the optimal cut-off values. A p-value of < 0.05 was considered statistically significant.
Results: 28 with PT and 36 with PC were included. Independent samples t-test showed statistically significant differences in multiple textural parameters in both groups. Logistic regression analysis using GLZLM HGZE parameter showed a maximum difference of -23.571 (p = .000) between the two groups. The logistic regression model was statistically significant 2 = 73.528 (p = 0.000). The model demonstrated 90.1% (Nagelkerke R2) of the variance and classified 97% of the cases correctly. (Sensitivity, specificity, positive predictive value, negative predictive values were 100%, 93.3%, 94.73%, and 100%, respectively). ROC curve was obtained from the data which showed an area under the curve of .965 (p = .000 and 95% CI= 0.913-1, respectively).
Conclusion: CTTA is reliable in differentiating between peritoneal tuberculosis and peritoneal carcinomatosis. The textural parameter GLZLM HGRE can be used as a model biomarker with 97% accuracy.
Limitations: The study was retrospective with a relatively small sample size.
Ethics committee approval: As a retrospective chart review, the study was approved by the institutional ethical review committee with a waiver of informed consent.
Funding: No funding was received for this work.

RPS 1001c-10 12:09
Assessment of peritoneal carcinomatosis using iodine overlays from spectral detector computed tomography
S. Lennartz, D. Zopfs, N. Abdullayev, M. Le Blanc, K. Slebocki, A. Wagner, C. Wybranski, N. Grosse Hokamp, T. Persigehl*; Cologne/DE (simon.lennartz@uk-koeln.de)*

Purpose: Peritoneal carcinomatosis (PC) is a prognostically relevant metastatic condition which may be difficult to differentiate from postoperative alterations. The study aim was to determine whether PC could be distinguished more accurately from such benign peritoneal alterations (BPA) with a combination of spectral detector CT-derived conventional and color-coded iodine overlay images (CI/IO) as compared to CI only.
Methods and materials: 30 patients with PC and 30 with BPA with portal-venous phase abdominal SDCT were retrospectively included. Four radiologists determined presence/absence of PC for each patient and assessed lesion conspicuity, diagnostic certainty, and image quality using 5-point Likert scales. Subjective assessment was conducted in two sessions comprising solely CI and CI/IO between which a latency of 6 weeks was set. Iodine concentration and

attenuation of 30 PC/BPA lesions each were determined ROI-based to analyse quantitative lesion differentiation.
Results: Overall specificity at visual assessment was significantly higher when using CI/IO as compared to CI only (0.86 vs. 0.78;p<0.05), while sensitivity was comparable (0.79 vs. 0.81; p=1.0). In postsurgical patients, the overall increase in specificity was highest (0.91 vs. 0.80, p<0.05). Lesion conspicuity was rated higher in CI/IO (4(3-5),CI:3(3-4);p≤0.05), while diagnostic certainty was comparable (both 4(3-5);p=0.5). CI/IO received the highest rating for image quality and assessability of relevant anatomical structures (5(4-5). Quantitatively, iodine measurements facilitated differentiation between PC and BPA (AUC_{Iodine}=0.95, AUC_{HU}=0.90).
Conclusion: For visual differentiation between PC and BPA, a combination of IO/CI improves specificity at comparable sensitivity, particularly when assessing patients with a history of abdominal surgery. Iodine may facilitate quantitative lesion differentiation compared to HU, however, this should be validated further.
Limitations: The sample size was limited and the study design retrospective.
Ethics committee approval: Waived due to retrospective study design.

Analysis of non-enhanced CT characteristics in patients with ultra-long-term continuous ambulatory peritoneal dialysis
J. Guan, X. Hu, F. Zhang, Y. Peng*; Guangzhou/CN*

Purpose: To investigate the characteristics of patients with ultra-long-term continuous ambulatory peritoneal dialysis (CAPD) on non-enhanced CT.
Methods and materials: 23 patients with a history of more than 10 years of CAPD (Group A) and 109 patients who failed to receive 5 years of CAPD and turned to hemodialysis (Group B) were retrospectively enrolled. General information (gender, age, primary disease) and CT manifestations, including parietal peritoneum thickening, degree of parietal peritoneum calcification (mild: <5 foci of calcifications; severe: ≥15 foci of calcifications), calcification of mesostenium mesenteric margin/free margin, calcification of mesenteric region, and abdominal visceral arterial calcification) of both groups were compared. CT images in group A were collected at the 10th year of CAPD, and in group B were collected 3 months before stopping CAPD.
Results: There was no significant difference in general information between the two groups (P>0.05). The incidence of following CT findings had statistically significant difference between group A and B (P<0.01): (1) extensive thickening of parietal peritoneum (21.7% vs. 78.9%); (2) degree of parietal peritoneum calcification (mild: 30.4% vs. 9.2%; severe: 8.7% vs. 60.6%); (3) calcification of mesenteric region (4.3% vs. 32.1%); (4) calcification of mesostenium free margin (13.0% vs. 49.5%). However, there was no significant difference in calcification of mesostenium mesenteric margin (30.4% vs. 40.3%) or abdominal visceral arterial calcification (61.1% vs. 56.9%) (P>0.05).
Conclusion: Patients with ultra-long-term CAPD usually showed slight parietal peritoneum thickening to mild parietal peritoneum calcification on non-enhanced CT. Adverse factors for persistence of long-term CAPD can be monitored by non-enhanced CT.
Limitations: No autopsy was performed in this study and there was no evidence indicating the mechanism of stopping CAPD.
Ethics committee approval: n/a

RPS 1001c-12 12:21
Distinguishing benign from malignant focal liver lesions (FLL) using the apparent diffusion coefficient (ADC): impact of post-processing on the diagnostic accuracy?
M. Dietzel[1], S. Ellmann[1], M. Saake[1], M. Hammon[1], M. Uder[1], R. Janka[1], P. A. T. Baltzer[2]; *[1]Erlangen/DE, [2]Vienna/AT*

Purpose: We investigated whether there is an impact of post-processing on ADC values of FLL.
Methods and materials: 51 consecutive cancer patients receiving standardised multiparametric liver-MRI for suspected FLL were prospectively recruited (1.5T: T2, dynamic T1 +/- Gd-EOB-DTPA; DWI: breath-hold EPI: TR/TE: 2100/62 ms, b0/b800).
Rescan-reliability of ADC values was addressed by double measurement of diffusion-weighted sequences giving ADC_1/ADC_2. Histological verification or imaging follow-up >24 months served as reference-standard (RS).
FLL were identified on dynamic T1 scans by two experienced blinded readers in consensus. Every FLL was assessed by one standardised region-of-interest (ROI) drawn into the most suspicious FLL-enhancement (automated ROI-transfer between sequences). Two ADC-metrics were investigated:
A) ADC_a (standard ADC-map by the proprietary scanner-software)
B) ADC_b (established open-source method)
Consequently four ADC-values were available to characterize each FLL (ADC_{1a}, …, ADC_{2b}). These four ADC-values were stratified by the RS (benign/malignant-FLL) and compared intraindividually (Friedman-test, Bland-Altmann-Plot, Area-under-the-ROC-curve/AUC-comparison; alpha=5%).
Results: 87 FLL in non-cirrhotic livers were diagnosed (42/45 malignant/benign, mean-age: 64years). For neither ADC_a (P=0.28) nor ADC_b (P=0.33) was a systematic or proportional bias observed comparing the initial and repeated scan. In malignant-FLL both for ADC_1 and for ADC_2 (median-difference: 0.60 and $0.57*10^{-3}$ mm^2/s) significant systematic (both P<0.001) and proportional bias (P<0.05) was observed if ADC_a was used instead of ADC_b (P<0.001). This bias was not observed for benign-FLL (P=0.88). Results translated to different intraindividual diagnostic performance between the four ADC-values. The biggest differences was observed between ADC_{1a} (AUC=0.79) and ADC_{1b} (AUC=0.71;P=0.004).
Conclusion: We identified a significant impact of post-processing methods on the ADC values of FLL. The results led to a different diagnostic accuracy depending on the post-processing method.
Limitations: Results should be validated in prospective trials with special focus on more ADC metrics and on longitudinal ADC comparison.

3D structural parameters predict future total hip replacement better than current 2D radiographic standards: an AGES-Reykjavik study
T. Turmezei[1], G. M. Treece[1], A. H. Gee[1], S. Sigurjonsson[2], H. M. M. Jónsson[2], T. Aspelund[2], V. Gudnason[3], K. E. S. Poole[1]; *[1]Cambridge/UK, [2]Reykjavik/IS, [3]Kopavogur/IS (tom@turmezei.com)*

Purpose: To compare analysis of hip CT with 3D joint space mapping (JSM) against radiographic criteria in a predictive model for future total hip replacement (THR).
Methods and materials: We undertook a nested case-control study within the AGES-Reykjavik cohort of healthy older adults, all with a baseline 1 mm slice thickness hip CT. After 2:1 age and gender matching then exclusions, there were 80 cases with THR within 5 years versus 187 controls, mean age 74.4±4.9 years. The Kellgren and Lawrence grade (KLG) and minimum 2D (min2D) joint space width (JSW) were assessed at each hip. After JSM delivered 3D JSW maps for each hip, statistical shape modelling determined 3D joint shape modes (SM). Statistical parametric mapping (SPM) revealed significantly different regions of 3D JSW between groups. Receiver operating characteristics with area-under-the-curve (AUC) values were calculated for hip pain (HP), KLG, min2D, minimum 3D JSW from the SPM region of interest (ROI) divided by mean JSW (min3D), and SM.
Results: SPM revealed a region superiorly where JSW was significantly dependent on THR, narrower in cases by up to 1 mm (p<0.05); this was the ROI used in the predictive model. Hip pain was the poorest predictor (AUC=0.69).

KLG (0.72) and min2D (0.73) were outperformed by SM (0.74) and min3D (0.79). AUC increased with a combination of min3D and SM (0.81) and maximal when KLG was also included (0.86).
Conclusion: JSM results in better prediction of THR than 2D radiographic standards in healthy older individuals. These findings support the exploration of JSM application in clinical trials with the potential for stratification, prediction, and monitoring of osteoarthritis.

CT assessment of muscle mass and quality for hip surgery: a feasibility study
S. Zannoni, D. Albano, M. Jannone, L. Pedone, C. Messina, L. M. M. Sconfienza*; Milan/IT (stefaniazannoni@hotmail.com)*

Purpose: The segmentation of psoas muscles at L3 is used to estimate sarcopenia status. However, this parameter is not useful when CT is performed in other districts. Our aim was to correlate the estimation of muscle mass around the hip with that obtained using psoas segmentation at L3 on CT.
Methods and materials: A radiologist reviewed abdominal CTs performed on 50 consecutive patients (29 males; mean age: 69.6±11y). Regions of interest were drawn to assess cross-sectional areas (CSA) and attenuation of psoas muscles at the L3 level, which was considered as the standard. These values were correlated with CSA and attenuation of the iliopsoas, rectus femoris, sartorius, and tensor fascia latae at the hip, separately on each side. After applying the Bonferroni correction for multiple comparisons, statistical significance was set as $P<0.002$.
Results: We found a significant correlation between attenuation values of both psoae at L3 and those of all the other hip muscles ($P<0.001$, $r>0.491$). A significant correlation was observed between CSA of the right psoas and the other muscles ($P\leq0.001$, $r>0.459$), except for the tensor fascia latae at the lesser trochanter ($P=0.004$, $r=0.401$). We observed a significant correlation between CSA of the left psoas at L3 and that of the psoas and rectus femoris at the hip ($P=0.001$, $r=0.456$), with no significant correlation with tensor fascia latae and sartorius ($P\geq0.002$, $r\leq0.430$).
Conclusion: CT segmentation of hip muscles is highly correlated to that performed on the psoas at the L3 level, except for tensor fascia latae. These measurements could be used to evaluate sarcopenia in patients undergoing hip surgery.
Limitations: A small population.

Does the use of magnetic resonance imaging in occult and suspected metastatic pathological neck of femur fractures affect the choice of surgical intervention?
B. Budair, M. J. H. Al-Tibi, T. Boutefnouchet*; Birmingham/UK (m.al-tibi@nhs.net)*

Purpose: Magnetic resonance imaging is often employed as the diagnostic modality of choice in occult and suspected pathological femoral neck fractures. The research question is: does the use of an MRI scan in occult and suspected metastatic pathological neck of femur fractures affect the choice of surgical intervention?
Methods and materials: A retrospective observational analysis was conducted of 104 consecutive patients who had an MRI scan of the hip from July 2009-August 2011 among a total population of 894 hip fractures managed in our institution. The findings of plain radiography, which preceded MRI, were recorded. The data was extracted from the medical records and an online image archiving system. Statistical analysis software SAS/STAT® SAS Institute Inc. USA© was used to conduct data collation and analyses.
Results: From a total of 894 femoral neck fractures treated in our institution, 100 patients had an MRI scan preoperatively for either an occult fracture or suspected fracture secondary to metastatic disease. MRIs confirmed the presence of 13 simple fractures. A total of 14 patients had pathological features suggestive of metastasis, of which 12 were clearly visible on plain radiographs. The surgical plan did not change after MRI for any of these pathological fractures.
Conclusion: Results of this study demonstrate that an MRI scan had an impact on treatment selection only when a simple but radiographically occult fracture is suspected, but not in the context of suspected metastatic pathological fractures.
Limitations: n/a

Potential of susceptibility-weighted imaging for the reliable assessment of angle measurements reflecting hip morphology
S. M. Böker, L. Adams, U. L. Fahlenkamp, B. Hamm, M. R. Makowski*; Berlin/DE*

Purpose: To evaluate the potential of susceptibility-weighted magnetic resonance imaging (SWMR) for angle measurements reflecting hip morphology, using radiographs as a reference standard.
Methods and materials: 40 patients were examined (04/2014-01/2019) with standard MR-sequences, coronal SWMR, and radiographs in anteroposterior pelvic view. Coronal maximum intensity projection (MIP) images of both hips were reconstructed on SWMR and T1-weighted images. Sharp's angle, Tönnis angle, and the lateral centre-edge angle of Wiberg were measured on coronal SWMR, T1-weighted MIP-images, and radiographs. Measurements were compared by linear regression analysis and Blant-Altmann plots, using radiographs as a reference standard. Additionally, a ratio between the signal intensity of muscles and bone on SWMR and T1w MIP-images was calculated and compared between sequences.
Results: 40 patients were examined. 69 hip joints could be evaluated. Sharp's angle ($y=1.04x+1.77$, $R^2=0.80$), Tönnis angle ($y=0.86x+1.60$, $R^2=0.86$), and the lateral centre-edge angle of Wiberg ($y=0.94x+2.49$, $R^2=0.88$) showed a strong correlation between SWMR MIP-images and radiographs. The correlation between T1-weighted MIP-images and radiographs was moderate for Sharp's angle ($y=0.69x+14.54$, $R^2=0.37$) and the lateral centre-edge angle of Wiberg ($y=0.79x+3.18$, $R^2=0.40$). Tönnis angle could not be measured reliably on T1-weighted MIP-images. The ratio between the intensity of muscles and the femoral head was significantly higher on SWMR than on T1-weigted images ($p<0.001$).
Conclusion: Coronal SWMR MIP-images enable the reliable measurement of Sharp's angle, Tönnis angle, and the lateral centre-edge angle of Wiberg compared to radiographs with higher accuracy compared to T1w MIP-images.
Limitations: Metal implants cause strong susceptibility artefacts, especially on SWMR, with the consequence being that hips with implants could not be evaluated.
Ethics committee approval: The institutional review board approved this prospective study. Written informed consent was obtained from all subjects.
Funding: No funding was received for this work.

Equivalence between MRI-based synthetic CT and conventional CT in the morphological assessment of the femoroacetabular joint

M. C. Florkow, K. Willemsen, F. Zijlstra, C. Wismans, B. van der Wal, H. Weinans, M. van Stralen, R. Sakkers, P. R. Seevinck; *Utrecht/NL (p.seevinck@umcutrecht.nl)*

Purpose: In paediatric orthopaedics, the use of potentially harmful CT could be avoided by generating synthetic CT (sCT) from radiation-free MR images. Although widely investigated for radiotherapy, sCTs have not been evaluated for orthopaedics. In this study, we compared clinically relevant measurements for hip dysplasia as performed on CTs and sCTs.
Methods and materials: 30 male prostate cancer patients without known orthopaedic conditions were included and scanned with MR and CT for radiotherapy treatment planning. Morphological assessment of the femoroacetabular joint was performed on CT and sCT reconstructions obtained from a BoneMRI prototype (BoneMRI v1.1-alpha, MRIguidance BV, Utrecht, the Netherlands). Clinical measurements for evaluation included centre-edge angle (CEA), sharp angle (SA), extrusion index (EI), acetabular index (AcetIncl), and femoral centre-to-midline distance (FCMD). Equivalence was tested for each measurement using a paired two-one sided test. The equivalency margins were defined using literature values of the intraobserver limit of agreement measured on x-ray. CT and sCT were considered equivalent for confidence intervals of the mean difference between the CT and the sCT within ±4.2° for CEA, ±5.6° for AcetIncl, ±2.9° for SA, ±6.1% for EI, and ±4.5 mm for FCMD.
Results: All measurements were proven equivalent between the CT and sCT. Bonferonni-corrected confidence intervals at 95% were -2.0° and 0.9° for the CEA, 0.3° and 1.4° for SA, -2.4% and 1.0% for EI, -1.5° and 0.9° for the AcetIncl, and 0 mm and 0.6 mm for FCMD. No patient presented a substantial difference for all measurements.
Conclusion: This study demonstrates that sCT is equivalent with CT for femoroacetabular morphological assessment in adults.
Limitations: Future studies are necessary to confirm these findings in paediatric patients.
Ethics committee approval: Medical-ethical approval was obtained.
Funding: Dutch Scientific Organisation NWO-TTW-15479.

Improved performance of orthopaedic metal artefact reduction in virtual mono-energetic spectral images compared to conventional poly-energetic images: a total hip arthroplasty phantom study

V. Stuivenberg[1], R. H. H. Wellenberg[2], L. van de Riet[1], I. M. Nijholt[2], J. van Osch[2], R. W. van Hamersvelt[1], P. A. de Jong[1], T. Leiner[1], M. F. Boomsma[2]; *[1]Utrecht/NL, [2]Zwolle/NL (m.f.boomsma@gmail.com)*

Purpose: To investigate whether the use of metal artefact reduction for orthopaedic implants (O-MAR) resulted in more effective metal artefact reduction in virtual mono-energetic images (VMI) of a total hip arthroplasty (THA) phantom when compared to the reduction achieved with O-MAR in conventional poly-energetic images using poly-energetic images without O-MAR as reference.
Methods and materials: A THA phantom containing 18 hydroxyapatite calcium carbonate pellets, which represented the same modular bone density, was scanned on a dual-layer spectral detector CT scanner with or without unilateral prosthesis. To quantify the effect of metal artefact reduction, the following image quality parameters were assessed for each pellet: CT values (Hounsfield units), noise (measured as standard deviation), signal-to-noise ratio (SNR), and contrast-to-noise ratio (CNR). In a previous study, we found CT numbers are similar in 74keV VMI and 140kVp poly-energetic images, whereas 130keV showed optimal CNRs in the CT imaging of metal hip prostheses. Therefore, conventional poly-energetic 140kVp images reconstructed with iterative model-based reconstruction (IMR) and VMI extracted at 74keV and 130keV were all analysed with and without O-MAR.
Results: The use of O-MAR resulted in a reduction of metal artefacts in 140kVp poly-energetic images and 74 130keV mono-energetic images. When using 140kVp poly-energetic images without O-MAR as a reference, metal artefacts were most effectively reduced in 130keV mono-energetic images reconstructed with O-MAR.
Conclusion: Results of this quantitative THA phantom study showed that 130keV VMI combined with O-MAR resulted in a more effective metal artefact reduction compared to 74keV VMI and conventional poly-energetic images combined with O-MAR. The clinical value of our findings should be further investigated in patients with THA.
Limitations: The phantom quantification.

Iliopsoas impingement after THR: our purpose of a diagnostic and therapeutic algorithm

A. Antón Jiménez[1], M. de Albert de Delas-Vigo[1], J. M. M. Escudero Fernández[1], D. Moreno Martínez[2], A. Gimeno[1], M. T. Veintemillas[1], L. Casas[1], C. Torrents[1], R. Dominguez[1]; *[1]Barcelona/ES, [2]Cornella de Llobregat/ES (alba.antonj@gmail.com)*

Purpose: To review iliopsoas impingement after a total hip replacement (THR) and the usefulness of US-guided infiltration as a diagnostic technique, to assess the effectiveness of the different treatment modalities for this condition, and to establish a relation between CT position parameters of the prosthesis and clinical response.
Methods and materials: This retrospective study from 2017-2019 included 35 patients (20 female; mean age 66.7 years; mean BWI 26.6) who underwent total hip replacement (60% right hip; 74.3% posterolateral surgical approach) at our institution. The mean time of pain appearance after THR was 11.1 months.
All patients had a positive test to anaesthesia and glucocorticoid US-guided infiltration of the iliopsoas tendon sheath. When pain recurrence appeared, endoscopic tenotomy was performed.
Inclination, corrected anteversion, medialisation, and axial and sagittal acetabular overhanging of the prothesis were measured on CT.
Therapeutic efficacy was evaluated by VAS and Harris score pre and post-treatment.
Results: 67% of the patients had a delayed pain recurrence after infiltration, which did not correlate with prothesis position CT parameters.
From the patients who underwent endoscopic tenotomy (n=13), the majority (n=8) had a total or partial positive clinical outcome.
High degrees of horizontal and vertical overhanging (>10 mm) correlated significantly with a negative response to treatment ($p<0.05$). So, CT parameters can help in clinical management decision (tenotomy vs acetabular change).
Conclusion: A US-guided anaesthesia and glucocorticoid infiltration test is a useful tool in iliopsoas impingement diagnosis and conservative treatment.
Endoscopic tenotomy will produce remission of pain in most of the patients. Nevertheless, an acetabular cup overhanging of >10 mm is a negative prognostic factor to surgical treatment response.

Integrity of the pectineal ligament in MRI correlates with radiographic superior pubic ramus fracture displacement

A. Klengel, H. Steinke, P. Pieroh, A. Höch, T. Denecke, C. Josten, G. Osterhoff; *Leipzig/DE (alexis.klengel@posteo.de)*

Purpose: Estimating the stability of pelvic lateral compression fractures solely by static radiographs can be difficult. The role of anterior pelvic soft tissues as potential secondary stabilisers of the pelvic ring has hardly been investigated. The purpose of this study was to assess the integrity of the pectineal ligament, a strong ligament along the pectineal line, and correlate it with the initial radiographic appearance of the pubic ramus fracture.

Methods and materials: The eligibility criteria included a pelvic lateral compression fracture with superior pubic ramus involvement, available post-traumatic radiographs (pelvis ap, inlet, and outlet), and MRI of the pelvis with fat-suppressed, fluid-sensitive coronal images within 6 weeks after the trauma. In a retrospective review, the degree of MR-morphologic alterations of the pectineal ligament was described (grade 0=intact, grade 3=rupture) and correlated to radiographic superior pubic ramus fracture displacement.
Results: 33 superior pubic ramus fractures in 31 patients were analysed. In the majority of fractures (72.7 %), associated MR-morphologic alterations of the pectineal ligament were present. Radiographic displacement and MRI grading showed a strong positive correlation (Spearman-Rho: 0.783, p<0.001). The sensitivity and specificity for a radiographic displacement of >3 mm on plain radiographs to detect a structural ligament lesion on MRI (grade 2 and higher) were 73% and 100% (Fisher's exact: p<0.001).
Conclusion: Radiographic displacement of superior pubic ramus fractures >3 mm is a strong indicator for a structural lesion of the pectineal ligament, which should be radiologically reported. Future studies should investigate the biomechanical importance of this ligament for pelvic ring stability.
Limitations: No surgical or histologic correlation. Heterogeneous MRI sequence protocols.
Ethics committee approval: Approval of the local institutional ethics committee was obtained.
Funding: No funding was received for this work.

RPS 1010b-9 12:03

Quantification of metal artefact reduction of various MRI techniques in 10 common total hip arthroplasty implants: when less is more!

S. Shah[1], D. Dalili[1], J. Spence[1], S. Hill[1], H. Connolly[1], S. A. Jengojan[2], J. Fritz[3], G. Charles-Edwards[1], A. Isaac[1]; [1]London/UK, [2]Vienna/AT, [3]Baltimore, MD/US (Dr.amandaisaac@googlemail.com)

Purpose: To quantify the metal artefact reduction capabilities of various metal artefact reduction MRI pulse sequences in 10 commonly used total hip arthroplasty implants (THAI).
Methods and materials: 10 different THAI systems were imaged on a commercially available 1.5T MRI system in a water-based phantom. T1-weighted MRI was acquired without and with the following metal artefact reduction techniques (MARS): high receiver bandwidth, high transmit bandwidth, view-angle-titling (VAT) at 50% and 100%, and slice-encoded-metal-artefact-correction (SEMAC) with 6, 10, and 14 encoding steps. The size of signal voids and pile-ups were assessed by fitting Rician and Gaussian distributions around each implant. Line profiles implant stems were used to assess signal pile-up at bone-metal interfaces.
Results: MARS improved the signal void in 7/10 THAI, with SEMAC-14 outperforming all other methods and reducing the signal void from 6% to 22%. Signal pile-up was reduced in all implants with SEMAC-14 and VAT both performing the best, reducing pile-up from 28% to 75%. At the bone-metal interface of all 7 hip implants which had femoral stems, SEMAC reduced signal pile-up from 11% to 86%.
Conclusion: SEMAC reduces implant-induced signal void up to 22%, depending on the implant design and metallurgy. While all MARS methods reduce signal pile-up, SEMAC and VAT perform best. SEMAC, however, incurs a significant time-penalty, which may be problematic in certain scenarios. SEMAC significantly reduced signal pile-up at the bone-metal interface, improving the ability of MRI to diagnose periprosthetic complications and abnormalities including tumour recurrence, collections, fractures, muscle integrity, and AI-guided preoperative revision surgery planning.
Limitations: In vivo with only 10 implants.
Ethics committee approval: A quality assurance study.
Funding: No funding was received for this work.

Validation of a physical examination test for ischiofemoral impingement with correlation of MRI findings

Z. M. Ozdemir[1], T. Yıldırım[1], L. Karaca[1], A. Sağir Kahraman[1], Ü. Aydingöz[2]; [1]Malatya/TR, [2]Ankara/TR (zynpmaras@yahoo.com)

Purpose: To validate a physical examination test for ischiofemoral (IF) impingement and correlate MRI findings.
Methods and materials: The population of this prospective study comprised of a symptomatic group of 24 women with hip pain, who had positive MRI findings (IF space narrowing and oedema), and an age-matched group of 27 asymptomatic women. Each group underwent a physical examination test that entailed hip adduction, external rotation, extension, and knee flexion, both in the recumbent and upright standing positions, within 7 days of an MRI. VAS scores were noted before and after the test. A single radiologist quantitatively and qualitatively evaluated the IF and quadratus femoris (QF) spaces on 1.5T MR images.
Results: Mean ages were 56.0 (34-76) and 55.2 (34-79) years in symptomatic and asymptomatic groups, respectively (p>0.05). Likewise, BMIs were not statistically significantly different between the groups. IF and QF spaces were significantly narrower (p<0.001), ischial angles wider (p<0.001, right; p=0.002, left), and soft tissue oedema at the IF space was more common (p<0.001) in the symptomatic group, which also had higher VAS scores (p<0.001) that increased significantly during both the recumbent (p<0.001 for both sides) and upright (p=0.003, right; p<0.001, left) parts of the physical examination test.
Conclusion: A physical examination test that entails hip adduction, external rotation, extension, and knee flexion significantly increases symptoms of IF impingement that are correlated on MRI.
Limitations: A small number of patients. A single radiologist performing MRI evaluation.
Ethics committee approval: We obtained institutional review board approval and informed consent.

Glycosaminoglycan chemical exchange saturation transfer imaging of the talocrural joint in patients with osteochondral lesions and healthy volunteers

M. Boschheidgen[1], M. Frenken[1], A. Müller-Lutz[1], L. Kasprowski[1], G. Antoch[1], C. Schleich[1], S. Nebelung[2], D. B. Abrar[1]; [1]Düsseldorf/DE, [2]Aachen/DE (Matthias.Boschheidgen@med.uni-duesseldorf.de)

Purpose: To optimise a glycosaminoglycan chemical exchange saturation transfer (gagCEST) protocol for imaging of glycosaminoglycans (GAG) at 3T and to compare gagCEST values between patients with osteochondral lesions and healthy volunteers (HV).
Methods and materials: We used Bloch-McConnel simulations for optimising the gagCEST protocol. The following T1 and T2 relaxation times of cartilage at 3T were used: T1=1.2s and T2=0.039s. 11 HV (age 24±5 years) and 4 patients (age 32±9 years) with osteochondral lesions were examined with the optimised gagCEST protocol. In addition, T1 and T2 values were determined to evaluate if the relaxation times used in the simulation were accurate. Sequence parameters of the gagCEST sequence were: FOV=160x160 mm², slice thickness=5 mm, and TE/TR=3.5ms/7.2ms. 25 CEST images with a frequency offset between -3 ppm and 3 ppm, and one S0 image, were recorded.
Results: The optimisation with the Bloch-McConnel simulations showed an ideal B1 amplitude of 0.8 µT and a pulse and interpulse duration of 300 ms. We found a mean T1 time of 0.88±0.13s and a mean T2 time of 0.033±0.005s. These values significantly differed from the values used in the simulation. Nevertheless, further simulations revealed the same optimal pulse sequence parameters for the CEST sequence. HVs showed a significant higher gagCEST effect compared to patients (HV: MTRasym=(1.40±0.71)%; patients: MTRasym=(0.05±0.28)%, p<0.01).
Conclusion: The proposed gagCEST protocol showed good performance and could distinguish between HV and patients with osteochondral lesions.

RPS 1010b-12 12:21
Patients with pincer FAI due to protrusio acetabuli or acetabular retroversion have intra- and extra-articular anterior subspine hip impingement on a 3D-CT-basedimpingement simulation
T. Lerch, F. Schmaranzer, I. Todorski, M. Hanke, C. Leibold, S. Steppacher, K. Siebenrock, M. Tannast*; Berne/CH (till.lerch@insel.ch)*

Purpose: Diagnosis and surgical treatment of hips with different types of pincer-FAI, such as protrusio acetabuli and acetabular retroversion, remains controversial as actual 3D acetabular coverage and location of impingement cannot be studied using standard 2D imaging. It remains unclear if pincer hips exhibit intra- or extra-articular FAI. Therefore, the purposes are to determine the impingement-free range of motion using osseous models based on 3D-CT scans and to determine the osseous intra-and extra-articular 3D impingement zones located using a 3D impingement simulation.
Methods and materials: This is a retrospective, comparative, controlled study involving 70 hips in 50 patients. 24 patients (44 hips) had symptomatic pincer-type FAI and 26 patients (26 hips) had normal hips. Surface models based on 3D-CT scans were reconstructed and compared for hips with acetabular retroversion (30 hips), protrusio acetabuli (14 hips), and normal asymptomatic hips (26 hips). Using CT-based 3D-models, impingement-free ROM and location of impingement were determined for all hips using validated 3D-collision detection software.
Results: The mean flexion was significantly ($p<0.001$) decreased in hips with protrusio acetabuli (104±9°) and acetabular retroversion (116±6°) compared to normal hips (125±13°). The mean internal rotation (IR) in 90° of flexion was significantly ($p<0.001$) decreased in hips with protrusio acetabuli (14±11°) compared to normal hips (32±9°).
The prevalence of extra-articular subspine impingement was significantly ($p<0.001$) higher (87%) in hips with acetabular retroversion compared to hips with protrusio acetabuli (14%) and normal hips (0%). The location of anterior acetabular impingement differed significantly ($p<0.001$) between hips with protrusio acetabuli and normal hips.
Conclusion: Extra-articular subspine impingement was detected in hips with acetabular retroversion. Osseous ROM and location of impingement differs between hips with protrusio acetabuli, acetabular retroversion, and normal hips. Patient-specific analysis of the location of impingement using 3D-CT could improve diagnosis and planning of treatment.
Limitations: A retrospective, single-centre study.

Radcount: an integrated system to represent essentials of the radiology examination and reporting processes
K. Nairz, J. Schuhmacher, P. Zingg, M. Sladek, M. Abu Baker, J. T. Heverhagen*; Berne/CH*

Purpose: Occupational processes can only run smoothly if all participants are getting relevant and essential information accurately, clearly, and without time lag. Current table-style process information from a single system (RIS) does not fulfil those criteria and presumably leads to inefficiencies.
Methods and materials: Patient-, process-, and time-information was obtained from the RIS relational database (GE, Oracle) and from the enterprise resource planning program (SAP) by ETL-programs. Time-stamps were directly extracted from DICOM images in a modality-independent manner. Process progression was calculated from those time points. A machine-learning tool (Prophet) was implemented to forecast daily patient numbers and increase the project ability. Data was visualised in a browser via an open-source client-server application or via a business intelligence software (Qliksense).
Results: RadCount prepares key numbers like throughput times, equipment occupancy, and patient lists in a visual and self-explaining manner. Predictive analytics technology was used to forecast the expected workload. Data was presented live and team-specifically, and thus facilitated the planning of radiological examination and diagnostic processes. Moreover, by combining data from different sources, typical interface problems were being alerted and hence could be prevented.
Conclusion: Radcount eliminated the problem of poor information transfer about VRE- and MRSA-infections at the interfaces. It also provided the data needed to devise an intelligent MR scheduling based on overbooking to manage no-shows. Its predictive functionality allows for resource management. Our solution is designed to be platform-independent and may be applicable to other platforms or high-throughput clinical processes. Thus, the tool proves oneself to enhance efficiency and safety.
Limitations: Radcount is expandable by further resolving the time sequence of the radiology processes.
Ethics committee approval: IRB exemption was obtained.
Funding: No funding was received for this work.

IILS: an intelligent imaging layout system to realise automatic imaging-report standardisation and to optimise intra-interdisciplinary clinical workflow
Y. Wang*; Nanjing/CN (wangzhang227@163.com)*

Purpose: To achieve imaging report standardisation and improve the quality and efficiency of the intra-interdisciplinary clinical workflow.
Methods and materials: We created a lung IILS based on deep learning for imaging report standardisation and workflow optimisation for the identification of nodules. Our IILS utilised a deep learning plus adaptive auto-layout tool, which trained and tested a neural network with imaging data from all the main CT manufacturers from 11,205 patients. Model performance was evaluated by the receiver operating characteristic curve (ROC) and calculating the corresponding area under the curve (AUC).
Results: Our IILS was clinically applicable due to the consistency with nodules detected by IILS, with its highest consistency of 0.94 and an AUC of 90.6% for malignant pulmonary nodules versus benign nodules with a sensitivity of 76.5% and specificity of 89.1%. Applying this IILS to a dataset of chest CT images, we demonstrated performance comparable to that of human experts in providing a better layout and aiding in diagnosis in 100% valid images and nodule display. The IILS was superior to the traditional manual system in performance, such as reducing the number of clicks from 14.45 ± 0.38 to 2, time consumed from 16.87 ± 0.38 sec to 6.92 ± 0.10 sec, number of invalid images from 7.06 ± 0.24 to 0, and missing lung nodules from 46.8% to 0%.
Conclusion: This IILS might achieve imaging report standardisation and improve the clinical workflow, therefore opening a new window for the clinical application of artificial intelligence.
Limitations: n/a
Ethics committee approval: This experiment was approved by the drum tower hospital ethics committee and written informed consent was obtained.

Machine learning-based assistance to context-sensitively suggest ASPECT score during the reporting of neuroradiological emergencies

C. G. Cho[1], A. Junge[1], B. Kämpgen[2], V. Saase[1], A. Ulfert[1], E. L. Gonzalez[1], T. Ganslandt[1], H. Wenz[1], M. E. Maros[1]; [1]Mannheim/DE, [2]Rimpar/DE
(matt.maros@gmail.com)

Purpose: The Alberta stroke programme early CT score (APECTS) is a 10-point quantitative CT scan score that predicts the functional outcome of stroke patients and serves as a surrogate when selecting patients for neurointerventional procedures. Although ASPECTS is considered a biomarker, it is frequently missing from reports. Here, we investigated whether machine learning (ML)-based approaches can be utilised to assist radiologists in providing ASPECTS, hence improving report quality.
Methods and materials: We generated a stratified random sample (age, gender, and year) of CT cases (n=206) with a suspected ischaemic stroke or haemorrhage between 2015-2019. Conventional free-text reports were retrieved from local RIS. Two blinded readers (R1,exp.:3yrs; R2,exp.:7yrs) assessed the clinical question, referring department, the findings, and impressions of the reports, whether (pc-)ASPECTS had been or should have been provided (necessary:154[74.7%] vs. -not: 52[25.3%]). Further, the presence of ischaemia, haemorrhage, tumour, incidental findings, and procedures including CT-angiography/perfusion or previous imaging were recorded. These key features were also automatically detected using a RadLex-based proprietary information extraction software (www.empolis.com). Next, tree-based and elastic net ML-algorithms were fitted on training/validation/test sets to learn rules required for ASPECTS reporting.
Results: Cohen's kappa was 0.635 for "APECTS necessary" (p<0.0001) corresponding to 86.4% agreement between the readers. Among the investigated ML-models, the 10-fold cross-validated elastic net showed the best independet test set (n=20) performance of 95% accuracy (95%CI:75.1-99.87%,P[Acc>NIR]=0.024), 100% sensitivity, 93% specificity, 83.3% PPV, and 100% NPV on this imbalanced classification task.
Conclusion: ML-based assistance to context-sensitively suggest ASPECTS during the reporting of neuroradiological emergencies is feasible. It produces high-quality reports, which are better suited for cohort identification and downstream analyses.
Limitations: Retrospective single-centre data, which was counteracted by 10-fold CV.
Ethics committee approval: Nr.:2017-825R-MA.

RANO check: a deep learning language model-based automatic response labelling using solely the findings sections of conventional free-text reports of brain tumours

M. E. Maros[1], A. Junge[1], V. Saase[1], C. G. Cho[1], B. Kämpgen[2], C. Groden[1], T. Ganslandt[1], H. Wenz[1]; [1]Mannheim/DE, [2]Rimpar/DE
(matt.maros@gmail.com)

Purpose: The response assessment in neuro-oncology (RANO) criteria for glioblastoma (GBM) and brain metastases are used for the standard response assessment of brain tumours in clinical trials. Human readers show large variations compared to deep learning (DL)-based segmentation tools. But the IT-infrastructure for such tools is scarcely available in most clinics. Therefore, we present DL-language model-based assistive tools that can generate RANO-GBM/BM labels solely using text from the findings section of a report.
Methods and materials: We performed a single-centre retrospective cohort study of 1,252 (GBM: 734[58.6%]; BM: 518[41.4%]) consecutive MRIs from 394 patients (GBM:243; BM:151) between 11/2011-07/2019. Conventional free-text reports were retrieved from the local RIS. The impressions were used to generate class labels. For training and inference, only the findings were used. RANO responses were distributed as follows: complete response (CR,n=94), partial response (PR,n=55), stable disease (SD,n=697), and progression (PD,n=406). We fitted universal language model fine-tuning (ULMFiT)[2] and fastText[3] models, which were task-specifically fine-tuned on binary (PD[32.4%] vs. CR+PR+SD[67.6%]) and multi-class RANO responses.
Results: Both FastText and ULMFiT showed an averaged accuracy ~79% on the binary RANO response task while showing significant differences (p<0.05) compared to the no information rate (NIR) of predicting the majority class (67.6%). ULMFiT showed a remarkable 79% specificity, 83% recall, and 47% precision. On the highly imbalanced multiclass RANO task, fastText and ULMFit showed ~68% and ~69% accuracies, respectively.
Conclusion: Computer-aided reporting using embedded DL-models is feasible, even for complex tasks such as RANO response assessment. Such models can support radiologists to improve report quality, thus strengthening radiological enpoints in clinical trials.
Limitations: Restricted general-domian German language model was used.
Ethics committee approval: Nr.:2017-825R-MA.
Funding: The authors gratefully acknowledge funding from BMWi-ZIM (MEM,CGC,BK grantnr.:ZF4514602TS8) and BMBF-MIRACUM (TG,MEM grantnr.:01ZZ1801E).

Automating quality control for standardised structured radiology reports using text analysis

C. Thouly[1], A. Dhrangadhariya[2], D. Fournier[1], H. Müller[2], H. Brat[1]; [1]Sion/CH, [2]Sierre/CH

Purpose: To assess a software prototype performance in measuring concordance between the indication and conclusion sections in standardised structured reports (SSRs) by comparing the results of automated and human evaluation.
Methods and materials: 200 randomly chosen French-language SSRs with "indication", "description" and "conclusion" sections were analysed. Indication and conclusion concordance regarding anatomy and disease was assessed by two expert radiologists and by a prototype software using falling rule-lists aided by MeSH (medical subject headings) terminology.
The software measured semantic similarity between any two MeSH codes with MeSHSim and an R-package with "-nodeSim" functionality. L'Extracteur de concepts multi-terminologique (ECMT) combining a rule-based and an NLP (natural language processing)-based approach was used to extract health-related concepts from French-language texts using French-language terminologies in HeTOP (health terminology/ontology portal), housing 70 health terminologies in 32 languages including MeSH and radiology lexicon (RadLex).
Results: Upon total concordance assessment between the indication and conclusion, the prototype reported 45% concordance for the anatomy information, while manual evaluation reported a 61% concordance. For disease information, the prototype reported 80% concordance versus 88% with the peer review. Based on ground truth, the algorithm accuracy for measuring anatomy concordance was 84% and for disease 92%. It took the experienced radiologists about 1.5 hours to conduct manual quality checks, but the prototype did it in a matter of seconds.
Conclusion: The automated prototype shows good performance compared to expert radiologists for the assessment of indication and conclusion concordance in SSRs. It also reduces the time and cost required for quality control.
Limitations: The prototype success is subject to the ability of ECMT to accurately extract the concepts from free texts and also upon availability of a particular concept in the MeSH vocabulary.

Automatic pre-population of normal chest x-ray reports using a high-sensitivity deep learning algorithm: a prospective study of clinical AI deployment

V. Mahajan, N. S. Batta, S. Gupta, V. K. Venugopal, H. Mahajan, M. Murugavel; *New Delhi/IN (vidur@mahajanimaging.com)*

Purpose: To evaluate a high-sensitivity deep learning algorithm for normal/abnormal chest x-ray (CXR) classification by deploying it in a real clinical setting.
Methods and materials: A commercially available deep learning algorithm (QXR, Qure.ai, India) was integrated into the clinical workflow for a period of 3 months at an outpatient imaging facility. The algorithm, deployed on-premise,

was integrated with PACS and RIS such that it automatically analysed all adult CXRs and reports for those which were determined to be “normal” were automatically populated in the RIS using HL7 messaging. Radiologists reviewed the CXRs as part of their regular workflow and ‘accepted’ or changed the pre-populated reports. Changes in reports were divided into ‘clinically insignificant’ and ‘clinically significant’ following which those CXRs with clinically significant changes were reviewed by a specialist chest radiologist with 8 years’ experience.
Results: A total of 1,970 adult CXRs were analysed by AI, out of which 388 (19.69%) were identified to be normal. 361/388 (93.04%) of these were accepted by radiologists and in 14/388 (3.60%) clinically less significant changes (e.g. increased broncho-vascular markings) were made in reports. Upon review of the balance 13/388 (3.35%) CXRs, it was found that 12 had truly clinically significant missed findings by AI, including 3 with opacities, 3 with lymphadenopathy, 3 with blunted CP angle, 2 with nodules, and 1 with consolidation.
Conclusion: This study shows that there is a great potential to automate the identification of normal CXRs to a great degree, with very high sensitivity.
Limitations: The evaluation is limited to the normal/abnormal classification of chest x-ray.
Ethics committee approval: Institutional ethics committee approval was obtained.
Funding: No funding was received for this work.

AI-based understanding and visualisation of spinal MRI reports
K. Orbán, E. Szabó, A. Kicsi, P. Pusztai Phd, K. Szabó Ledenyi, P. Németh, L. Vidács Phd, Z. T. Kincses, T. Gyimóthy Dsc Phd*; Szeged/HU (orban.krisztina@outlook.hu)*

Purpose: We propose an artificial intelligence-based method for the comprehension of textual radiological reports. Thousands of reports are created annually which represent textual information that is often expressed in the native language of the radiologist. Comparison and later examination of their content are rather cumbersome. To our knowledge, we are the first to introduce an intelligent comprehension and detailed visualisation technique that supports Hungarian language reports.
Methods and materials: Our method relies on deep learning and various artificial intelligence procedures. The classification builds upon data from almost 500 anonymised reports manually annotated by two radiologists with 0.79 Cohen's kappa agreement. The classification process detects anatomic locations and pathologies with quantification, which are further specified with natural language processing techniques. Several linguistic characteristics are also addressed and negative statements and non-pathological disorders are separated.
Results: Our AI classification model achieves a three-class classification with an F-score of 90-96%. The recognised disorders are displayed in a tree structure and also highlighted in the text itself. Furthermore, they are also visualised on a schematic illustration indicating the anatomical position of the disorders. This detailed view is obtained automatically by AI and NLP methods and is not yet available in existing RIS applications.
Conclusion: We introduce an AI-based method for the automatic comprehension and visualisation of radiological reports, working currently with lumbar spine MRI reports written in Hungarian. The results can be used to filter the core of the report content and for quality assurance. Our process can be extended to other languages and to any field where large amounts of text are created routinely and would benefit from automatic processing.
Limitations: Our method currently supports reports written in Hungarian and concerning the spinal region.

Radiology report generation using pointer networks: a step towards radiology report standardisation
A. Kharat[1], J. Tandale[2], A. Ahmad[2], R. Lokwani[2], A. Pant[2], A. Jaju[2], K. Saoji[2], A. Patil[2]*; [1]Maharashtra/IN, [2]Pune/IN (kharatamit75@gmail.com)*

Purpose: We study automated report generation using deep learning (DL) techniques to reduce radiologist's work load with the aim of creating report templates which can be used by radiologists.
Methods and materials: The dataset, available from 800+ bed hospital, contains 13,000 images along with their reports. The convolutional neural network (CNN) Chex-Net model for detecting pathologies was used, which is a 121-layer dense CNN called densenet. The original model was trained to detect 14 pathologies and we extended this model to 15 pathologies. We used the following steps to create a report template: 1) fed images into the ChexNet model to get 15 predicted probabilities for respective pathologies, 2) of the 15 predicted probabilities, the ones which exceeded the threshold value were said to be present in that image, and 3) we generate a template-based report combining the predicted pathologies with the heuristic rules provided by radiologists.
Results: A sequence to sequence (StS) model with pointer networks (PN) was used. Method: 1) The selected template is modified by a radiologist if needed and modifications by the radiologist are stored. 2) For the StS model, the created report is the input sequence while the modified report from the radiologist is the output sequence. 3) Mapping is learnt between these two sequences, one accounts for expert knowledge and the other utilises real-time expert output to further remove inconsistencies. For the randomly selected set of 100 studies, reports are generated using the proposed methodology. Generated reports are validated by 2 radiologists. Validation is done based on understanding and auto-generated reports to reduce the radiologist's time in writing reports.
Conclusion: More than 52% of reports were accepted for report generation by making minor changes and edits by our team of validating radiologists. This process can be a stepping stone towards radiology report standarisation.

Validation of a high precision semantic search tool using a curated dataset containing related and unrelated reports of clinically relevant search terms
V. K. Venugopal[1], N. Kumar[2], V. Jagannatha[2], V. Mahajan[1], H. Mahajan[1], S. Rajan[1], A. Shastry[2], R. Rao K.[2]*; [1]New Delhi/IN, [2]Bangalore/IN (vasanthdrv@gmail.com)*

Purpose: To validate a sematic search tool by testing the search results for complex terms.
Methods and materials: The tool consists of two pipelines: an offline indexing pipeline and a querying pipeline. The raw text from both reports and queries were first passed through a set of pre-processing steps; sentence tokenisation, spelling correction, negation detection, and word sense disambiguation. It was transformed into a concept plane followed by indexing or querying. During querying, additional concepts were added using a query expansion technique to include nearby related concepts. The validation was done on a set of 30 search queries, carefully curated by two radiologists. The reports that are related to the search queries were randomly selected with the help of keyword search and the text was re-read to determine its suitability to the queries. These reports formed the "related" group. Similarly, the reports that were not exactly satisfying the context of the search queries were categorised as the "not related" group. A set of 5 search queries and 250 reports were used for tuning the model initially. A total of 500 reports of the 10 search queries formed the corpus of the test set. The search results for each test query were evaluated and appropriate statistical analysis was performed.

Results: The average precision and recall rates on 10 unseen queries on a small corpus for respective queries containing related and unrelated reports were 0.54 and 0.42. On a larger corpus containing 60 K reports, the average precision for these 15 queries was 0.6.
Conclusion: We describe a method to clinically validate a sematic search tool with high precision.
Limitations: A small corpus of test reports.

RPS 1005b-10 12:09

Decision support system for automated CT abdominal imaging protocol selection using natural language processing with machine learning

P. Rogalla[1], S. Carey[1], B. E. Hoppel[2], K. Noro[3], M. D. Y. Yamazaki[3], M. Y. Shimomura[3], M. Nakatsugawa[4]; *[1]Toronto, ON/CA, [2]Vernon Hills, WI/US, [3]Otawarai/JP, [4]Kawasaki/JP (kazumasa1.noro@medical.canon)*

Purpose: To evaluate the accuracy of a protocol recommendation engine with natural language processing with machine learning (NLP-ML) for automatic protocolling of abdominal CTs.
Methods and materials: 110,001 historical imaging requests for abdominal CT were extracted from a RIS database containing the executed imaging protocols and 16 associated patient information values (e.g. indication, primary diagnosis, and free-text comment). Keywords were extracted from the free-text comment by TF-IDF to create a bag-of-words feature. A multinomial naïve Bayes model was trained to classify the 9 most frequent protocols. A protocol recommendation engine with NLP-ML was developed, which interfaced to the RIS and provided radiologists with a recommended protocol and its probability based on the free-text imaging request. Three radiologists protocolled the imaging requests twice: first without and then with the aid of the protocolling engine. The radiologist categorised each recommendation as "good catch", agreement, minor error, and severe error. The accuracy of the protocolling engine was calculated by using the second selection as the ground truth.
Results: The protocolling engine's accuracy by a radiologist and an average was 84.7% (161/190), 88.0% (132/150), 90.8% (138/152), and 87.6% (431/492, p<0.001), respectively. Radiologists changed their protocolling based on the engine's recommendation ("good catch") in 2% (5/190), 1.3% (2/150), 2.6% (3/152), respectively, and on average in 2.0% (10/492) of the cases. On average, minor errors of the NLP-ML occurred in 11.2% and severe errors in 1.2% of all protocols.
Conclusion: A protocolling engine with NLP-ML shows promising accuracy and has the potential to eliminate the time consuming and tedious task of protocolling CT imaging requests.
Limitations: The number or selectable imaging protocols (9), number of readers (3), and body regions (abdomen).
Ethics committee approval: Institutional research ethics board approval.

RPS 1005b-11 12:15

Natural language processing enables a correlation of clinical information with positive findings in low-dose computed tomography in patients with suspected urolithiasis

T. Jorg[1], B. Kämpgen[2], P. Mildenberger[1], C. Düber[1], P. Mildenberger[1], F. Jungmann[1]; *[1]Mainz/DE, [2]Rimpar/DE (tobias.jorg@googlemail.com)*

Purpose: To automatically extract clinical and epidemiological information from past narrative radiological reports on low-dose computed tomography (CT) for suspected urolithiasis using natural language processing (NLP) and to correlate findings with clinical information.
Methods and materials: Narrative reports of low dose CT-examinations of the retroperitoneum from 04/2016 to 07/2018 (n=1714) were analysed using NLP. Reports were automatically structured based on RadLex® concepts. Manual feedback was used to test and train the NLP engine to reach adequate test accuracy (F1-Score ≥0.80). Chi-square test, phi-coefficient, and logistic regression were performed to determine the effects of clinical information on the positive hit rate of urolithiasis.
Results: Urolithiasis was affirmed in 72% of the reports. In 38% of the reports, at least one stone was described in the kidneys and in 45% in the ureter. In 22% of the reports, patients suffered from combined nephrolithiasis and ureterolithiasis.
Affirmed clinical information such as previous stone history and obstructive uropathy could be found significantly more frequently in reports with affirmed urolithiasis (p=.001). The combination of obstructive uropathy and loin pain showed the highest rate for positive urolithiasis with an odds ratio of 1.16.
Conclusion: Generating data from past radiological reports allows for the calculating of positive hit rates for pathologies, which can be used for epidemiological studies or to evaluate the appropriateness of CT-examinations. The evaluation of our data indicates that the occurrence of clinical information such as stone history and obstructive uropathy, or a combination of obstructive uropathy and loin pain, was higher in patients with affirmed urolithiasis. NLP can collect and monitor the data automatically in high quality.
Limitations: Clinical information may not be revealed correctly or entirely by the referring physicians which could lead to limitations.

Development of a software application for the automatic determination of CT protocols using natural language processing

A. Ciritsis, T. Frauenfelder, C. Rossi, A. Boss; *Zurich/CH (alexander.ciritsis@usz.ch)*

Purpose: To develop a software application for CT protocol determination using natural language processing (NLP) based on free-text classification and to evaluate the agreements by comparing protocols determined via NLP with those determined by radiologists.
Methods and materials: The database of report information system (RIS) was queried for a list of CT examinations with the referring department and its corresponding medical questioning, suspected diagnosis, and conducted CT protocol over a period of one year. For each of the departments referring patients to the radiological institution, three separate models for most common, less common, and rare protocols based on a support vector machine (SVM) and term frequency–inverse document frequency (TFIDF) were trained. Thereby, the medical questioning, as well as the suspected diagnosis by the referring department, served as features and the conducted CT protocol as a label.
Results: After data query in a total of 7,211 CT examinations with the referring department, corresponding medical questioning and suspected diagnosis were extracted. Medical questioning and suspected diagnosis formulated by the referring department were combined and preprocessed using predefined stop words and regular expressions before being translated into a feature space for the SVM via TFIDF. 15 different models for the most frequent referring departments were trained and model accuracy varied from 71% to 92%. For eventual implementation, a GUI implementing the previously trained models was developed.
Conclusion: NLP shows promising results in the automation and standardisation of CT protocol determination. The presented technology may be integrated into the clinical routine and result in a lean workflow for CT protocol determination in radiological institutions.
Limitations: Models were trained on clinical data from only one institution.
Ethics committee approval: Ethics committee approval obtained.
Funding: SPHN project NLPforTC.

Morphometric and subjective frailty assessment in transcatheter aortic valve implantation
M. Giannoudi[1], M. A. Waduud[2], M. Drozd[1], T. Slater[1], P. P. J. Sucharitkul[1], D. Blackman[1], J. Scott[1]; *[1]Leeds/UK, [2]Glasgow/UK (ll16ppjs@leeds.ac.uk)*

Purpose: To determine the prognostic impact of objective and subjective measures of frailty and their relationship to existing validated assessment methods after transcatheter aortic valve implantation (TAVI).
Methods and materials: Consecutive patients were identified from the Leeds Teaching Hospital Trust TAVI database. Frailty was quantified objectively by measuring total psoas muscle area (TPMA) on routine CT scans and subjectively using a clinician-based judgement of overall frailty, termed the Leeds-Subjective Assessment of Frailty in the Elderly (L-SAFE) score. Post-intervention morbidity and mortality were examined between these scoring systems and validated scoring systems.
Results: This study included 420 patients having undergone TAVI between January 2013 and December 2015. Median clinical follow-up was 4.0 years (IQR 2.9-5.0). Standardised measurements of TPMA were not associated with overall all-cause mortality (adjusted HR 1.11, 95% CI 0.94 to 1.31, p=0.206). The L-SAFE score was associated with the duration of hospital stay (adjusted regression co-efficient -0.93, 95% CI -1.71 to -0.15, p=0.019) and overall all-cause mortality (adjusted HR 0.66, 95% CI 0.53 to 0.82, p<0.001). Only the L-SAFE score significantly correlated with traditional methods of frailty assessment.
Conclusion: We demonstrate a purely subjective measure of frailty to be prognostic in determining post-TAVI morbidity and mortality when compared to the measurement of the TPMA.
Limitations: The retrospective nature of the study meant that there were elements of data that could not be collected. The biggest weakness is the lack of interobserver measurements for the L-SAFE score, however, this is the start of our team's work using this scoring system with the aim of further research including multiple assessor scores.

RPS 1003b-2 11:31
Possibility of estimating the aortic valve calcium score based on the angiographic phase of multidetector computed tomography performed before transcatheter aortic valve implantation
P. Gac, B. Kedzierski, P. Macek, G. Mazur, R. Poreba, K. Pawlas; *Wroclaw/PL (pawelgac@interia.pl)*

Purpose: To assess the possibility of estimating the aortic valve calcium score (AVCS) based on the angiographic phase of multidetector computed tomography (MDCT) performed before transcatheter aortic valve implantation (TAVI).
Methods and materials: The study group consisted of 31 patients who had undergone two-phase MDCT of the heart and large vessels before TAVI: the native phase for AVCS assessment and the angiographic phase for assessment of the aortic valve size and assessment of the access route. Mean age was 78.61±6.04 years. The semi-automatic evaluation of AVCS in slices thickness 3 mm and 2 mm ($AVCS_{native3.0}$ and $AVCS_{native2.0}$) was made on the basis of the native phase. Using the angiographic phase, AVCS was estimated for slices thickness 0.6 mm, with increased differentiation thresholds for contrasting aortic lumen with calcifications in the aortic valve from a typical 130 HU to 500 HU and 600 HU ($AVCS_{CTA0.6\ 500HU}$and $AVCS_{CTA0.6\ 600HU}$).
Results: AVCS measured by various methods were: $AVCS_{native3.0}$- 3640.58±2289.03, $AVCS_{native2.0}$- 3397.09±2138.25, $AVCS_{CTA0.6\ 500HU}$- 1871.94±1304.46, and $AVCS_{CTA0.6\ 600HU}$- 1586.06±1723.89. There were statistically significant positive linear correlation between AVCS values evaluated on the basis of the native phase and AVCS values estimated on the basis of the angiographic phase: r $AVCS_{native3.0}$ vs. $AVCS_{CTA0.6\ 500HU}$ - 0.90, r $AVCS_{native3.0}$ vs. $AVCS_{CTA0.6\ 600HU}$ - 0.40, r $AVCS_{native2.0}$ vs. $AVCS_{CTA0.6\ 500HU}$ - 0.89, and r $AVCS_{native2.0}$ vs. $AVCS_{CTA0.6\ 600HU}$ - 0.39. Using regression analysis, mathematical formulas for calculating native AVCS based on AVCS values estimated on the basis of angiographic phase were defined: $AVCS_{native3.0}$= 644.7+1.8 $AVCS_{CTA0.6\ 500HU}$, $AVCS_{native3.0}$= 2922.1+0.5 $AVCS_{CTA0.6\ 600HU}$, $AVCS_{native2.0}$= 689.2+1.6 $AVCS_{CTA0.6\ 500HU}$, and $AVCS_{native2.0}$= 2789.4+0.5 $AVCS_{CTA0.6\ 600HU}$.
Conclusion: AVCS can be reliably estimated using only the angiographic phase of MDCT of the heart and large vessels.
Limitations: Small size of study group

CT-coronary angiography in high-pitch-TAVI-planning-CT: why it rarely works
P. Seitz, R. F. Gohmann, S. Gottschling, D. Holzhey, H. Thiele, M. Abdel-Wahab, C. Lücke, C. D. Krieghoff, M. Gutberlet; *Leipzig/DE*

Purpose: Depiction of the access-route and annular dimensions are essential prior to transcatheter-aortic-valve-implantation (TAVI). Seemingly coincidently, coronary-arteries are sometimes depicted diagnostically. In this analysis, we investigated factors influencing the diagnostic depiction of coronary-arteries in pre-TAVI-CT.
Methods and materials: 100 patients (46 women; mean age 79,0±5,9 years) were retrospectively included. All patients underwent dual-source-CT-scans (Siemens, Definition FLASH) in prospectively-ECG-triggered-high-pitch-mode after injecting 70 ml contrast-medium (Iomeprol 400 mg iodine/ml, Flow 3,5 ml/s) for evaluation of the access route and annular dimensions.
The number of diagnostic coronary-segments per patient (DSpP) was determined and set in relation to heartrate, BMI, coverage along the z-axis (CaZA), and heart-rhythm.
Results: Overall, 30.3% of coronary-segments were diagnostically depicted. Mean heartrate correlated inversely with DSsP (75±19 bpm; r=-0,35; p<0,001). CaZA (% of RR-interval) correlated inversely with DSpP (r=-0,33; p<0,001). CaZA correlated strongly with heartrate (r=0,71; p<0,0001). BMI correlated negatively with DSpP (r=-0,26; p<0,01).
DSpP was not significantly different between patients with atrial fibrillation and sinus rhythm (p=0,11). Mean heart rate variability was 15±23 bpm and showed no correlation to DSpP (p=0,11; r=0,256).
Conclusion: Fully diagnostic studies in high-pitch-TAVI-planning-CT are rare and only occur under very special circumstances (low heartrate and narrow CaZA). Nevertheless, relevant coronary-findings can frequently be observed with this technique.
The most significant factors influencing DSsP are CaZA, HR, and BMI. As all these parameters are either intrinsic to the patient or are difficult to influence in this patient collective, fully diagnostic exams are rare with this technique. However, limiting the FoV to optimise scan metrics could improve the frequency of fully diagnostic studies and should be investigated further.
Limitations: Retrospective study design.
Ethics committee approval: The study was approved by the local ethics committee.
Funding: No funding was received for this work.

Sinus of Valsalva thrombosis detected on computed tomography after transcatheter aortic valve replacement

S. J. Lim, H. J. J. Koo, J.-W. Kang, D. H. Yang; *Seoul/KR*
(vitamindasa@hanmail.net)

Purpose: Leaflet thrombosis after transcatheter aortic valve replacement (TAVR) has been reported recently, whereas thrombosis in the sinus of Valsalva has not been fully evaluated. We described the clinical and radiological findings of the patients with sinus of Valsalva thrombosis using cardiac computed tomography (CT).
Methods and materials: Between March 2011 and August 2019, 192 patients underwent cardiac CT after TAVR. In this study, after retrospective review of the CT images, we included 8 patients who had sinus of Valsalva thrombosis identified on cardiac CT. Patients demographics, the interval between TAVR and cardiac CT scan, location and CT attenuation of sinus of Valsalva thrombosis, and presence of concurrent leaflet thrombosis were collected.
Results: The median interval between TAVR and cardiac CT was 11 days. Sinus of Valsalva thrombosis was frequently detected in a non-coronary sinus (88%) and mainly located in the bottom of the sinus (100%), growing up to the sinotubular junction. 2 patients had concomitant leaflet thrombosis and 3 patients had subclinical ischemic stroke on the brain magnetic resonance imaging. All patients had taken aspirin and clopidogrel after TAVR for at least 6 months without anticoagulation.
Conclusion: Cardiac CT after TAVR can detect sinus of Valsalva thrombosis and attention should be paid to this potential source of systemic embolisation.
Limitations: Selection bias could not be avoided because it was a retrospective observational study. We could not know when the sinus of Valsalva thrombosis had developed because we obtained CT scans with various time intervals. We could not suggest the optimal antithrombotic therapy for the sinus of Valsalva thrombosis, leaflet thrombosis, or post-TAVR strokes.
Ethics committee approval: This study was approved by Institutional Review Board of our hospital (Approval number: 2019-0312). Informed consent; n/a

RPS 1003b-5 11:49

The impact of coronary artery disease and pre-procedural percutaneous coronary intervention on the short and long-term mortality after transcatheter aortic valve implantation

T. P. W. van Den Boogert, J. Vendrik, J. Gunster, M. van Mourik, B. Claessen, F. van Kesteren, N. R. Planken, J. Baan, J. Henriques; *Amsterdam/NL*
(t.p.vandenboogert@amsterdamumc.nl)

Purpose: Coronary artery disease (CAD) is a common concurrent condition in patients receiving transcatheter aortic valve replacement (TAVR), but consensus on the prognostic implications of CAD and its pre-procedural treatment with percutaneous coronary intervention (PCI) is missing. If we could select the coronary segments in which pre-procedural PCI treatment will have a positive effect on the outcome, we could evaluate these segments for CAD on pre-procedural CTA.
Methods and materials: An institutional TAVR database was complemented with data extracted from coronary angiography and PCI reports. The extent of CAD, lesion location, lesion severity, and the location of PCI were scored. Survival analysis was performed to investigate the impact on mortality within 3 years after TAVR.
Results: Among the 1,514 included patients, the mean age was 82 years, 55% were female, 31% had diabetes mellitus, and CAD prevalence was 55%. Survival analysis revealed no significant association of CAD extent on mortality, but significant LAD-lesions (≥70% DS) were significantly associated with increased 3-year and short-term mortality (HR:1.6, 95%CI:1.0-2.4 and HR:3.4, 95%CI:1.4-8.1, respectively). Pre-procedural PCI of unselected lesions was significantly associated with an increased 3-year and short-term mortality (HR:1.7, 95%CI:1.0-2.7 and HR:2.3, 95%CI:1.1-4.9, respectively), but selective PCI of proximal lesions resulted in comparable mortality rates.
Conclusion: Not the extent of CAD but only significant LAD lesions are independently associated with higher mortality after TAVR. Pre-procedural PCI of unselected lesions is also associated with higher mortality, but there was no significant difference in mortality between patients with and without selective pre-procedural PCI of proximal LAD and LM lesions.
Limitations: Single-centre, non-randomised cohort and we used CAG and PCI reports from local and referral hospitals.

Cardiac computed tomography versus transoesophageal echocardiography in preoperative sizing of ostium secundum atrial septal defect prior to transcatheter closure

S. T. Wong[1], T. Pressat-Laffouilhère[1], K. Warin Fresse[2], S. Bejar[1], F. Bauer[1], J.-N. Dacher[1]; [1]*Rouen/FR*, [2]*Nantes/FR*
(tatianawong27@gmail.com)

Purpose: To investigate the feasibility and accuracy of cardiac multidetector computed tomography (MDCT) prosthesis sizing of ostium secundum atrial septal defect (ASD).
Methods and materials: 70 consecutive patients were included in this retrospective bicentric study between May 2012 and June 2018. They underwent cardiac MDCT and transoesophageal echocardiography (TEE) before transcatheter closure of ASD; dimensions of the defect and peripheral rims were measured. Defect measurements obtained at TEE and MDCT were compared to prosthesis size. Our primary criterion was the comparison of ASD maximal diameter obtained at MDCT (CT-Dmax) to prosthesis size. Intraclass correlation coefficient (ICC), Bland Altman plots, and linear regression were calculated. Intraobserver and interobserver agreement were calculated for MDCT defect measurements.
Results: 43 patients were finally included for defect measurements: 17 did not undergo transcatheter closure and 10 had incomplete data. For CT-Dmax, ICC was 0.88 (CI95% = [0.78 – 0.93]; p=0.06), mean difference was – 0.82 +/- 5.73 mm, and regression linear equation was 0.9 x + 3.2 ($p < 0.001$). For maximal diameter at TEE versus prosthesis size, ICC was 0.46 (CI95% = [0.21 – 0.61]; $p = 0.003$), mean difference was – 6.06 +/- 8.26 mm, and regression linear equation was 0.91 x + 7.6 ($p < 0.001$). Intraobserver and interobserver agreement for CT-Dmax was 0.97 (CI95% = [0.95 – 0.98]) and 0.86 (CI95% = [0.73 – 0.93]), respectively.
Conclusion: MDCT is a reliable tool for sizing the defect of ostium secundum ASD, making it an accurate alternative to pre-procedural TEE.
Limitations: Retrospective and small cohort.

Role of CT in the preoperatory setting of transcatheter mitral valve interventions: which is the correct phase for mitral annulus sizing?

V. Nicoletti, A. Palmisano, D. Vignale, L. Pannone, C. Colantoni, A. Del Maschio, F. de Cobelli, A. Esposito; *Milan/IT (nicoletti.valeria@hsr.it)*

Purpose: Transcatheter mitral valve interventions (TMVI) are emerging as alternative treatments in patients with severe mitral regurgitation (MR) who are non-eligible for surgery. Cardiac CT plays a crucial role in TMVI planning, guiding the assessment of patient suitability, prosthesis sizing, and access planning. However, the entity of the modifications of mitral valve geometry throughout the cardiac cycle and the best phase for annulus sizing are still unclear.
Methods and materials: 44 patients with severe MR candidate to TMVI (3 type-I, 16 type-II, 10 type-IIIa, 15 type-IIIb according to Carpentier classification) and 21 patients without significative MR (control group) were retrospectively evaluated. Each patient underwent a multiphase (0-90%) retrospective ECG-gated cardiac CT. Mitral valve annulus was manually extracted every 10% steps

of the R-R interval, according to the recommended D-shape segmentation model.
Results: Patients with severe MR had enlarged left ventricle (LV-EDV=248,7±112,2 ml) and atrium (LA-ESV=201,6±71,1 ml) with reduced ejection fraction (EF=40,5±15,9%) compared to control patients (p<0,05). Moreover, MR patients showed larger maximum annular area (16,0±4,0 vs 9,5±1,8cm²; p<0,001), particularly in the case of type-II MR. Only the TT diameter showed no significant difference between the two groups (p=0,252). In MR patients, the largest annular area was found predominantly (48%;21/44) during systolic phases (20-40%), while in control patients (67%;14/21) during proto-diastolic phases (40-60%). In the remaining patients, the maximum area was randomly distributed among the remaining phases.
Conclusion: We can conclude that a multiphase acquisition with the inclusion of the systole and a personalised approach to the segmentation of the mitral annulus could be important for the correct planning of TMVI.
Limitations: Limited sample size. No comparative data in a population without MR.
Ethics committee approval: This study has been approved by the istitutional review board.
Funding: No funding was received for this work.

Predictors of cerebral embolisation after percutaneous transfemoral aortic valve implantation: a RETORIC substudy
F. I. Suhai, A. Varga, B. Szilveszter, J. Karady, A. Panajotu, A. Bartykowszki, A. I. Nagy, B. Merkely, P. Maurovich-Horvat*; Budapest/HU*
(suhaiimi987@gmail.com)

Purpose: To evaluate the predictors, occurrence, and distribution of TAVI-related silent ischemic brain lesions using diffusion MRI.
Methods and materials: We investigated 109 consecutive patients from the prospective arm of the RETORIC study (NCT02826200) who underwent brain MRI one week after percutaneous transfemoral aortic valve implantation (TAVI). To determine the occurrence and distribution of periprocedural cerebral ischemic lesions, averaged diffusion-weighted images (trace), and mean diffusivity (MD) maps from the DTI dataset were used. To evaluate the aortic valve calcium score (AVCS), we assessed the preoperative prospectively ECG-triggered cardiac CT (256-slice MDCT). We also assessed the periprocedural factors such as periprocedural time and pre- and postdilatation. Linear regression analysis was performed to identify the independent predictors of TAVI-related ischemic lesions.
Results: After TAVI, a total of 918 new cerebral ischemic lesions were detected in 100/109 patients (92%). The median ischemic lesion volume was 237 µl (interquartile range 89.5-650) with a median lesion number of 6 (2-10) per patient. 759/918 lesions (83%) were supratentorial (389 left vs. 370 right). Most lesions (628/918, 68%) were subcortical; the left and right MCA territories were the most affected (left: 190/918, 21% vs. right: 177/918,19%). The vast majority of ischemic lesions were clinically silent (96%); 4% of patients had a stroke which was proven by MRI. The median AVCS was 2,769 (interquartile range 1,858-4,537). Ballon pre-dilatation during TAVI procedure showed significant correlation with increased total ischemic lesion volume (p<0.001, ß = 0.370) on univariate analysis, AVCS, periprocedural time, or post-dilatation were not associated with ischemic load on MRI (p>0.05).
Conclusion: Periprocedural ischemic lesions are frequent (92%), however, most of them are clinically silent. Only balloon pre-dilatation during TAVI was a predictor of increased ischemic load.
Limitations: n/a
Ethics committee approval: Written informed consent.

Combined coronary CT-angiography and TAVI-planning: a contrast-neutral and efficient routine approach to exclude significant coronary artery disease
R. F. Gohmann, P. Lauten, C. D. Krieghoff, P. Seitz, C. Lücke, M. Abdel-Wahab, D. Holzhey, H. Thiele, M. Gutberlet*; Leipzig/DE*
(robin.gohmann@gmx.de)

Purpose: To analyse the ability of coronary CT-angiography (cCTA) for ruling out significant coronary artery disease (CAD) during routine evaluation for transcatheter aortic valve implantation (TAVI) in patients with a high pre-test probability of CAD.
Methods and materials: 460 consecutive patients undergoing pre-TAVI-evaluation (238 women; mean-age 79,6±7,4 years) were retrospectively included. Patients with prior CABG were excluded. All patients were examined with a standard protocol consisting of a retrospectively gated CT-scan of the heart, immediately followed by a high-pitch scan of the vascular access route utilising a single bolus of 70 ml iodinated contrast-medium. No beta-blockers or nitrates were applied.
Heart rate and heart rate variability during the scan were 74,5±19,5 and 23,3±33,2 beats per minute; attenuation at the ascending was 465,4±145,4 HU. Images were evaluated for significant CAD (stenosis >50%); examinations where CAD could not be ruled out were read as positive. Patients routinely received invasive coronary angiography (ICA) 84,3% (388/460), which was omitted if the renal function was impaired and CAD could be ruled out on cCTA. All stenoses visually identified on ICA were graded qualitatively (QCA) using the same cut-off.
Results: cCTA could rule out for significant CAD in 40,2% (188/460). As detailed in the table, sensitivity, specificity, PPV, NPV, and accuracy per patient were 97,8%, 45,2%, 49,6%, 97,4%, and 63,9%, respectively. The stenoses additionally identified on ICA were located in the mid LAD, mid RCA, or obtuse marginal 1.
Conclusion: cCTA and pre-TAVI-evaluation can be performed jointly with no need for additional contrast medium or medication. cCTA is able to exclude significant CAD in a relatively high proportion of this high-risk collective. Thereby cCTA can reduce the number of ICA and the total amount of contrast-medium needed, with the potential of making pre-procedural-evaluation for TAVI-Planning safer and faster.
Limitations: Retrospective study design.

RPS 1003b-10 12:19
Cardiac magnetic resonance imaging parameters of right ventricular function predict mortality in a cohort of patients undergoing transcatheter aortic valve implantation (TAVI)
J. Schmid, C. Kamml, D. Zweiker, D. Hatz, A. Schmidt, M. Fuchsjäger, A. Zirlik, J. Binder, P. Rainer*; Graz/AT (johannes.schmid@medunigraz.at)*

Purpose: Recent studies show that right ventricular (RV) function is closely associated with the outcome of different cardiac conditions. This study aims to evaluate the value of RV functional parameters obtained from cardiac magnetic resonance imaging (cMR) for predicting mortality in patients undergoing transcatheter aortic valve implantation (TAVI).
Methods and materials: Patients with severe aortic stenosis were prospectively recruited to undergo cMR before TAVI. After exclusion of 11 patients due to insufficient image quality, cMR images of 112 patients (mean age 82±6 years; 34% women) were analysed using dedicated tissue tracking software (Circle cvi42). Obtained parameters included RV ejection fraction (RV-EF), RV global longitudinal, circumferential strain (RV-GLS, RV-GCS), RV longitudinal systolic velocity (RV-vel), left ventricular ejection fraction (LV-EF), and left ventricular global circumferential strain (LV-GCS).
Results: Mean follow-up was 3.5±1.8 years. Mortality after one and three years was 14% (16/112) and 29% (32/112), respectively.
RV-EF, RV-GLS, and RV-vel significantly predicted 3-year-all-cause-mortality in univariate Cox-regression (p=0.012, p=0.033, p=0.007), while RV-GCS, LV-EF, and LV-GCS did not (p=0.25, p=0.32, p=0.33). Results remained significant for RV-EF and RV-vel when adjusted for sex and age (p=0.015, p=0.013).

In ROC-analysis, RV-EF, RV-GLS, and RV-vel (AUC=0.64; 0.62; 0.63) outperformed current clinical risk scores (EuroSCORE-II, AV-Score, STS-Score) in predicting 3-year-all-cause-mortality.
Conclusion: cMR-derived RV functional parameters, especially parameters of longitudinal contraction, predicted mortality in our cohort. They performed better than left ventricular functional parameters and currently used clinical risk scores, and may improve outcome-prediction after TAVI.
Limitations: Only patients without contraindications for cMR were included, which may potentially bias the study cohort.
Ethics committee approval: The study was approved by the local ethics committee. Patients provided written informed consent.
Funding: No funding was received for this work.

RPS 1003b-12 12:25
Imaging of the left atrial appendage prior to occluder device placement: introduction of a new single-contrast bolus dual-phase protocol adapted to spectral-detector CT
K. R. Laukamp[1], S. Dastmalchian[2], L. Ciancibello[2], L. Pennig[1], C. Nelles[1], T. Hickethier[1], R. Gilkeson[2], A. Gupta[2]; [1]Cologne/DE, [2]Cleveland, OH/US (kai.laukamp@uk-koeln.de)

Purpose: Preimplantation cardiac-CT is ideal for assessing left-atrial-appendage (LAA) regarding size for selection of proper device and detection of contraindications such as in situ thrombi. Due to poor contrast-medium distribution in arterial-phase, the distinction between artificial filling-defects versus true thrombi is difficult. A delayed-phase is required for confirmation, which needs a second bolus to maintain adequate contrast. In this study, we investigated if a second bolus can be omitted when virtual-monoenergetic-images (VMI) from dual-energy spectral-detector-CT (SDCT) are used to enhance contrast in the delayed-phase.
Methods and materials: 51 consecutive patients undergoing SDCT-imaging of the LAA were prospectively included. Imaging-protocol comprised dual-phase acquisitions with single-bolus contrast-injection. Conventional images (CI) from both phases and 40keV VMI from the delayed-phase were reconstructed. Mean and standard deviation of attenuation were calculated by placing regions-of-interest in the LAA, left-atrium (LA), and pericardial fat. Additionally, two radiologists evaluated conspicuity, homogeneity of contrast distribution, and diagnostic certainty for the presence of a thrombus.
Results: The difference of mean attenuation between LAA and LA was significantly lower in the delayed-phase (arterial-phase: 10.8±37.7HU, delayed-phase: 2.1±12.5HU, p<0.05), indicating more homogenous contrast distribution. The contrast of the LAA decreased significantly in the delayed-phase, but was significantly improved by VMI; attenuation and image quality parameters were comparable to CI of the arterial-phase (attenuation/SNR/CNR, CI arterial-phase: 263.9±116.9HU/13.9±7.3/6.4±3.9; CI delayed-phase: 106.2±35.2HU/5.8±3.1/1.0±0.9; VMI delayed-phase 256.6±108.5/17.7±10.7/4.7±3.4). The subjective reading confirmed the objective findings and showed significantly improved diagnostic certainty for the evaluation of the LAA when VMI of the delayed phase were used.
Conclusion: The investigated single-bolus dual-phase acquisition protocol improved visualisation of the LAA; homogeneity of contrast media was higher in the delayed-phase while VMI could maintain high contrast and image quality comparable to arterial-phase.
Limitations: No echocardiography for evaluaiton of presence of LAA-thrombus was available.
Ethics committee approval: IRB-approved.
Funding: No funding was received for this work.

Direct detection of metabolic changes in rat brain slices during perfusion arrest: implications for imaging of cerebral ischaemia with hyperpolarised MR
D. Shaul[1], B. Grieb[2], G. Sapir[1], S. Uppala[1], J. Sosna[1], J. M. Gomori[1], R. Katz-Brull[1]; [1]Jerusalem/IL, [2]Ravensburg/DE

Purpose: The DAWN trial has shown that patients with acute stroke who had a mismatch between clinical deficit and infarct volume could benefit from endovascular thrombectomy even 24h after the onset of stroke. As the assessment of the patients' neurological deficits is by definition a subjective assessment, it raises the need for an objective marker of salvageable brain tissue. Perfused brain slices prove an *ex-vivo* model of the brain in which the perfusion can be controlled. In this study, we were interested in monitoring instantaneous changes in lactate dehydrogenase (LDH) and pyruvate dehydrogenase (PDH) activities in perfused rat brain slices by hyperpolarised [1-^{13}C] pyruvate MRS. The slices were exposed to an ischaemic insult which was achieved by arrested-perfusion. In this model, [1-^{13}C] pyruvate delivery is not hindered by the blood-brain-barrier and therefore its metabolism by brain cells can be determined directly.
Methods and materials: Brain slices were produced from Sprague-Dawley rats (n=11) and placed in an NMR tube perfused with oxygenated aCSF. In the control group (n=6), well-oxygenated [1-^{13}C] pyruvate was administered continuously. In the arrested-perfusion group (n=5), the perfusion was stopped 30 seconds before the injection of [1-^{13}C] pyruvate. LDH and PDH activities were quantified by measuring the production of [1-^{13}C] lactate and [^{13}C] bicarbonate with product-selective-saturating-excitations that were designed to quantify enzymatic rates.
Results: During 94 seconds of ischaemic insult, LDH activity increased by 56±25% and PDH activity decreased by 51±16% (n=5). No significant changes in LDH nor PDH activities were observed in the control group (n=6).
Conclusion: Hyperpolarised [1-^{13}C] pyruvate MRS shows promise in identifying the dynamically changing ischaemic penumbra as it could detect rapidly and non-invasively temporal changes in cerebral metabolic activity following ischaemia.
Limitations: Further research is needed to test this approach *in-vivo*.
Ethics committee approval: The study was approved by the Hebrew-University Institutional-Animal-Care

Evaluation of the diagnostic role of shear-wave elastography in patients with carpal tunnel syndrome
S. A. Seyed Mokhtari[1], A. Mohammadi[2], A. Afshar[2]; [1]Tabriz/IR, [2]Urmia/IR (armanmxt@yahoo.com)

Purpose: To evaluate median nerve (MN) stiffness by quantitative shear-wave elastography (SWE) in patients with carpal tunnel syndrome (CTS).
Methods and materials: A total of 124 wrists of 62 patients (36 CTS patients and 26 healthy subjects), bilaterally, were enrolled in the study. All diagnoses in patients and controls were confirmed with nerve conduction studies (NCS). High-resolution ultrasonography (US) and SWE were performed on the MN and cross-sectional area (CSA) and nerve stiffness was measured. The t-test was performed to compare CSA and SWE of the nerve in the CTS, control, and subgroups based on NCS tests. ROC analysis was also performed. P<0.05 was considered as significant.
Results: Patients with CTS had higher elasticity values of MN (55.53±18.54 kPa) compared to control subjects (23.05±9.97 kPa) (P<0.0001). Patients with moderate-severe CTS had higher elasticity values (59.88±15.69 kPa) compared

to patients with mild CTS (46.79±20.47 kPa) (P=0.006). A 34.0-kPa cut-off value on SWE revealed a sensitivity, specificity, PPV, NPV, and accuracy of 92.85%, 90.74%, 92.85%, 90.74%, and 91.93%, respectively.
Conclusion: Median nerve stiffness at the carpal tunnel inlet is significantly higher in patients with carpal tunnel syndrome. These findings suggest that the SWE-based stiffness measurement of the median nerve was a useful diagnostic modality.
Limitations: We performed measurements from only the tunnel inlet and do not know how the nerve stiffness changes at the distal tunnel or the forearm level by SWE.
Ethics committee approval: Approved by the ethical committee of the Urmia University of Medical Sciences. Written informed consent was obtained from all patients.
Funding: No funding was received for this work.

S 11-3 14:25
Time-depended cardiovascular effects of intra-arterial milrinone and nimodipine application in cerebral vasospasm
J. Jentzsch, H. Merkel, S. Ziganshyna, K. Gaber, D. Lindner, S. Schob, U. Quäschling, K.-T. Hoffmann, C. Richter*; Leipzig/DE*

Purpose: Cerebral vasospasm is the major cause of morbidity and mortality in patients with ruptured cerebral aneurysms who survived an initial haemorrhagic event. A recent randomised clinical trial validated the significant benefit of intra-arterial treatment over conservative treatment. However, risk-benefit-profiles of the drugs used for pharmaceutical angioplasty have not yet been analysed. Our study compares the efficacy and side-effects of intra-arterial nimodipine versus milrinone in patients treated for symptomatic vasospasm.
Methods and materials: 35 patients were treated intra-arterially for severe cerebral vasospasm. 12 received nimodipine only, 6 received milrinone only, and 3 were treated with a combination of both. Totally, 144 procedures were reviewed, 82 finally included. Spasm-relief, dosage and duration of application, mean-arterial-pressure (MAP), the requirement for systemic vasopressor therapy, and functional outcomes after 3-6 months were reviewed.
Results: Both drugs strongly increased the calibre of MCA- and ACA-segments. Less markedly, they reduced the vasotonus of the intradural ICA-segments (192% vs 120%). The time required to achieve significant spasm-relief was much higher for nimodipine compared to milrinone (6mg:55min vs 20mg/20min). The effect on the vasotonus after milrinone application was dose-dependent (maximum increase in diameter: 187% vs 166%, 20mg vs10mg). Milrinone showed the maximum effect after 10 minutes, whereas nimodipine efficacy appeared in a more delayed manner. Comparing the compensatorily required vasopressor dosages to avoid critical drops in MAP and nimodipine demanded significantly more systemic vasopressor than milrinone (0.08+/-0.13µg/kg/min vs 0.07+/-0.07µg/kg/min). All except for one patient (nimodipine) developed DCI but unfavourable outcomes were lower in the nimodipine cohort (mRS mean 3 vs 4.2).
Conclusion: The immediate vaso-relaxing-effect of nimodipine is inferior to milrinone, but nimodipine may have additional neuroprotective effects. However, cardiovascular comorbidities, an initial Hunt and Hess scale and individual susceptibility to pharmaceutical agents, are most considerable confounders.
Limitations: A retrospective, unicentric study with a small sample size.
Ethics committee approval: Local IRB granted.
Funding: No funding was received for this work.

The treatment of wide-necked bifurcation aneurysms with the use of a pCONus device and its complications: a meta-analysis
K. Krupa, I. Kucybała, P. Brzegowy, A. Urbanik*; Cracow/PL*
(kamilkrupa955@gmail.com)

Purpose: Endovascular treatment of wide-necked bifurcation aneurysms represents a technical challenge for interventional radiologists. In order to achieve better results of the embolisation, the pCONus device was developed. The aim of the study was to summarise the overall safety and efficacy of the pCONus device in the treatment of wide-necked bifurcation aneurysms.
Methods and materials: The major electronic medical databases were thoroughly searched to identify relevant studies. Data regarding the type of included studies, type of aneurysm, and its localisation, as well as results and complications of the treatment, were extracted from the eligible studies and included into a meta-analysis.
Results: A total of 9 studies (218 patients with 220 aneurysms) were included in the meta-analysis. The most common localisation of treated aneurysms was the middle cerebral artery with a pooled prevalence estimate (PPE) of 45.3%. Significantly less often aneurysms were located on the anterior communicating artery (PPE 29.7%) and the basilar artery (PPE 15.1%). Immediately after the procedure, in 41.6% of patients, RROC I (complete obliteration of the aneurysm) was observed. RROC II (residual neck) was present in 31.3% of patients, while RROC III (residual aneurysm) was present in 27.1% of patients. The results of short-term follow-up showed that most frequently RROC I was observed in 53.9% of cases. Less often, RROC II with a PPE of 24.9% was seen, followed by the RROC III with a PPE of 21.2%. The PPE of intraprocedural complications was 15.2%.
Conclusion: The use of a pCONus device with coiling in the treatment of wide-necked bifurcation aneurysms provides good occlusion rates and high safety.
Limitations: The low quality of evidence.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Stenting of intracranial stenosis in acute stroke: single-centre experience from the last decade
M.-S. Schüngel, S. Schob, K.-T. Hoffmann, U. Quäschling*; Leipzig/DE*
(Marie-Sophie.Schuengel@medizin.uni-leipzig.de)

Purpose: To summarise our experience from the last decade with stenting of symptomatic intracranial stenosis (SIS) causing acute, progressive stroke.
Methods and materials: Our retrospective study included 71 interventions (66 patients, mean age: 68.5 years) with average stenosis of 76% (modified NASCET-calculation). Balloon-expandable-stents (BES: Liberté, Pharos, Rebel, Coroflex) and self-expandable-stents (SES: Enterprise, Solitaire, Wingspan, Leo+Baby, p48MW_HPC, Silk Vista Baby) were applied. In total, 86 stents were used, but only 69 were implanted with adequate success. 77.3% of patients presented in the context of acute progressive stroke. Lysis (rtPA) was initiated in 12 patients.
Results: 77.3% were successfully treated. In 60.6%, BES, in 22.7%, SES+PTA ,and in 7.6%, other combinations (BES+SES+balloon, low-profile flow diverter) were used. In 9.1%, proper vessel-reconstruction failed.
77.3% regained at least partial functional independence (90days-mRS: ≤3), however, 22.7% died despite successful intervention. Except for one patient, all remaining presented with initial mRS-scores>3. 66.7% of deaths were related to poorly-collateralised basilar stenosis and 33.3% had high-grade stenosis at the C7/M1 segment.
Conclusion: SIS, especially in the posterior circulation, bears an extraordinarily high-risk for mortality and permanent disability despite early causative treatment. In this condition, collateralisation and comorbidities are most significant for the individual outcome. Off-label use of BES yields a good success-to-risk ratio, however, considerable stiffness and restricted manoeuvrability of BES empirically renders implantation impossible in demanding cases. Application of SES+balloon-PTA represents a promising bail-out-technique (especially with low-profile-flow-diverters) in these situations. Hence, considering the devastating natural course of SIS and accounting for the substantial evolution of neuro-interventional techniques which revolutionised stroke-treatment in the post-SAMMPRIS era, endovascular treatment of SIS has become obligatory especially, but not exclusively, during acute interventions as thrombectomy. Yet asymptomatic high-grade intracranial stenosis should be evaluated critically before deciding for conservative treatment only.
Limitations: Only single-centre experiences were presented.

Patient feedback on the consenting process for radiologically-guided interventional procedures
H. Iqbal, A. Maqsood-Shah, G. Ayub*; Leeds/UK (ll15hi@leeds.ac.uk)*

Purpose: This audit assessed the local consenting practice in interventional radiology using a patient feedback form provided by the RCR. The questionnaire contained 14 questions looking at different aspects of consenting and recorded the patient's satisfaction in terms of yes, no, and not sure. The target was for 95% of patients answering 'yes' to all questions. In the first cycle, 30% of patients answered 'Yes' to all questions. Areas needing improvement included providing information leaflets and providing information about pain and procedure benefits. The action plan after the first cycle included providing feedback to the radiologists to improve awareness and providing leaflets in advance.
Methods and materials: In the second cycle, 33 patients filled out a questionnaire form within 48 hours of their procedure. The anonymised data was quantitatively analysed.
Results: 36% of patients answered 'Yes' to all questions, showing a 6% increase. 90% answered yes to 10 out of 14 questions when analysed separately, confirming good progress. 100% of patients understood their procedure and had enough information to give consent. 55% answered yes to having sufficient information regarding alternative treatment.
Conclusion: A separate analysis of questions showed improvements in most areas, although the overall improvement was small. The worst outcome was seen in the question regarding discussing alternative treatments. Arguably, the day of the procedure is unsuitable for these conversations due to time limitations and a lack of complete history. It is assumed these conversations have taken place by the referring clinical team. Actions to take forward include revision of the questionnaire; we feel the RCR set questionnaire is not well suited to our practice. We intend to analyse these results alongside the relevant consent form to look for discrepancies and a repeat audit is prudent.

Tibial nerve calliber in MR neurography is negatively correlated with conduction velocities and compound motor action potentials in patients with diabetic neuropathy
L. Schimpfle, D. J. Jende, F. Kurz, D. S. Kopf, D. J. Gröner, D. Z. Kender, P. D. P. Nawroth, M. Bendszus*; Heidelberg/DE*

Purpose: Diabetic polyneuropathy (DPN), being one of the most common and most burdening complications in patients with diabetes mellitus, is still poorly understood. Magnetic resonance neurography (MRN) allows for the detection of pathological changes in the tibial compartment of the sciatic nerve. The aim of this study is to combine MRN with clinical, serological, and electrophysiological patient assessments in order to achieve a better understanding of the pathophysiology and possible treatment options in DPN.
Methods and materials: MRN of the sciatic nerve at 3 Tesla (Siemens Magnetom TIM TRIO) was performed in 130 patients with diabetes mellitus using a T2-weighted, fat-suppressed sequence with the following parameters: Tr: 5970ms, TE: 55ms, FOV: 160x150 $mm^{2,}$ matrix size: 512x512, slice thickness: 4mm, interslice gap: 0.35 mm, voxel size: 0.5x0.3x4.0 mm^3)
Segmentation of the tibial compartment of the sciatic nerve was carried out manually using the software Image J (version 1.52o, 2019) while nerve lesions were quantified semi-automatically with MATLAB (version 7.14.0.0739 (R2012a)).
In addition, every patient underwent clinical, electrophysiological, and serological assessment. MRN and clinical data were subsequently correlated using GraphPad Prism (Version 8).
Results: At the time of abstract submission, preliminary results of 42 patients were available. The cross-sectional surface area (CSA) correlated negatively with tibial nerve conduction velocity (NCV) (r=-0.37, p<0.01) and negatively with tibial compound motor action potential (Amp) (r=-0.37,p<0.019).
Conclusion: The preliminary results described above indicate that the thickening of nerve fascicles seen in DPN patients results in poorer nerve conduction values (NCV, Amp) implying advanced nerve damage. With all 130 patients being analysed, we expect more correlations of nerve pathologies with clinical and serological data.
Limitations: A cross-sectional study.
Ethics committee approval: Ethics number: S-383/2016, clinicaltrials.gov identifier: NCT03022721.

Introducing medical students to functional MRI and neuroscience research: myopia may induce changes in visual cortex activation
N. Rodríguez Albacete[1], R. Acosta Hernández[1], B. García Martínez-Lozano[1], A. Inuggi[2], J. M. M. Garcia Santos[1]; *[1]Murcia/ES, [2]Milan/IT (nicorodriguezal96@gmail.com)*

Purpose: To assess differences in visual cortex BOLD signal between myopic and emmetropic subjects.
Methods and materials: fMRI EPI was performed using a block-design stimulation in 6 emmetropic (3 men) and 6 myopic (3 men) healthy young volunteers. Two medical students manually mined the following data in a commercial workstation: highest BOLD magnitude and cross-correlation coefficient (CCC) using a 9-voxel ROI, whole cluster BOLD magnitude/CCC, total activated pixels, and number of activated slices. Variables were compared between groups (Mann-Whitney U test) and correlated (Spearman's correlation) with age, myopia duration, and dioptres in myopic subjects. One of the students was further trained in imaging analysis within the Erasmus Program. He performed a two-sample t-test group comparison and multiple regression modelling dioptres and myopia duration as regressors within SPM software.
Results: Total activated pixels (P=0.046) were significantly higher in myopic subjects. Significant correlations were observed between the highest BOLD magnitude and number of activated slices (ρ -0.928; P=0.008), the highest CCC and total activated pixels (ρ 0.943; P=0.005), and the total activated pixels and number of activated slices (ρ 0.943; P=0.005) only in myopic subjects. In addition, the highest BOLD magnitude (ρ 0.986; P<0.001) and whole cluster CCC (ρ -0.899; P=0.015) were correlated with dioptres. Imaging analysis showed four significant voxels in the occipital lobe in myopic>emmetropic and none in myopic<emmetropic. Some voxels correlating positively to myopia duration and negatively to dioptres were also demonstrated.
Conclusion: Myopic may have more extensive activation than emmetropic subjects, which might be a first adaptive mechanism. Increasing peak activation might be a subsequent compensation.
Limitations: The sample size, short block length, and lack of refraction correction.
Ethics committee approval: Ethics committee approval waived.
Funding: No funding was received for this work.

Achievable doses and diagnostic reference levels for computed tomography for EUCLID (European study on clinical DRLs) clinical indications: data from a multinational dose registry
D. Bos[1], S. Yu[2], J. Luong[2], P. Chu[2], Y. Wang[2], A. Wetter[1], R. Smith-Bindman[2]; *[1]Essen/DE, [2]San Francisco, CA/US*

Purpose: Radiation doses for computed tomography (CT) examinations are highly variable between patients, institutions, and countries. Achievable doses (target doses reflecting the 50% in distribution) and diagnostic reference levels (reference doses reflecting the 75% in distribution) are often created to help reduce unnecessary variation by providing guidance to radiologists and technologists. The European Society of Radiology has identified common indications for CT (EUCLID, European study on clinical DRLs) in order to create benchmarks.
Methods and materials: Standardised data on 2.3 million CT examinations in adults ages 18 years and older was collected between January 2016-December 2018 from 155 institutions across 7 countries as part of the UCSF international CT dose registry. This data was used to calculate the target and reference doses for each EUCLID indication for CT-dose index (CTDIvol) and dose-length product (DLP).
Results: The number of included patients for the EUCLID categories ranged from 3,176 (coronary angiography) to 721,263 (appendicitis). Doses were significantly different across the different categories. E.g., the target dose for DLP for suspected brain haemorrhage was 861 mGy-cm, whereas for chronic sinusitis was 250 mGy-cm. The observed target and reference doses for DLP in mGy-cm were: suspected brain haemorrhage target DLP=861 and reference DLP=1,067, chronic sinusitis 250 and 373, cervical spine trauma 450 and 962, pulmonary embolism 372 and 558, coronary calcium score 66 and 102, coronary angiography 497 and 915, lung cancer 329 and 555, hepatocellular carcinoma 1,304 and 2,016, abdominal pain 519 and 773, and appendicitis 661 and 1,059.
Conclusion: Reference and target dose levels for EUCLID clinical indications from diverse organisations can be used for dose optimisation and institutional evaluation, and to inform indication-specific dose-optimised protocols.

Achievable doses and diagnostic reference levels for paediatric computed tomography for different age groups and clinical indications: data from a multinational dose registry

D. Bos[1], S. Yu[2], J. Luong[2], P. Chu[2], Y. Wang[2], R. Smith-Bindman[2]; [1]*Essen/DE,* [2]*San Francisco, CA/US*

Purpose: Radiation doses vary across patients, institutions, and countries. Achievable doses (target doses) and diagnostic reference levels (reference doses that should not be exceeded) for children by size and clinical indication would help physicians optimise their doses.
Methods and materials: Standardised computed tomography (CT) examinations were collected in children up to the age of 15 years between January 2016-December 2018 from 156 institutions across 7 countries as part of the UCSF international CT dose registry. Achievable doses (target doses, defined as the 50% in observed distribution) and diagnostic reference levels (reference doses, defined as the 75% in distribution) were calculated for the CT-dose index (CTDIvol) and dose-length product (DLP) stratified by age for the most common clinical indications for CT scanning.
Results: Data was analysed for 51,107 CT examinations including 6,373 (12%) in children under age 1, 10,928 (21%) in children aged 1-5, 13,759 (27%) in children aged 5-10, and 20,047 (39%) in children aged 10-15. For the anatomic area and clinical indication category, there was an increase in dose by age. The target doses for DLP for head CT increased from 211 mGy-cm among children <1 year old to 604 mGy-cm in children aged 10-15 and corresponding reference doses increased from 295 to 808 mGy-cm. Doses also varied significantly by indication. Among children aged 10-15, the target dose for a head CT was 808 mGy-cm, whereas it was 328 mGy-cm for CT sinus and 1,038 mGy-cm for trauma head CT.
Conclusion: Indication- and protocol-specific target and reference doses for paediatric CT examinations can help to reduce unnecessary variations in dose by providing guidance to radiologists and technologists, thereby reducing a potential harm of CT exposure.

A 3-years retrospective study of cumulative radiation exposure from recurrent imaging for oncological patients

I. Dyakov[1], V. Stoynova[2]; [1]*Sofia/BG,* [2]*Vienna/AT (iliya.dyakov@acibademcityclinic.bg)*

Purpose: To estimate the cumulative effective dose (CED) from diagnostic, radiotherapy treatment planning and follow-up imaging studies for oncological patients and review the potential for dose reduction through improved justification and optimisation.
Methods and materials: The study was performed in an oncological hospital in Sofia, Bulgaria. 6,318 patients who underwent CT studies during 2016-2019 were retrospectively reviewed by means of dose monitoring software Dose Watch (GE Healthcare). Patients with more than 3 CTs were identified and, for each of them, CED was estimated by adding radiography, fluoroscopy, and nuclear medicine studies retrieved from Dose Watch and PACS in 3 connected hospitals. Clinical appropriateness was evaluated by a comparison to existing guidelines.
Results: Out of 6,318 patients, 1,406 (22%) underwent 3 or more CT and other imaging studies. The CED of 718 (11.4%) of all patients exceeded 100 mSv and in 263 (4 %), it was above 200 mSv, with a maximum of 1,658 mSv. From all 5,806 procedures, 64% were CTs, followed by PET-CT (13%), radiography (7%), radiotherapy CT simulation (7%), SPECT-CT (6%), mammography (2%), and angiography (1%). The follow-up studies showed no dynamic of the disease in 11% of patients and no malignancy findings in 19%.
Conclusion: The recurrent imaging studies of oncological patients are well justified in most cases. No consensus was found between existing guidelines about the type and frequency of the follow-up imaging procedures. Optimisation of CT protocols for treatment planning and follow-up was identified as the priority. A unified exposure monitoring system at a regional or national level with access to individual exposure histories of patients would help improve the care and safety of oncological patients.

RPS 1113-4 14:28

Dose optimisation for CT scans of the temporal bone using a spectral shaping tin filter

N. Saltybaeva, A. Stüssi, C. Blüthgen, S. Tanadini-Lang, M. Guckenberger, S. Winklhofer*; Zurich/CH (Sanata5@yandex.ru)*

Purpose: Despite the clinical benefits of computed tomography (CT), there are relevant concerns associated with radiation exposure to patients. Novel spectral shaping usually represented by a tin-filter (Sn) have already shown improved dose efficiency in chest and abdomen CTs. This study aims to investigate the feasibility of an Sn-filter in head CTs and to evaluate possible dose reduction.
Methods and materials: This retrospective study involved 20 patients (mean age 55.9±18.3 years). 12 patients underwent temporal bone CTs using conventional 120kVp-protocol (220 reference mAs) while 8 were scanned using 130kVp-Sn-protocol (420 reference mAs). Objective image quality for each patient was evaluated by the signal-to-noise ratio (SNR), calculated as the mean signal divided by the noise measured in the internal auditory canal (IAC), the external auditory canal (EAC), and squama temporalis (ST). Subjective image quality was evaluated by two experienced radiologists using a 5-point Likert scale (1=excellent, 2=good, 3=moderate, 4=fair, and 5=non–diagnostic). The radiation dose was assessed by the mean of CTDIvol values collected from patient dose reports. Finally, the differences in SNR and radiation dose between investigated protocols were checked for statistical significance using unpaired t-tests.
Results: The mean CTDIvol for the protocol with an Sn-filter was significantly lower than the one for the conventional protocol (26.8±2.5mGy vs 38.3±4.8mGy, p<0.001). SNR comparison has shown no significant difference between the two protocols (p=0.18, 0.11, and 0.35 for IAC, EAC, and ST, respectively). Subjective image quality assessment has shown substantial inter-reader agreement (79%) with moderate reliability (k=0.45). For both protocols, image quality for all the cases was rated as either “good” or “excellent”.

Conclusion: The study indicated that Sn-filtration in temporal bone CT allows for substantial dose reduction without compromising diagnostic image quality.
Limitations: The small cohort.
Ethics committee approval: Approved by the local ethics committee.

Accelerated Monte Carlo simulation of patients' doses in interventional radiology procedures using the MC-GPU code
M. Ginjaume, M. A. Duch, D. Fernández Bosman, C. Delgado*; Barcelona/ES (david.fernandez.bosman@upc.edu)*

Purpose: The directive 2013/59/EURATOM establishes the need to establish quality assurance programmes and the assessment of patient dose, in particular, in practices such as interventional radiology (IR) and cardiology (IC). In the framework of the European project MEDIRAD, we have developed a method for organ dose and peak skin dose monitoring of patients undergoing IR/IC procedures based on the accelerated Monte Carlo code, MC-GPU.
Methods and materials: MC-GPU has been validated by comparing the simulations with experimental measurements using TLD using regular shaped phantoms made of tissue-equivalent materials under realistic conditions. In addition, several tools have been developed to accelerate the patient organ dose calculation for a complete IR/IC procedure. On the one hand, we have prepared an interface between radiation dose structured reports and the MC-GPU code. The tool automatically generates the input files needed for the simulation. The patient is represented by the voxelised anthropomorphic phantom "REX" (Schlattl H et. al. 2007). Moreover, a graphical interface has been implemented to have a 3D colour-map of the patient's dose in the different tissues.
Results: The results show good agreement between the simulations and the experimental measurements. Differences between measured and calculated doses for the different experimental configurations were, in general, lower than 10%. The computational time needed for the simulation of a single irradiation event is a few seconds using 2 GPU cards (GeForce GTX 1080Ti).
Conclusion: It has been verified that MC-GPU is a good tool for the assessment of the absorbed dose in the different organs and for the maximum skin dose determination in patients undergoing an IR procedure.

X-ray dark-field chest radiography: the first clinical implementation
K. Willer[1], T. Urban[1], W. Noichl[1], M. Frank[1], R. C. Schick[1], B. Renger[2], T. Koehler[3], J. Herzen[1], F. Pfeiffer[1]*; [1]Garching/DE, [2]Munich/DE, [3]Hamburg/DE (konstantin.willer@ph.tum.de)*

Purpose: To demonstrate the first successful implementation of x-ray dark-field chest radiography on patients and to provide a novel medical imaging tool that generates structure sensitive information for an improved diagnostic assessment of the lung's physical condition.
Methods and materials: A prototype scanner, capable of simultaneously acquiring dark-field and attenuation chest x-rays, has been developed and installed on-site for a first experimental study on COPD patients. The system is assembled from medical x-ray components and a 3-grating interferometer. Within the currently ongoing study, 78 patients have already been examined. The subject collective includes patients without lung disorders for reference and patients with mild to severe stages of COPD. Through a questionnaire, computed tomography, and spirometry, the individual severity of the disease is assessed.
Results: The dark-field and attenuation images are obtained simultaneously in one 7s scan at an average effective dose of 0.04 mSv. We found that healthy patients exhibit a distinct and homogeneous signal over the entire pulmonary region. Here, intact alveolar structure with a lot of air-tissue interfaces induces strong small-angle scattering. In contrast, a weak signal is obtained for COPD patients, where parenchyma degradation prevails.
Conclusion: These preliminary results indicate that x-ray dark-field radiography is capable of probing the lung's underlying microstructure, which remains inaccessible with currently deployed medical imaging methods, while it is highly affected by disorders such as emphysema, fibrosis, or lung cancer. Particularly with regard to the early detection of COPD, we consider the technique's transfer to a human application as a breakthrough.
Limitations: n/a
Ethics committee approval: The study was approved by the institutional ethics review board and the federal office for radiation protection. Participants gave written informed consent.

X-ray dark-field chest radiography: scatter artefact reduction
T. Koehler[1], K. J. Engel[2], A. Yaroshenko[1], K. Willer[3], W. Noichl[3], T. Urban[3], A. A. Fingerle[4], D. Pfeiffer[4], F. Pfeiffer[3]*; [1]Hamburg/DE, [2]Eindhoven/NL, [3]Garching/DE, [4]Munich/DE (franz.pfeiffer@tum.de)*

Purpose: Dark-field x-ray imaging is a new technology to visualise the alveolar structure of lung tissue which relies on coherent small-angle x-ray scattering. Incoherent Compton scatter overlaying the dark-field signal impedes image formation and hampers diagnostic interpretation. The purpose was to develop and validate an algorithm to eliminate the contribution of Compton scatter to the dark-field signal.
Methods and materials: A slot-scanning dark-field x-ray system was used to acquire data of phantoms and subjects. Correction for Compton scattering was performed in a two-step approach. First, conventional x-ray transmission and dark-field images were generated by standard phase-retrieval. The conventional images were the input for a kernel-based scatter estimation method. Estimates for scattered intensity were calculated for each slot position and were accounted for as additional incoherent background radiation during a second-pass phase-retrieval.
Results: Dark-field images without scatter correction show artificial dark-field signal in areas with a large scatter fraction, i.e. in image areas of the spine, heart, and abdomen.
The developed scatter correction greatly reduces this artificial signal and allows for a better quantitative measurement of the true dark-field signal generated by lung tissue. Typically, the correction of the dark-field signal by application of the scatter correction algorithms is in the order of 30% in areas of the spine, 10% in the area of the heart, and 15% in the abdomen.
Conclusion: The developed method provides more quantitative dark-field signal.
Preclinical studies demonstrated the potential of dark-field radiography to detect early stages of various lung diseases. By using the proposed method, more accurate dark-field images are obtained.
Limitations: Evaluation was done on sample cases.
Ethics committee approval: The study was IRB approved. Patients signed informed consent.

The probability and impact of a high radiation dose in patients undergoing CT examinations
C. Jeukens, H. Boere, B. A. J. M. Wagemans, P. J. Nelemans, E. C. Nijssen, J. E. Wildberger, A. M. H. Sailer*; Maastricht/NL (cecile.jeukens@mumc.nl)*

Purpose: To determine the probability of receiving a high radiation dose from single or multiple CT examinations and to assess the potential impact by

evaluating clinical indications for multiple CT examinations and associated prognosis of high-dose patients.
Methods and materials: All CT examinations performed at our institution between 01/07/2013-01/07/2018 for which radiation dose data was available were included. The effective dose received by single or multiple CT examinations was assessed for each patient using dose monitoring software. The probability of receiving a high dose (i.e. ≥50mSv (single) or ≥100mSv (multiple)) was evaluated using survival analysis for women, men, different age categories, and the total number of CT examinations received. Baseline characteristics and the probability of survival up to 4.5 years were assessed for high-dose patients, taking clinical indication into account.
Results: An effective radiation dose was available for 100,672 CT examinations performed amongst 49,978 patients, 649 of whom received a high radiation dose. The estimated high radiation dose probability was 0.43% for a single examination and 1.5% (men) to 1.9% (women) for repeated examinations over a period of 4.5 years. Factors increasing this probability are female sex, especially in the age category 51-64 (probability=3.02%), and >6 CT examinations (probability>16%). The impact on survival is limited because high-dose patients are often severely ill: 65% of high-dose CT examinations were oncology-related and 48% of high-dose patients died within 4.5 years from pre-existing medical conditions.
Conclusion: The probability of receiving a high radiation dose from CT examinations is small but not negligible. High-dose patients often had pre-existing conditions with a high risk of premature death. Consequently, the impact of a high radiation dose is expected to be small on a population level.
Limitations: The data originates from a single centre.
Ethics committee approval: The study was approved and written informed consent was waived.
Funding: No funding was received for this work.

First SSDE reference values for paediatric head CT examinations

A. S. L. Dedulle, K. Houbrechts, N. Fitousi, J. Jacobs, H. Bosmans*; Leuven/BE (an.dedulle@qaelum.com)*

Purpose: To investigate the water equivalent diameter (WED) and size-specific dose estimates (SSDE) for paediatric head computed tomography (CT) examinations on two CT devices.
Methods and materials: Paediatric brain CT examinations from one year were investigated for two Siemens devices, with one located at the emergency (ER) department (CT_1 and CT_{ER}). The WED of the middle slice of the CT series was determined and used to calculate the SSDE according to AAPM report 293. The paediatric patients were categorised into 5 age groups (A: 0-1y, B: 1-5y, C: 5-10y, D: 10-15y, and E: 15-18y). A Mann-Whitney test was used to compare the WED and SSDE of the age groups for both scanners.
Results: At CT_1 and CT_{ER}, respectively, 128 and 207 scans were carried out. The correlation between patient age and WED was significant (CT_1: r^2=0.73, CT_{ER}: r^2=0.71). The mean WED and SSDE of the age groups CT_1 were A: 14 cm, 16 mGy; B: 16 cm, 16 mGy; C: 17 cm, 19 mGy; D: 18 cm, 21 mGy; E: 18 cm, 29 mGy. For the same age groups, the WED was not significantly different (p>0.05) between the two devices. For the age groups up to 10 years (A-C), the SSDE was also not significantly different (p>0.05), however, SSDE differed significantly (p<0.05) for the age groups above 10 years (D-E), with a mean SSDE of 24 mGy and 31 mGy for CT_{ER}.
Conclusion: Several European documents suggest the use of patient weight rather than age for dose investigation purposes. As weight may not be available at the moment of dose monitoring, SSDE is a valid alternative. It can be calculated and scaled with $CTDI_{vol}$ (and therefore attenuation). We provide the first set of reference values.
Limitations: No access to the clinical indication of the head CT examinations.

The small-size detail detection performance of digital breast tomosynthesis, synthetic 2D, and conventional full-field digital mammography images for different mammography systems: a multicentre study

V. Ravaglia[1], L. Angelini[2], M. Bertolini[3], G. della Gala[4], S. Farnedi[1], P. Golinelli[5], L. Pagan[6], N. Scrittori[1], G. Venturi[7]*; [1]Ravenna/IT, [2]Rimini/IT, [3]Reggio Emilia/IT, [4]Sassuolo/IT, [5]Modena/IT, [6]Bologna/IT, [7]Forli'/IT (valentina.ravaglia@auslromagna.it)*

Purpose: To compare the small-size detail detection of combined modalities DBT+S (digital breast tomosynthesis and synthetic 2D) and DBT+FFDM (DBT and conventional full-field digital mammography) for mammography systems of different models and vendors.
Methods and materials: 15 different mammography systems of 9 different models were compared. We used a home-made phantom composed by CDMAM (Artinis), homogeneous PMMA slabs, and BR3D tissue-equivalent slabs (Cirs) containing an anatomic noise in order to obtain different phantom configurations equivalent to 32, 60, and 90 mm breast thicknesses.
The CDMAM phantom was composed of an aluminium slab with gold details of different diameter and thickness. For this study, we focused only on small details ranging from 0.5 to 0.1 mm that simulate microcalcifications.
We exposed at 2 different dose levels (one obtained with a clinical automatic exposure programme and the other with manual “fixed” parameters) and the processed images were successively divided into squared sub-images, each containing a detail of different size and contrast. The sub-images were rotated and displayed in random order on a 5MP calibrated monitor to 4 trained readers. The percentage correct rate for DBT+S and DBT+FFDM was evaluated.
Results: As an example, the percentage correct rate for 4 different systems for details 0.4 mm and 0.1 mm is shown.
Conclusion: For details greater than 0.4 mm, the combined modalities DBT+S and DBT+FFDM show a similar detectability in all the systems. For smaller details, the difference in the detection between the 2 combined modalities depends on the system.
Limitations: The use of a physical phantom, composed of aluminium and gold details, could affect the reconstruction algorithm for DBT and s-2D.

RPS 1113-11 15:10

Image quality evaluation of a new high-resolution 3-D digital breast tomographic (DBT) imaging system

J. C. O' Driscoll[1], E. Ranahan[1], M. F. M. McEntee[2], J. McCullagh[1]*; [1]Cork/IE, [2]Sydney/AU (jessicadrscll1@gmail.com)*

Purpose: To compare the performance of the Hologic Selenia 3Dimensions, the newest generation high-resolution DBT imaging system with the Dimensions 8000 model, the standard resolution DBT imaging system. The high-resolution system saves pixels to their native detector resolution of 70 µm while the standard resolution system 2 x 2 rebins pixels to 140 µm for tomosynthesis acquisitions.
Methods and materials: Spatial resolution was assessed using a modulation transfer function (MTF). Contrast performance was analysed using a signal difference to noise ratio (SDNR) and the BR3D test object. Contrast detectability was evaluated using the CDMAM 3.4 test object. The noise was examined using the normalised noise power spectrum (NNPS). The mean glandular dose (MGD) was also assessed.
Results: The 70 µm high-resolution system demonstrated a mean improvement of the $MTF_{0.5}$ value by 40% and 27% in the x and y directions. An average reduction of 64% in SDNR was observed. The detection of features in the BR3D test object improved. The mean threshold gold thickness for the 0.1 mm detail size was 58% lower. Increased NNPS values of 8% at 0.5 mm^{-1} and 16% at 2

mm^{-1} were calculated. For breast thicknesses over 45 mm, MGD was reduced for 2-D imaging. Similar MGDs were calculated for both systems for volumetric imaging.
Conclusion: An overall improvement in image quality with no subsequent increase in patient dose for the 70 µm high-resolution system was demonstrated. Findings suggest that saving pixels to 70 µm provides an improvement in spatial resolution, improved visibility of pathological features, and enhanced detection of thinner discs at detail diameters similar to calcifications. Further work will examine whether these improvements impact clinical outcomes.

The use of automatic software for quality controls to detect defective phantoms
G. Gennaro, F. Caumo*; Padua/IT (gisella.gennaro@iov.veneto.it)*

Purpose: To use a software package designed for the automation of routine quality control (QC) tests in digital mammography to detect phantoms with manufacturing defects.
Methods and materials: 24 Leeds TORMAS phantoms to be employed in routine tests of mammography units used within a regional screening programme were preliminarily tested to exclude the possible presence of defects. Two images of each test object were acquired using the same digital mammography equipment, one in a manual exposure mode to enhance possible differences while minimising variability due to the imaging system itself and one in an automatic exposure mode (AEC) with the phantom on the top of a 35 mm polymethyl-methacrylate (PMMA) stack to reproduce the same conditions as in the routine use. 15 image quality indices (IQIs) automatically calculated by the software tool used for routine tests were selected to evaluate phantom homogeneity and detect possible defects. Outliers were computed for each IQI and their impact on phantom homogeneity analysed.
Results: 8 outliers were found in 5 different IQIs from the images acquired in the manual mode associated to 7 phantoms. The impact of 4/7 outliers (57%) was mitigated in the images acquired with the PMMA in the AEC mode as used for routine tests; the 4 phantoms generating those outliers were thereby assumed to be acceptable. The 3 phantoms including outliers measurable from both datasets (without and with PMMA) were considered defective and were replaced with new phantoms.
Conclusion: Software tools employed for routine QC tests can be successfully used to test phantom quality and detect possible manufacturing defects.
Limitations: The limited number of images acquired per phantom due to time constraints.
Ethics committee approval: n/a
Funding: No funding was received for this work.

RPS 1113-13 15:22
The evaluation of the quality of education in courses on radiation protection in Germany
P. Strauß*; Münster/DE (patrick.strauss@ukmuenster.de)*

Purpose: In Germany, a specific qualification is required to get permission to justify medical exposure in accordance with German regulations to diagnose and applicate x-ray. For this, specific courses on radiation protection are legally mandatory. One focus is on the correct use of equipment for radiation protection and justifying medical exposure. For comparison, the legal bases of the course concepts in Switzerland and Austria were also examined.
Methods and materials: Investigators attended all mandatory courses on radiation protection for their entire length (basic, advanced, and up-to-date refresher courses). A total of 15 different courses from 6 different organisers were evaluated. Structured interviews with course organisers were conducted. The participants' prior and gained knowledge during the attended courses was determined separately by multiple-choice questions. Structured checklists were developed, assuring consistent evaluations of the courses. The investigator's methods and checklists were developed and affirmed by experts in workshops. Representatives of professional societies were interviewed.
Results: Following the evaluation, it was concluded that the quality of knowledge transfer was divergent. An increase of knowledge could always be confirmed statistically, but often the clinical relevance and up-to-date contents were missing. All investigated courses complied with the mandatory content guidelines. The compulsory up-to-date refresher courses were found to be refreshing basic knowledge mostly instead of presenting new developments and technologies in radiation protection.
Conclusion: To achieve a more appropriate learning situation in the courses, proposals are made, including a new target-group-specific course configuration with reduced attendance times. A specific course for radiation safety officers similar to Austria's concept is suggested. Subject catalogues for the redesigned courses were created and could be used for harmonisation throughout Europe.
Limitations: Only courses on radiation protection in Germany were evaluated.
Ethics committee approval: n/a
Funding: Funding by Bundesamt für Strahlenschutz.

Response to balloon pulmonary angioplasty in treated versus untreated pulmonary arteries in CTEPH patients
Z. Zhai[1], H. Ota[2], M. Staring[1], J. Stolk[1], K. Sugimura[2], K. Takase[2], B. Stoel[1]*; [1]Leiden/NL, [2]Sendai/JP (z.zhai@lumc.nl)*

Purpose: Balloon pulmonary angioplasty (BPA) is a treatment of obstructed pulmonary arteries (PAs) for patients with inoperable chronic thromboembolic pulmonary hypertension (CTEPH). Since the effect of BPA in untreated (unobstructed) PAs is unknown, we investigated the treatment response in treated and untreated PAs by analysing CT pulmonary angiography (CTPA).
Methods and materials: We studied 22 consecutive CTEPH patients (20 female; age 67±14) who underwent CTPA and right-heart catheterisation (RHC) pre- and post-BPA. In consensus, 3 experts selected treated artery segments based on the BPA locations and approximately 5 untreated artery segments at a similar level. Post-BPA CTPA scans were registered to pre-BPA scans and local intravascular density changes were measured. The median density change in treated (MDC_T) and untreated segments (MDC_U) was calculated based on manual selections. The difference between MDC_U and MDC_T was tested by a paired t-test. The difference in density changes (ΔMDC) between treated and untreated PAs was calculated (MDC_T-MDC_U). Changes in RHC parameters included systolic, diastolic, and mean pulmonary artery pressure (ΔsPAP, ΔdPAP, and ΔmPAP) and in pulmonary vascular resistance (ΔPVR). The relation between haemodynamic changes and ΔMDC was studied with Spearman's correlation.
Results: MDC_T (51±85 HU) and MDC_U (-23±103 HU) were significantly different and in the opposite direction (p=0.001). ΔMDC was significantly correlated with ΔdPAP (R=-0.55, p=0.008) and ΔPVR (R=-0.47, p=0.026), and marginally correlated with ΔmPAP (R=-0.4, p=0.068).
Conclusion: Perfusion in treated PAs increased, whereas perfusion in untreated PAs decreased. Not only improved perfusion in treated arteries but also the normalisation in untreated arteries may play a significant role in improving haemodynamics by BPA.
Limitations: The normal vascular perfusion of healthy people is lacking.
Ethics committee approval: Approved by the local ethics committee and written informed consent from patients was obtained.

Pulmonary artery enlargement is independently associated with 1-year mortality in transcatheter aortic valve replacement patients: a retrospective longitudinal study

V. L. Turner[1], M. J. Willemink[1], A. Jubran[2], J. B. Kim[1], E. M. Maret[3], K. J. Moneghetti[1], F. Haddad[1], D. Fleischmann[1]; [1]*Stanford, CA/US,* [2]*Haifa/IL,* [3]*Stockholm/SE (vturner@stanford.edu)*

Purpose: Pulmonary hypertension has been shown to be an independent predictor of poor outcome in patients undergoing transcatheter aortic valve replacement (TAVR). In this retrospective longitudinal study we sought to evaluate whether pulmonary artery enlargement measured on pre-procedural computed tomography angiography (CTA) is associated with 1-year mortality in patients after TAVR.
Methods and materials: We retrospectively included 402 patients undergoing TAVR from July 2012-March 2016. Clinical parameters and pre-procedural CTA scans were retrospectively reviewed. Patients were followed for all-cause mortality. The main pulmonary artery (MPA) area and diameter were measured on pre-procedural CTAs near the bifurcation on double-oblique reformations. Kaplan-Meier and Cox proportional hazards regression analyses were performed.
Results: The median follow-up time of 402 patients was 433 (interquartile 339-797) days. A total of 56/402 (14%) died within 1 year after TAVR. MPA area ($p<0.001$) and the Society of Thoracic Surgery risk scores (STS-score) ($p=0.001$) were significantly larger in 1-year non-survivors (N=56) versus survivors (N=346). Multivariate Cox analysis adjusted for age, gender, STS score, cardiac risk, frailty, and NYHA classification showed that both MPA area (HR1.30 [95%-CI 1.16–1.46] per cm^2, $p<0.001$) and STS-scores (HR1.10 [1.02–1.20] per STS point, $p=0.0016$) were independently associated with 1-year mortality. The area under the curve for 1-year mortality was similar for MPA area (AUC=0.67 [95%-CI 0.59–0.75]) compared to STS-score (AUC=0.64 [95%-CI 0.57–0.72]). Kaplan-Meier analysis showed that the mortality of patients with a pre-procedural MPA area of ≥7.4 cm^2 was significantly higher compared to patients with a smaller MPA area of <7.4c m^2 (mortality 23% vs 9%; log-rank $p<0.001$).
Conclusion: The enlargement of MPA on pre-procedural CTAs is independently associated with post-procedural 1-year mortality in patients who undergo TAVR.
Limitations: A retrospective single-centre design. Further studies are needed to demonstrate the reproducibility of our results in other CT scanners and cohorts.

The cost-effectiveness of contrast-enhanced ultrasound (CEUS) for the detection of type I and III endoleaks after EVAR: the role of CEUS as the most cost-effective imaging modality

M. F. Froelich[1], W. G. Kunz[2], S. H. Kim[3], D.-A. A. Clevert[2], J. Rübenthaler[2]; [1]*Mannheim/DE,* [2]*Munich/DE,* [3]*Frankfurt am Main/DE*

Purpose: Follow-up after endovascular aortic repair (EVAR) is necessary to detect complications. Computed tomography or magnetic resonance angiography (CT-A/MR-A) are used as a standard of care. Contrast-enhanced ultrasound (CEUS) has been shown to be an imaging modality with equipollent diagnostic accuracy. The aim of this study was to determine the cost-effectiveness of this imaging method in comparison to others for the evaluation of type I and III endoleaks.
Methods and materials: A decision model based on Markov simulations estimated lifetime costs and quality-adjusted life-years (QALYs) associated with CT-A, MR-A, CEUS, and colour-Doppler. Model input parameters were obtained from recent literature. Probabilistic sensitivity analysis was performed to estimate the uncertainty of model results. Net monetary benefits, incremental costs, incremental effectiveness, and incremental cost-effectiveness ratios were derived from the probabilistic sensitivity analysis. The willingness-to-pay (WTP) was set to $100,000/QALY.
Results: In the base-case scenario for a WTP of $100,000 per QALY, CT-A and MR-A were dominated strategies resulting in lifetime costs of $20,374.77 for CT-A and $20,673.71 for MR-A, with expected effectiveness of 9.556 QALYs vs 9.564 QALYs. Colour-Doppler showed an expected cost of $19,868.57 with 9.532 QALYs whereas CEUS reached costs of $20,050.19 with 9.564 QALYs, resulting in an ICER of $5,720.91/QALY.
Conclusion: CEUS is a cost-effective imaging method for the evaluation of type I and III endoleaks in endovascular aortic repair surveillance.
Limitations: The average age of patients entering the model was set to 70 years, which is in line with existing literature for the likelihood of endoleaks, but neglects the fact that there must also be younger patients with endoleaks after EVAR.

Value of dynamic perfusion computed tomography in the detection and classification of endoleaks after endovascular aortic repair (EVAR)

J. Stroeder[1], D. Kerner[1], A. Massmann[1], J. F. M. Gawlitza[1], A. Bücker[1], R. Kubale[2], P. Fries[1]; [1]*Homburg/DE,* [2]*Pirmasens/DE*

Purpose: To assess the value of dynamic perfusion computed tomography (CT) in the detection and classification of endoleaks in patients after EVAR.
Methods and materials: 10 patients (9 males/1 female; mean age 76.8 years +/- 5 years) after EVAR with known endoleaks diagnosed with contrast-enhanced ultrasound or standard CT were included. They underwent a contrast-enhanced dynamic perfusion CT using a third-generation dual-source scanner (Somatom Force, Siemens Healthineers, Erlangen, Germany) to identify the origin of the endoleaks. We retrospectively performed contrast attenuation measurements for all time points based on region of interest (ROI) measurements within the stent lumen and the perfused endoleak within the aneurysm sac and in the inferior mesenteric artery. Perfusion characteristics were graphed for the assessment using commercially available software (SyngoVia, Siemens Healthineers, Erlangen, Germany). Differences between areas under the curves (AUC) were analysed by ANOVA and Tukey's test.
Results: The contrast attenuation time curve pattern and the AUC for the perfused endoleak within the aneurysm sac is similar to the feeding vessel, allowing for differentiation between type 1 and type 2 endoleaks. The dynamic perfusion CT and the graphing of the findings was a helpful tool in the assessment of endoleak characteristics. Significance of AUC differences for Type 2 endoleaks was $p<0.0001$.
Conclusion: Dynamic perfusion CT helps to correctly identify and classify endoleaks after EVAR, which has a marked impact on patient management.
Limitations: A single-centre, retrospective study.
Ethics committee approval: Written informed consent was obtained.
Funding: No funding was received for this work.

Dual-energy CT iodine mapping and virtual monochromatic series applications in the diagnosis of endoleak after endovascular aortic repair (EAVR) planning

P. Hou; *Zhengzhou/CN (houping1221@163.com)*

Purpose: To assess the diagnostic value of endoleak conspicuity amongst DECT monochromatic series, iodine mapping, and conventional images with follow-up CTA after EAVR planning.
Methods and materials: 19 patients that required follow-up CTA after EVAR with 23 endoleaks (17 medium endoleaks; 6 small endoleaks) underwent spectral CT to generate conventional 140-kVp polychromatic images (group A), monochromatic images with energy levels from 40 to 70keV (group B), and iodine mapping (group C). Clinical and operative outcomes were recorded as the reference standard. Two radiologists independently analysed lesion conspicuity to assess sensitivity and specificity.
Results: Sensitivity and specificity were both 100% for medium endoleaks on images among all groups. For small endoleaks in the comparison of the conventional images, sensitivity for detection increased from 63.6% (95% CI, 30.8-89.1%) to 98.1% (95% CI, 68.2-100%), 98.7% (95% CI, 75.5-100%), and 100% (95% CI, 71.5-100%) when iodine mapping, 50kev, and 60keV images were assessed, respectively. The number of false-positives were increased with

40keV images. The small endoleaks were poorly visualised in group A and 70kev images. Interobserver agreement were moderate (κ=0.45) and substantial (κ=0.63) among iodine mapping and monochromatic images, respectively.
Conclusion: Iodine mapping and virtual monochromatic images (50kev and 60kev levels) increase the conspicuity of endoleaks of the aorta, resulting in improved diagnostic accuracy compared with a review of conventional CT images alone.
Limitations: This investigation reflects our preliminary experience with a relatively small number of patients. Different detector configurations caused some variability in the imaging parameters.
Ethics committee approval: This prospective single-institution study was approved by the Human Research Committee of our institutional review board and all patients provided written informed consent.
Funding: No funding was received for this work.

The incidence of penetrating aortic ulcer (PAU) as a cause for non-aneurysmal rupture of the abdominal aorta: a single-centre experience

K. Andreychuk[1], N. Chernaya[2], V. E. Savello[1], N. N. Andreychuk[1], O. Krotova[1]; *[1]St. Petersburg/RU, [2]Moskow/RU (andreychuk@cvsurgery.ru)*

Purpose: Selected reports declare that spontaneous ruptures of non-aneurysmal, non-infected abdominal aortas are extremely rare. Many authors suppose the main cause is a penetrating aortic ulcer (PAU). Unfortunately, only single reports regarding single cases of PAU located in the abdominal aorta can be revealed. In this study, we analysed our experience in the diagnosis and management of complicated PAU in the abdominal aorta.
Methods and materials: 48 patients with non-aneurysmal rupture of the abdominal aorta due to PAU (median age 61 years; 32 women) were included in this report. In all cases, patients had clinical signs of internal bleeding, so aneurysmal rupture was suspected as the main cause on admission. The diagnosis was determined by ultrasound and CTA.
Results: The radiologic findings included typical signs of PAU (the same as the signs in the thoracic aorta) represented by non-dilated aorta with a strong calcified wall, single or multiple crateriform ulcers, and ulcer bottom defect with extravasation. In this area, retroperitoneal haematoma with contrast uptake was detected. In rare cases where the PAU and consequent rupture were located in the posterior wall of the aorta, a temporary restricted (two-stage) rupture without signs of continuing bleeding could be observed. The following histopathological examination confirmed PAU with wall destruction. The majority of patients underwent surgical repair (35 open and 9 endovascular). 7 patients died.
Conclusion: Our experience indicates that PAU in the abdominal aorta and following non-aneurysmal rupture is quite rare, but not a casuistic aortic emergency condition. This should be suspected in each case of non-traumatic retroperitoneal bleeding. The diagnostical and tactical approach should be the same as in cases of acute aortic syndrome based in the thoracic aorta.

An evaluation of the changes of renal blood flow before and after an operation in patients with aortic dissection

D. Liu*; Beijing/CN (dongting0530@163.com)*

Purpose: To investigate the changes of renal CT perfusion in aortic dissection (AD) patients before and after an operation and to access the feasibility of the clinical diagnosis.
Methods and materials: 31 patients with AD who underwent 320-row CT renal perfusion before and after operation were included. Blood flow (BF), blood volume (BV), and the clearance of the bilateral kidneys were measured. A comparison of the difference of perfusion parameter values before and after the operation and various CT imaging signs of AD were observed.
Results: The BF values measured between the true lumen, false lumen, and overriding groups were different (p<0.05); the false lumen group was the lowest. The BV of the true lumen and the overriding group was statistically different (P<0.05) after the operation; the overriding group was the lowest while other groups had no significant difference (P>0.05). The value of BV and clearance decreased after the operation (P<0.05), BF had no significant difference (P>0.05), the BV of the false lumen group decreased (P<0.05), and BF and clearance had no significant difference (P>0.05). The perfusion parameters of the overriding group had no significant difference (P>0.05) before and after the operation.
Conclusion: Perfusion imaging using 320-slice dynamic volume CT can be used to evaluate haemodynamic features of the kidneys. Both surgical and interventional operations can affect renal perfusion. Perfusion imaging is helpful in evaluating the renal functional status preoperation and in discovering renal ischaemia postoperation.
Limitations: The number of participants included in this study was relatively small, which was based on a single-centre experience. Further studies based on the analysis of more cases are required.
Ethics committee approval: This prospective study was approved by our institutional review board.
Funding: No funding was received for this work.

A feasibility study of virtual non-contrast imaging derived from single-source fast kVp-switching dual-energy CTAs in patients with aortic dissection

B. Wen, J. Liu, L. Xu*; Beijing/CN (wwwyyner@163.com)*

Purpose: To study the feasibility of virtual non-contrast (VNC) imaging derived from single-source fast kVp-switching dual-energy arterial phase CTAs in evaluating the status of patients with aortic dissection and to calculate the potential radiation dose reductions.
Methods and materials: 50 consecutive patients with aortic dissection were examined with CT scans including TNC imaging using conventional single-energy mode at 120 kVp and arterial phase CTA utilising the rapid kVp-switching dual-energy CT technique (80 kV/Sn140 kV) of the aorta. VNC images were obtained from an arterial phase CTA dataset. Two radiologists independently evaluated the image quality of TNC and VNC images. The mean attenuation and image noise of various regions of the aorta and abdominal organs were measured on TNC and VNC images.
Results: Interobserver agreement was excellent. For almost all locations, the CT value and image noise were lower at VNC than at TNC. The CNR of different locations showed no significant difference. Subjective image score was lower for VNC (4.52±0.53 vs 4.31±0.51, P>0.05) but there were no cases rated non-diagnostic. The effective dose for dual-phase was 11.22±1.91mSv and for single-phase was 6.85±1.76 mSv. The dose saving by removing the TNC was 4.37±0.54 mSv (39.7%).
Conclusion: In patients with AD, the VNC images derived from single-source fast kVp-switching dual-energy CTs can provide comparable image quality to TNC images and reliable diagnostic information. Replacing TNC images will lower radiation dose by 39.7%.
Limitations: The study was only a single-centre study applicable to the GE revolution CT. Our results were vendor-specific and the results may vary with other patient populations.
Ethics committee approval: The study was approved by our hospital's ethics committee and all patients provided written informed consent.
Funding: No funding was received for this work.

High-frequency 3D lumen volume ultrasound is a sensitive method to detect early aneurysmal changes in elastase-induced murine abdominal aortic aneurysms

M. A. Waduud, P. Kandavelu, M. Reay, J. Scott, M. Bailey*; Leeds/UK (m.a.waduud@leeds.ac.uk)*

Purpose: To investigate the reproducibility of anterior-posterior diameter (APDmax) and three-dimensional lumen volume (3DLV) measurements of abdominal aortic aneurysms in a classical murine AAA model. We also investigated the sensitivity of each method to detect changes in AAA size.
Methods and materials: Peri-adventitial application of porcine pancreatic elastase (PPE AAA) or sham surgery was performed in two cohorts of mice. Cohort 1 was used to assess for observer variability with APDmax and 3DLV measurements. Cohort 2 highlighted the relationship between APDmax and 3DVL and the changes in AAA detected.
Results: There was no significant observer variability detected with APDmax measurement. Similarly, no significant intraobserver variability was evident with 3DLV, however, a small but significant interobserver difference was present. APDmax and 3DLV measurements of PPE AAA significantly correlated. Changes in the AAA morphology were detected earlier with 3DLV.

Conclusion: APDmax and 3DLV are both reliable methods of measuring an AAA. Both these methods correlate with each other. However, changes in AAA morphology are detected earlier with 3DLV, which is important in detecting subtle but important changes to aortic geometry in a laboratory setting.
Limitations: This was a proof-of-principle animal study.
Ethics committee approval: Animal work was carried out in accordance with the UK Animals (Scientific Procedures) Act 1986 under Home Office Project Licence PPL: P606320FB.
Funding: This work was funded by the British Heart Foundation (BHF). MAW is a BHF clinical training research fellow and MAB is a BHF intermediate clinical fellow.

Sex differences in vulnerable plaque composition and morphology in patients with mild-to-moderate carotid artery stenosis

D. H. Dam-Nolen[1], N. C. van Egmond[1], M. E. Kooi[2], J. Hendrikse[3], P. J. Nederkoorn[4], P. J. Koudstaal[1], D. Bos[1], A. van der Lugt[1]; [1]*Rotterdam/NL,* [2]*Maastricht/NL,* [3]*Utrecht/NL,* [4]*Amsterdam/NL (h.nolen@erasmusmc.nl)*

Purpose: For not yet fully understood reasons, the stroke incidence rate is higher in men than in women. Carotid atherosclerosis is a major cause of ischaemic strokes. Several plaque components are important determinants for plaque progression and rupture. Sex differences in these so-called vulnerable plaque characteristics, including intraplaque haemorrhage (IPH), lipid-rich necrotic core (LRNC), thin or ruptured fibrous cap (TRFC), and ulcerations, may help further explain sex differences in strokes. This study aims to analyse sex differences in plaque composition and morphology in symptomatic patients.
Methods and materials: We selected 238 patients from the Plaque At RISK-study (PARISK), which included patients with recent ischaemic symptoms and <70% ipsilateral carotid artery stenosis. Plaque characteristics were assessed with MRI (n=224) and MDCTA (n=188). We used multivariable logistic regression analyses to assess the effects of sex on the presence and volume of plaque characteristics. Differences in volumes were analysed using multivariable linear regression models in those patients in whom the plaque component of interest was present.
Results: Men had significantly higher plaque burden (β=23.05, 95%CI:15.81-30.29). Men also had a higher prevalence of IPH (OR=3.29, 95%CI:1.54-7.50) and LRNC (OR=2.40, 95%CI:1.25-4.62) after an adjustment for age and plaque burden. These associations remained significant after additionally adjusting for cardiovascular risk factors and medication (OR=2.79, 95%CI:1.25-6.60; OR=2.48, 95%CI:1.23-5.07). In patients with IPH and/or LRNC in their symptomatic carotid plaque, the volume of IPH and LRNC was not significantly associated with sex after an adjustment for age and plaque burden. Sex was not associated with the presence of TRFC, ulcerations, and calcifications.
Conclusion: Vulnerable plaque components like IPH and LRNC are more common in men than women in symptomatic patients with mild-to-moderate carotid stenosis.
Limitations: n/a
Ethics committee approval: Institutional review board approval was obtained. All patients gave written informed consent.

Carotid plaque neovascularisation detection and assessment accuracy with the contrast-enhanced ultrasound (CEUS) method

A. Lioznovs, M. Radzina, A. Lacis, A. Jukna, I. Briede, Y. Solskaya, L. Dronka, S. Pavlovics*; Riga/LV (lioznov1@gmail.com)*

Purpose: Contrast ultrasound (CEUS) is an effective method that can detect the presence of neovascularisation in unstable atherosclerotic plaques and significantly reduce cerebral stroke risk. The purpose of the study was to analyse the CEUS technique ability to confirm plaque instability in correlation with CTA and histological findings in order to determine the method's accuracy and limitations.
Methods and materials: During the prospective research, conducted from 2017-2019, 54 patients with 72 plaques detected with a duplex US were included. Every patient was analysed with CEUS, DUPLEX, and CTA to compare the accuracy of the imaging methods. 30 endarterectomies were performed and the histology of the atherosclerotic plaques was acquired. Based on CEUS results, two groups were identified: poor (grade 1) neovascularisation and well visible (grade 2) vasa vasorum. Each group was correlated with histological findings.
Results: The neovascularisation was diagnosed in 27/72 (37.5%) patients by CEUS. In 12 cases (16.7%), plaques showed grade 1 neovascularisation and in 15 cases (23.2%), grade 2. The presence of neovascularisation was proved by histology in all CEUS positive cases from 2-39 microvessels. Comparing the CEUS method and results of histology, a statistically significant correlation was found (r_s=0.099; p=0.704) and the method's sensitivity, specificity, positive predictive value, negative predictive value, and accuracy were 82.4%, 69.2%, 77.8%, 75%, and 76.7%, respectively. A statistically significant correlation between neovascularisation was found in terms of contrast time and CEUS for neovascularisation grades (0.633; p=0.06).
Conclusion: CEUS imaging provides additional information in the detection of plaque instability with high accuracy, sensitivity, and specificity, regardless of the stenosis grade and corresponding well to histological results.
Limitations: It was observed that calcified and partially calcified plaques had a smaller number of microinvasions, but no significant correlation was found, possibly due to the small number of patients (rs–0.9; p=0.31).

Vessel wall imaging using CT: an innovative dual-energy protocol for differentiating vascular pathologies

W. Zhou, A. C. C. Goh*; Sydney/AU (kimwx.zhou@gmail.com)*

Purpose: Vascular diseases have traditionally been evaluated with luminal imaging, however, pathologies such as fibromuscular dysplasia, intramural haematoma, vasculitis, and atheroma can be better differentiated if the vessel wall can be directly imaged (Alexander, 2017).
We describe a novel technique to image the blood vessel wall using dual-energy CT rather than the established techniques with MRI.
Methods and materials: Contrast-enhanced exams were performed on a clinical CT scanner with the capability for dual-energy and calcium suppression. Routine dual-energy scan protocol was selected, including gated and non-gated aortogram, pulmonary angiogram, renal/mesenteric angiogram, portal venous abdomen, and other angiographic studies of the head, neck, and limbs. Calcium suppressed image reconstruction was performed in addition to routine reconstructions using a selection of experimental parameters including calcium suppression strength, slice thickness, the field of view, and kernel sharpness.
Results: Using calcium suppression reconstruction, contrast-enhanced blood is effectively suppressed to negative modified-HU, allowing the direct visualisation of the vessel wall for the aorta, pulmonary vessels, portal vein, coeliac artery, superior mesenteric artery, and renal artery. Small visceral vessels of the chest and abdomen are also well reconstructed by this method to show the vascular wall.
Conclusion: Prior knowledge of vessel wall imaging has required the use of MRI. We propose a novel method for high-resolution CT imaging of vessel wall morphology, with advantages such as short exam time and better patient tolerance. This has the potential for improving the diagnosis and management of vasculopathies.
Limitations: The study is limited by the number of scans analysed and the lack of same-patient comparison with MRI as the existing gold standard of vessel wall imaging.

Inguinal lymphadenopathy as a predicting factor for primary amputation in patients after endovascular treatment
D. Raskin, S. Balan, O. Mozes, D. Silverberg, A. Aburamila, M. Halak, U. Rimon*; Ramat Gan/IL (oshry.mozes@sheba.health.gov.il)*

Purpose: To assess the correlation between inguinal lymph node characteristics and ipsilateral primary limb amputation rates in patients with ischaemic foot ulcers who underwent technically successful endovascular treatment.
Methods and materials: A retrospective review of patients who were endovascularly treated for ischaemic foot ulcers from January 2015-May 2017. Unilateral lymph node size, contrast enhancement, necrosis, and perinodular fat infiltration were assessed on pre-procedural computed tomography angiography. Primary endpoints were amputation and sepsis within six months following treatment. Independent samples t-tests and a Chi-square test of independence examined the relationship between lymph node characteristics and limb amputation and septic shock.
Results: Endovascular treatment of 202 limbs in 202 patients (135 males; median age 72.8 years [range, 42.2-93.7]) was technically successful. 42/202 (20.8%) patients underwent amputation and 6/202 (3%) patients had sepsis. There was a significant difference in lymph node sizes between the amputated and the non-amputated limbs (P=0.000). Lymph node characteristics were significantly related to amputation (P<0.001). Perinodular fat infiltration or increased node size were associated with the likelihood to undergo limb amputation than the others, respectively. Lymph node characteristics were also related to septic shock (P<0.05).
Conclusion: Limb amputation and ipsilateral lymph node size and characteristics are associated with the technically successful endovascular treatment of patients with ischaemic foot ulcers. Moreover, increased lymph node size and perinodular fat infiltration predicted limb amputation.
Limitations: A retrospective study restricted to the imaging characteristics of the inguinal lymph nodes of selected patients with ulcers lacking apparent infection.

The effect of different compression stockings on venous malformations: a systematic assessment of morphology and quality of life
R. Heiß, A. Dr. Mükke, M. S. May, W. Wuest, M. Uder, R. Janka, W. Lang*; Erlangen/DE (Rafael.Heiss@uk-erlangen.de)*

Purpose: To analyse the effect of different compression therapies on venous malformations (VM).
Methods and materials: Patients with VM in the upper and lower extremities (N=20) were eligible for the study. Patients were treated with compression stockings class I and II for 4 weeks in a randomised order. Patients and physicians were blinded to the compression class. The absolute volume of the VM was measured by segmentation in MRI images. The volume of the extremity was obtained by perimetry measurements (PER). Quality of life was assessed by the SF-12 score. MRI and PER were performed at baseline and after the wearing period of 4 weeks of each compression class.
Results: In comparison with baseline measurements, both compression classes showed a significant reduction of the volume of the VM in MRI scans (p<0.001), whereas the decrease of the lesions' volume was inforced by compression class II (p=0.039). In contrast, PER did not reveal significant differences in comparison to the baseline for both compression classes (p=0.26, p=0.055). No subgroup in the quality of life assessment showed a significant difference between compression classes.
Conclusion: MRI is an applicable tool for the systematic assessment of the total volume of VM. Both compression stockings class I and II reduce the total volume of VM, with superiority in class II. As there is no difference in the quality of life between both compression classes, class II compression stockings may be recommended for conservative treatment of patients with local swelling and pain caused by VM.
Limitations: The limited number of patients with intraindividual comparison of different interventions.
Ethics committee approval: IRB (Institutional Review Board) approval was obtained from Friedrich-Alexander-University Erlangen-Nuremberg, Germany (124_17 B).

The results of an ultrasound vein valve study change current saphenous therapy
J. C. Ragg, J. Grünwald*; Berlin/DE (jcr@gmx.eu)*

Purpose: Novel high-resolution ultrasound systems (16-32 MHz) allow for new insights in venous anatomy, physiology, and pathophysiology. Which novel information is depictable in particular in the detection of small structures like vein valves and low-flow phenomena?
Methods and materials: 1,300 consecutive patients, aged 6-92 years, were examined with the newest high-resolution ultrasound systems (16-23 MHz: Zonare One Pro, Mindray M9; Siemens Juniper 16 MHz, Vevo MD-peak 32 MHz), with a focus on the saphenous veins and their valves. Video loops of the intra- and epifascial systems were recorded for evaluation by 3 independent investigators.
Results: 3 groups of vein valve lesions could be detected, representing different origins. First, embryonic valve lesions showing commissural mismatch, incomplete, or missing cusps were found in 47% of candidates 6-8 years of age, comprising just one or two valves in 78% of the cases. A second mechanism was pressure-induced valve decompensation, marked by progredient dilatation and loss of functional reserve. It was seen after the age of 25 years and mainly concerned terminal GSV valves or medial perforators (76%). A third mechanism was stasis-related valve degeneration with a typical sonographic marker called "persistent aggregates" blocking the valve sinus increasing unto sclerotic degression or even loss of valve structures. Reflux of this mechanism was not seen before the age of 35 years, but was in 63.2% of the cases aged above 70 years.
Conclusion: Different kinds of valve lesions will need different therapies. Embryonic lesions need repair, pressure problems need internal compression, and just stasis-related early stages may benefit from stockings. Lesion-specific modalities for prevention and therapy now have to be evaluated.
Limitations: General limitations of ultrasound (e.g. obesity).
Ethics committee approval: n/a
Funding: No funding was received for this work.

µCT-monitoring of neutrophil elastase deficiency on a mouse model of cystic fibrosis-like lung disease
L. Zhu, Z. Zhou-Suckow, J. Salomon, D. Leitz, W. Stiller, W. Wagner, H.-U. Kauczor, M. O. Wielpütz*; Heidelberg/DE (monica_zhul@163.com)*

Purpose: Cystic fibrosis (CF) is characterised by chronic obstructive lung disease, driven by recurrent infections and inflammation. Our aim was to elucidate the value of micro-CT (µCT) for monitoring disease progression in a mouse model of CF-like lung disease and for quantifying effects of neutrophil elastase (NE) knock-out as a potential target for therapeutic intervention.
Methods and materials: 60 conserved lungs from mice with four different genotypes combining CF-like lung disease (Scnn1b-Tg) or wild-type (WT) with neutrophil elastase knock-out (Scnn1b-Tg/NE$^{-/-}$, WT/NE$^{-/-}$) were scanned by µCT (8.6µm resolution) three times (newborn, 5-6, and 14-16 days old). Alveolar size measured by mean linear intercepts (LM), lung volume, and air proportion were quantified on µCT.
Results: Average LM was similar in newborn mice among all four groups. At 5-6 days and 14-16 days, the alveolar size was larger in Scnn1b-Tg compared to WT (p<0.01), indicating the development of emphysema. Lung volume was significantly increased at 14-16d in Scnn1b-Tg (p<0.05) and air proportion was

increased from 5-6 days (p<0.01). Importantly, Scnn1b-Tg/NE$^{-/-}$ showed a significantly reduced air proportion at both 5-6 days and 14-16 days compared to Scnn1b-Tg alone, though the alveolar size and lung volume only showed a trend towards reduction be NE knock-out, indicating that NE knock-out reduces emphysema in CF-like lung disease.
Conclusion: µCT detects early development of emphysema in a mouse model of CF-like lung disease, which can potentially be mitigated by NE deficiency. Non-invasive imaging of µCT allows for longitudinal quantification of CF-like lung disease and it may be used as an endpoint for novel therapeutic trials in this mouse model.
Limitations: Data from adult mice has not yet been analysed and more parameters are being collected.
Ethics committee approval: Approved by the federal animal protection authority.
Funding: Supported by the German BMBF.

Application of ultra-high-resolution computed tomography target scan in lateral or oblique body position in predicting histological invasiveness of persistent pure ground-glass nodules

H. Ren, L. Xu, F. Sun, F. Liu, J. Cai, L. Yu, W. Guan, H. Xiao, H. Li*; Shanghai/CN (renhuadoc@163.com)*

Purpose: To retrospectively investigate whether ultra-high-resolution computed tomography (U-HRCT) target scan in lateral or oblique body position (scan protocol G) could predict histological invasiveness of pulmonary adenocarcinoma manifesting as persistent pure ground-glass nodules (pGGNs).
Methods and materials: 306 pathologically confirmed pGGNs in 260 patients who had undergone protocol G examinations were enrolled in this study. There were 213 preinvasive lesions (59 of atypical adenomatous hyperplasias and 154 of adenocarcinomas in situ) and 93 invasive pulmonary adenocarcinomas (IPAs) (53 minimally invasive adenocarcinomas and 40 invasive adenocarcinomas). The U-HRCT findings of the two groups were analysed on orthogonal multiplanar reformation images manually.
Results: Compared with preinvasive lesions, IPAs exhibited significantly larger diameter, higher mean and representative attenuation, lower relative attenuation and higher frequencies of heterogeneity, air bronchogram, bubble lucency, pleural retraction, and vascular convergence (P<0.01). Higher AUC and specificity could be achieved by using representative attenuation than mean attenuation or relative attenuation for predicting invasiveness. The multivariate logistic analysis revealed that larger diameter (OR=1.328, 95% confidence interval [CI]: 1.208-1.461) and higher representative attenuation (OR=1.005, 95% CI: 1.003-1.007) were significant predicting factors of IPAs from preinvasive lesions (P<0.05). The optimal cut-off of the maximum diameter for IPAs was larger than 10 mm.
Conclusion: The imaging features based on scan protocol G can effectively help predict histological invasiveness of persistent pGGNs.
Limitations: Some selected bias may be unavoidable. Intraobserver and interobserver variability were not analysed in this study. All scans and data used in our study were obtained on an available workstation provided by only one company. Therefore, further validation studies are required.
Ethics committee approval: This retrospective study was approved by the institutional review board.
Funding: This study was funded by 2018 Xinhua-uOttawa Joint Clinical Research Project.

RPS 1104-3 14:12

Pulmonary MR imaging with ultra-short echo time (UTE): a comparison of vapabilities for nodule detection and lung-RADS classification with low- and standard-dose CTs

Y. Ohno[1], M. Yui[2], D. Takenaka[3], T. Yoshikawa[4]; *[1]Toyoake/JP, [2]Ohtawara/JP, [3]Akashi/JP, [4]Kobe/JP (yohno@fujita-hu.ac.jp)*

Purpose: To compare capabilities of pulmonary MR imaging with ultra-short echo time (UTE-MRI) for lung nodule detection and lung-RADS classification with thin-section low- and standard-dose CTs.
Methods and materials: 110 consecutive patients were examined with chest standard- and low-dose CTs (270 mA [SDCT] and 60 mA [LDCT]) and UTE-MRI. In each patient, the probability of presence at each pulmonary nodule was assessed on all three methods by means of a 5-point visual scoring system. In addition, all nodules were classified based on lung-RADS on each method by the same radiologists. To compare nodule detection capability, Jackknife alternative free-response receiver operating characteristic analysis was performed among all methods. To evaluate lung-RADS classification capability, inter-method agreements were also assessed by kappa statistics with χ^2 test performed.
Results: On comparison of nodule detection capability by consensus reading, figure-of-merits (FOMs) of all methods (UTE-MRI: FOM=0.89, LDCT: FOM=0.86, SDCT: FOM=0.89) had no significant difference (p>0.05). For lung-RADS classification, interobserver agreement of each method was determined as almost perfect (UTE-MRI: κ=0.92, p<0.0001; LDCT: κ=0.93, p<0.0001; SDCT: κ=0.96, p<0.0001). In addition, inter-method agreements were also assessed as almost perfect (UTE-MRI vs. LDCT: κ=0.86, p<0.0001; UTE-MRI vs. SDCT: κ=0.87, p<0.0001; LDCT vs. SDCT: κ=0.95, p<0.0001).
Conclusion: Pulmonary MR imaging with UTE is considered at least as valuable as low- and standard-dose CTs for lung nodule detection and lung-RADS classification.
Limitations: This study was performed as a comparison of nodule detection capability and lung-RADS classification among MRI and low- and standard-dose CTs. However, there was no direct comparison of screening capability among them.
Ethics committee approval: This prospective study was approved by the institutional review board of Kobe University Hospital and written informed consent was obtained from each subject.

RPS 1104-4 14:18

Chronic lung allograft dysfunction (CLAD) after lung transplantation: comparing CT features between bronchiolitis obliterans syndrome, restrictive allograft syndrome, and non-CLAD patients

P. Agarwal[1], C. L. Schlett[1], A. Wielandner[2], P. Jaksch[2], C. Wassipaul[2], A. Benazzo[2], H. Prosch[2]; *[1]Freiburg/DE, [2]Vienna/AT (prerana.vkag@gmail.com)*

Purpose: To describe the CT features in patients with chronic lung allograft dysfunction (CLAD), including bronchiolitis obliterans syndrome (BOS) and restrictive allograft syndrome (RAS) post double-lung-transplantation(DLuTx), and compare these to non-CLAD patients to find the most valuable discriminating features between the two groups.
Methods and materials: This retrospective study analysed data of 451 patients who underwent DLuTx from 01/2008 to 12/2012 at Vienna-General-Hospital, Austria. After applying some exclusion criteria, patients were stratified based on clinical presentation and a pulmonary function test into BOS, RAS, and non-CLAD. The last available CT scan in each group was scored by two thorax radiologists in consensus, based on a semi-quantitative scoring system similar to one described previously. Data was analysed using logistic regression deriving area under the ROC curve (AUC).
Results: A total of 171 patients were included and median post-transplantation follow-up was 2,373 days. Of them, 41 were classified as BOS, 16 as RAS, and 114 as non-CLAD. There was a significant difference in almost all features between non-CLAD and CLAD (p<0.001). Four strongest CT features, airway-wall-thickening, peripheral ground-glass-opacities, sub-pleural thickening, and air-trapping, provided independent and incremental value with an AUC of 0.823 (95%CI:0.745-0.901) to differentiate between CLAD and non-CLAD. Within CLAD, two CT-parameters allowed nearly perfect separation of BOS from RAS: septal-and-non-septal-lines (AUC 0.936 [95%CI:0.870-1.000) and peripheral-consolidations (AUC 0.939 [95%CI:0.840-1.000).

Conclusion: Several CT features differ between CLAD and non-CLAD; within CLAD, septal-and-non-septal lines, as well as peripheral consolidations, allow a high accuracy to separate BOS from RAS. Imaging allows phenotyping of CLAD patients by identification of specific morphological features and can be used as an adjunct to lung function evaluation.
Limitations: A retrospective design, small sample size, and semi-quantitative scoring system.
Ethics committee approval: Approved by the IRB.
Funding: No funding was received for this work.

Functional MRI diffusion and chemical shift imaging in the assessment of anterior mediastinal masses

Y. Sabri[1], M. A. Fouad[1], S. A. E. H. Abd El Rahman[2], Y. El Hinnawy[1];
[1]Cairo/EG, [2]Giza/EG (mona.fouad@kasralainy.edu.eg)

Purpose: To investigate the potential of non-contrast enhanced functional MRI modalities, including diffusion-weighted imaging (DWI) and chemical shift imaging (CSI), to characterise anterior mediastinal lesions and differentiate benign from malignant spectrum, as well as different subtypes in the same pathological category, in an attempt to improve non-invasive approaches for the diagnosis and follow-up of patients with mediastinal lesions.
Methods and materials: This study included 71 patients with anterior mediastinal lesions detected by multi-slice computed tomography (MSCT). All cases were evaluated by diffusion-weighted imaging, ADC mean and minimum values, assessed and chemical shift MRI imaging, chemical shift ratio (CSR), and signal intensity index (SII), and were calculated and compared.
Results: In diffusion-weighted imaging benign and malignant lesions cut off value was for the ADC mean (1.267 x10-3 mm2/sec) and for ADC min (1.215 x10-3 mm2/sec). For differentiation between sarcoidosis and malignant lymphadenopathy, the cut-off value for ADC mean was 1.298 x10-3 mm2/sec and ADC min was 1.215 x10-3 mm2/sec. In chemical shift imaging quantitative assessment, thymic hyperplasia showed lower CSR and higher SII values than the thymoma and thymic carcinoma, however, germ cell tumour showed borderline CSR and high SII.
Conclusion: Functional MRI findings, both qualitative and quantitative assessment using diffusion-weighted images and chemical shift MR-images of the anterior mediastinum, has a diagnostic potential to differentiate between benign and malignant tumours. Patient's demographics, the mediastinal compartment in question, and conventional MR findings were all taken into consideration.
Limitations: The limited number of cases in each group.
Ethics committee approval: This study was conducted after institutional and departmental ethical committee approval number I- 091016 and informed consent was obtained from patients or their authorised representatives.
Funding: No funding was received for this work.

A comparison of capability for therapeutic effect prediction between CEST imaging and FDG-PET/CT in non-small cell lung cancer patients with chemoradiotherapy

Y. Ohno[1], M. Yui[2], T. Yoshikawa[3]; *[1]Toyoake/JP, [2]Ohtawara/JP, [3]Kobe/JP (yohno@fujita-hu.ac.jp)*

Purpose: To compare the capability of therapeutic effect prediction for chemoradiotherapy between chemical exchange saturation transfer (CEST) imaging at 3.5 ppm and FDG-PET/CT in non-small cell lung cancer (NSCLC) patients.
Methods and materials: 32 stage III NSCLC patients underwent CEST imaging, FDG-PET/CT, and chemoradiotherapy and follow-up examinations. All patients were then divided into recurrence (n=7) and non-recurrence (n=25) groups. From CEST data in each patient, magnetisation transfer ratio asymmetry (MTR_{asym}) map was computationally generated. In each lesion, MTR_{asym} and maximum value of standard uptake value (SUV_{max}) were assessed by ROI measurements. To compare each index between two groups, Student's t-test was performed. Then, multivariate logistic regression analyses were performed to investigate the discriminating factors of the two groups. Finally, disease-free between responders and non-responders assessed by each index were compared by the Kaplan-Meier method followed by a log-rank test.
Results: MTR_{asym} and SUV_{max} had significant differences between the two groups ($p<0.05$). Multivariate regression analyses identified MTR_{asym} (Odds ratio [OR]: 0.23, p=0.04) and SUV_{max} (OR: 0.09, p=0.008) as significant differentiators. Both indexes had significant differences in disease-free survival between the two groups (MTR_{asym}: p=0.01, SUV_{max}: p=0.0006).
Conclusion: CEST imaging has potential for predicting the therapeutic effect of chemoradiotherapy and is considered at least as valuable as FDG-PET/CT in NSCLC patients.
Limitations: No comparison of survival assessed by each index was considered as one of the limitations in this study.
Ethics committee approval: This prospective study was approved by the institutional review board of Kobe University Hospital and written informed consent was obtained from all patients.
Funding: It was financially and/or technically supported by Canon Medical Systems Corporation.

RPS 1104-7 14:36

Non-contrast-enhanced assessment of lung perfusion in patients with cystic fibrosis during respiratory tract exacerbation using Fourier decomposition magnetic resonance imaging (FD-MRI)

A. Mazzaro[1], F. Serafini[2], P. Ciet[3], S. Bertolo[4], M. Ros[4], N. Landini[5], G. Morana[4]; *[1]Verona/IT, [2]Padua/IT, [3]Rotterdam/NL, [4]Treviso/IT, [5]Arezzo/IT (andrea.mazzaro1558@gmail.com)*

Purpose: To evaluate the potential of FD-MRI, a validated technique for lung perfusion assessment, in differentiating CF patients with respiratory tract exacerbation and its correlation with clinical parameters.
Methods and materials: We selected 32 consecutive CF patients at their visit, performing a clinical examination, spirometry, and pulmonary MRI. Patients with exacerbations, identified with a Pex score, underwent antibiotic treatment, while those who were stable were not treated. A second examination was performed after therapy in exacerbated and after 30 days in the stable patients. For FD-MRI, an untriggered two-dimensional SSFP coronal sequence was used. The data obtained was converted into perfusion maps by a specific FD software. Two readers independently analysed the maps for perfusion defects using a field-based scoring system (0-18). We assessed intra- and inter-rater agreement (Cohen's k), differentiation between stable and exacerbated (OR), and correlation with spirometry parameters (Kendall's Tau).
Results: There were 14 patients with exacerbation and 17 stable patients. The score showed an inter- and intra-rater agreement k of 0.85 and 0.93 ($p<0.05$). Exacerbated patients had a significantly higher score than stable patients in the first examination (OR:4.0, IC95%:1.4-12.3), while after therapy there wasn't any difference (OR:1.1, IC95%:0.4–2.5). The score showed an inverse correlation with FEV1, FEF, and FVC in exacerbated patients, both in the first (Tau: -0.59,-0.61,-0.66, p<0,05) and in second examinations (-0.41,-0.43,-0.58, $p<0.05$). No correlation was found for the stable patients.
Conclusion: The score applied to FD-MRI perfusion maps showed good reproducibility. It appeared to be effective in differentiating CF patients with pulmonary exacerbation and could play a role in monitoring as it seems correlated with spirometry parameters.
Limitations: A small patient population. There were very few studies about the clinical use of FD-MRI.
Ethics committee approval: Approved by local ethics committee. Informed consent obtained.
Funding: No funding was received for this work.

Repeatability of the phase-resolved functional lung (PREFUL) MRI derived ventilation and perfusion dynamics in COPD and healthy controls

G. H. Poehler, A. Voskrebenzev, F. Klimes, L. Behrendt, T. F. Kaireit, M. Gutberlet, F. Wacker, J. Hohlfeld, J. Vogel-Claussen; *Hanover/DE (poehler.gesa@mh-hannover.de)*

Purpose: In COPD, patient-friendly imaging tools that integrate morphological and functional pulmonary assessment are currently translated into the clinic and clinical trials. Recently, based on conventional Fourier decomposition (FD), phase-resolved functional lung (PREFUL) MRI was established as a contrast-free, non-invasive 2D-imaging tool to detect and quantify regional pulmonary blood flow and ventilation dynamics in free-breathing (Voskrebenzev et.al MRM. 2017).
The purpose of this study was to assess the repeatability of PREFUL-MRI based ventilation and perfusion quantitative biomarkers in COPD and healthy volunteers.
Methods and materials: 28 COPD patients/12 healthy volunteers were examined twice on a 1.5T MR. Baseline and follow-up data of the lung PREFUL-MRI after 1 min (healthy volunteers)/after 14 days (COPD patients) was analysed using regional ventilation (RVent) flow-volume loops (FVL) by means of cross-correlation (ccVent) and quantified perfusion maps. Ventilation defect percentage based on correlation metrics (VDPcc), perfusion defect percentage (QDP), and ventilation/perfusion match based on cross-correlation (VQMcc) were calculated. Bland-Altman/power-calculation analyses were performed.
Results: Bland-Altman plots confirmed good reproducibility of V/Q PREFUL. A power calculation for n=30 using the data from this calculation revealed in COPD/healthy volunteers the smallest detectable difference of 0.031/0.017 RVent, 0.031/0.0017 ccVent, 2.4/2.3% QDP, 5.6/0.5% VDPccVent, and 4.5/6% VQMccVent. T-tests showed no significant differences between baseline and follow-up data (p>0.05).
Conclusion: Considering the high repeatability, contrast agent-free PREFUL-MRI derived ventilation and perfusion biomarkers in free-breathing are ready to be used as endpoints in clinical respiratory trials.
Limitations: n/a
Ethics committee approval: This study was approved by the local ethics commitee and all participants gave written informed consent.
Funding: No funding was received for this work.

RPS 1104-9 14:48

Acquiring CT scans in different respiratory phases in patients with pulmonary emphysema: a comparison of quantitative CT analysis and clinical data

L. Song[1], J. Leppig[2], R.-H. Huebner[2], D. B. C. Lassen-Schmidt[3], Z. Jin[1], F. Doellinger[2]; [1]*Beijing/CN,* [2]*Berlin/DE,* [3]*Bremen/DE*
(Jonas-Alexander.Leppig@charite.de)

Purpose: To investigate whether CT scans in maximum inspiration or expiration correlate more adequately with clinical data.
Methods and materials: 172 patients with COPD GOLD stage III or IV underwent non-enhanced thin-section MSCT at maximum inspiration and expiration, pulmonary function testing (PFT), exercise testing, and quality of life assessments within a narrow time frame. Quantitative CT (QCT) analysis was performed to determine total lung volume (TLV), total emphysema score (TES), and the 15th percentile of lung attenuation (P15) at both inspiration (IN) and expiration (EX) using MeVisPULMO 3D software. Spearman correlation analysis was used to correlate QCT analysis with PFT parameters and clinical measurements.
Results: QCT parameters showed a varying correlation with PFT, exercise testing, and quality of life assessments: e.g. TLVIN showed a very strong correlation with TLC (r=0.81, P<0.001), a moderate to strong correlation with RV, FVC, and FEV1/FVC (r=0.60, 0.56, -0.49, P<0.001). TLVEX showed a moderate to strong correlation with TLC, RV, and FEV1/FVC (r=0.75, 0.66, -0.43, P<0.001). P15Diff showed a moderate correlation with KCO% and TLCO% (r= 0.41, 0.40, P<0.001).
Conclusion: This study showed QCT parameters and PFT are complementary tools to evaluate pulmonary emphysema in patients of GOLD stages III and IV. TES and P15 at expiration might usefully reflect pulmonary function. Furthermore, P15 can be used as an effective parameter for evaluating lung diffusion capacity.
Limitations: As we investigated CT scans and clinical data of patients with pulmonary emphysema, our results might not be applicable to the full extent to different subgroups.
Ethics committee approval: n/a

Chest MRI in cystic fibrosis and chronic obstructive pulmonary disease: reproducibility and comparison with pulmonary function testing

M. O. Wielpütz[1], M. Eichinger[1], S. M. F. Triphan[1], S. Wege[1], H.-U. Kauczor[1], M. Puderbach[1], F. Risse[2], C. P. Heussel[1], G. Heussel[1]; [1]*Heidelberg/DE,* [2]*Biberach an der Riß/DE (wielpuetz@uni-heidelberg.de)*

Purpose: Recent studies support radiation-free morpho-functional magnetic resonance imaging (MRI) as a potential endpoint in cystic fibrosis (CF) lung disease and chronic obstructive pulmonary disease (COPD). Our aim was to determine the mid-term reproducibility of morphological and functional MRI abnormalities in clinically stable CF and COPD patients with repeat MRI studies one month apart, and to correlate morphological and perfusion abnormalities with spirometry.
Methods and materials: 15 CF (29.3±9.3y, FEV1%=66.59±15.83%) and 20 COPD (66.5±8.9y, FEV1%=42.04±13.26%) patients prospectively underwent clinical work-up, spirometry, and chest MRI twice one month apart (MRI1, MRI2). MRI scans were assessed using a validated MRI score, blinded for clinical and demographic data.
Results: The MRI morphology, perfusion, and global score did not differ between MRI1 versus MRI2 in patients with CF and COPD, with the exception of the MRI global score which increased slightly in COPD from 14.6±3.8 to 15.2±3.8 (p<0.05). Limits-of-agreement between MRI1 and MRI2 were approximately ±4 for the MRI global score. Importantly, FEV1% also did not change from MRI1 to MRI2. MRI scores showed a moderate inverse correlation with FEV1% in CF (r=-0.57 to -0.70, p≤0.001), but not in COPD, which was mostly due to a narrow range of disease severity.
Conclusion: Chest MRI abnormalities were highly reproducible within one month in clinically stable CF and COPD patients. Correlation with spirometry in CF further supports MRI's role as a sensitive and robust modality for the assessment of regional disease severity.
Limitations: Our study was performed in adult CF patients and the results may not be readily transferable to paediatric CF patients.
Ethics committee approval: This study was approved by the institutional ethics committee and written informed consent was obtained from all participants.
Funding: This study was funded by Boehringer Ingelheim Pharma GmbH & Co. KG, Germany.

RPS 1104-11 15:00

Measuring ventilation inhomogeneity in cystic fibrosis using unenhanced functional 3D-UTE MRI

J. F. Heidenreich[1], A. Weng[1], C. Metz[1], T. Benkert[2], H. Hebestreit[1], T. A. Bley[1], H. Köstler[1], S. Veldhoen[1]; [1]*Würzburg/DE,* [2]*Erlangen/DE*
(Heidenreic_J@ukw.de)

Purpose: To assess the clinical feasibility of proton-based non-contrast-enhanced functional lung MR imaging with a 3D-UTE sequence for the monitoring of cystic fibrosis (CF).
Methods and materials: 20 CF patients and 10 healthy volunteers underwent functional lung MRI using a prototypical stack-of-spirals 3D-UTE sequence. Images from in- and expiration were acquired during single breath-holds. The fractional ventilation (FV) was calculated voxelwise from the signal intensity amplitude. The interquartile range of the ventilation rate (FV normalised to the mean of the entire lung) was calculated for each subject and compared between groups. For the CF patients, the IQR was correlated to the lung clearance index (LCI) from multiple breath washout and the results of pulmonary function tests (PFT). Mann-Whitney U tests and the Spearman correlation coefficient were used for statistical analyses.

Results: Ventilation maps revealed increased ventilation inhomogeneity in patients with CF. A significantly higher IQR was observed in patients with CF compared to healthy controls (mean ± standard deviation, 0.66 ± 0.16 vs. 0.50 ± 0.04, respectively; P= 0.007). In the patient group, the IQR correlated negatively with the obstruction markers FEV1/FVC ratio (Tiffeneau index), MEF25 (r = 0.70/0.78), and positively to the LCI (r = 0.90).
Conclusion: Increased IQR was found in patients with cystic fibrosis. IQR demonstrated a significant correlation to established markers for airway obstruction (Tiffeneau index, MEF25) and ventilation inhomogeneity (LCI). The interquartile range of the normalised FV could be used as a measure of ventilation inhomogeneity and thus for disease management in cystic fibrosis.

Radiomic features: the biomarker used for distinguishing EGFR DEL19 and L858R sensitising mutation subtype

J. Ji[1], Q. Weng[1], H. Wang[1], J. Hui[1], C. Lan[1], M. Chen[1], P. Pang[2], M. Xu[1]; *[1]Lishui/CN, [2]Hangzhou/CN (lschrjjs@163.com)*

Purpose: The evidence that DEL 19 mutations are different from L858R mutation is accumulating since the different chemosensitivities. The aim of this study was to establish a CT derived approach to differentiate the EGFR DEL19 and EGFR L858R sensitising mutation in non-small cell lung cancer (NSCLC) patients.
Methods and materials: A total of 396 CT-based phenotypic characteristics were extracted from NSCLC preoperation images. On the basis of CT features extracted from 149 NSCLC patients, a CT-based phenotypic signature was proposed using a Cox regression model with LASSO penalty for the prediction of EGFR mutation. Furthermore, a joint prediction model incorporating the CT based image radiomic features and clinicopathologic characteristics was proposed for EGFR sensitising mutation subtype prediction.
Results: Of 396 radiomic features, 4 features were considered to be independent features represented as Rad-score. Cox regression was applied and 4 clinical features were selected. We found the radiomics signature showed good discrimination performance in both the primary and validation cohorts. In the training set, the radiomic signature successfully discriminated the EGFR DEL19 and EGFR L858R sensitising mutation (AUC=0.698, P<0.0001). Combining the imaging signature with a clinical feature model of EGFR status (AUC=0.778, P=0.0143) significantly improved prediction accuracy (AUC=0.874, P<0.0001). Furthermore, the joint prediction model showed a significant difference when compared to a radiomic signature model alone (P=0.0041, 95%CI: 0.0558-0.296) and with good calibration.
Conclusion: Radiomic features can be used as an approach to predict the EGFR sensitising mutation subtype between EGFR DEL19 and EGFR L858R. The clinical features enhanced the prediction accuracy of radiomic features model. Our study has implications for the use of imaging-based biomarkers in the clinic, as applies noninvasively, repeatedly, and at low cost.

The prognostic utility of reporting the ordinal coronary artery calcification score in routine chest CTs to prevent cardiovascular events

H. Bernardo Fernandez[1], M. Perez-Peña Del Llano[2], A. Renilla[2]; *[1]Oviedo/ES, [2]Mieres/ES (hugo.bernardo@hotmail.com)*

Purpose: To establish a link between total coronary calcification (CAC), detected on routine chest CT exams following a visual ordinal scoring system (OSS), and the possibility of developing a cardiovascular event (CE) over time.
Methods and materials: A retrospective case-control study was conducted selecting patients referred to our hospital for CE during 2015-16 who had a previous chest CT done, then two same-gender control patients with chest CT performed the same day and in previous dates were added. A total of 84 patients were included. An OSS was used to evaluate length coronary calcification and correlated with the presence or absence of CE.
Probabilities and curves of disease-free survival were calculated with the Kaplan-Meier method. The differences between curves were evaluated with the log-rank test.
SPSS 20.0 statistical analysis software was used, including Pearson $\chi 2$ test, t-Student, or Mann-Whitney tests and ANOVA or Kruskal-Wallis for group comparison.
Statistical significance was considered at a 5% probability level ($p<0.05$).
Results: CAC was observed in 92.85% of cases and 64.81% of the controls, with the descent coronary artery being the most commonly calcified.
A significative relationship between the number of calcified arteries and the total score obtained in the visual scoring system with having suffered a CE (Pearson correlation 17 and 21 with $p< 0.001$, respectively) was found using the Chi-square test ($p< 0.001$) and survival Kaplan-Meier curve.
A score of >4.9 determined a strong posibility of CE in a 36 month follow-up period.
Conclusion: Performing a visual score of CAC in routine chest CT can provide prognostic information concerning cardiovascular risk and should be incorporated in all radiological reports.
Limitations: A retrospective study and small sample.
Ethics committee approval: n/a
Funding: No funding received for this work.

RPS 1104-14 15:18

A comparison of quantitative lung parenchyma and airway parameters in low and ultra-low dose computed tomography

O. Weinheimer[1], L. Yu[2], J. G. Fletcher[2], M. O. Wielpütz[1], C. P. Heussel[1], H.-U. Kauczor[1], C. J. Galban[3], T. E. Robinson[4], B. Bartholmai[2]; *[1]Heidelberg/DE, [2]Rochester, MN/US, [3]Ann Arbor, MI/US, [4]Palo Alto, CA/US (weinheimer@uni-heidelberg.de)*

Purpose: Various quantitative evaluation techniques of computed tomographic (CT) images have been proven to deliver useful and objective biomarkers describing lung parenchyma and airways. Because low dose (LD) CT is becoming the standard in lung CT imaging, the question arises how an ultra-low dose (ULD) CT at dose level like that in chest x-ray influences quantitative CT (QCT).
Methods and materials: In the present study, 198 individuals (age: 54.4±16.4yrs) with a clinical indication for low-dose CT, such as malignancy screening or follow-up of a known lung nodule, were scanned twice, once with LD (mean effective dose: ~2.18mSv) and once with ULD (~0.18mSv). Advanced modelled iterative reconstruction (ADMIRE) was used. LDCT was reconstructed with strength level 2 ($LDCT_2$), ULDCT with strength level 2, and 4/5 ($ULDCT_2$, $ULDCT_{4/5}$). Numerous fully automated QCT parameters were generated on global and lobar generation-based levels. LDCT served as ground truth.
Results: The mean lung volume (LV) for $ULDCT_2$ was 0.58% smaller compared to $LDCT_2$ ($ULDCT_{4/5}$: 0.60%) and the differences were not significant. The mean lung density (MLD) was significantly increased by 6.56HU ($ULDCT_{4/5}$: 3.73HU), linear regression parameters for $ULDCT_2$~$LDCT_2$: r^2=0.97, slope=0.99, intercept=0.52HU ($ULDCT_{4/5}$~$LDCT_2$: r^2=0.97, slope=1.01, intercept=13.6HU), largest deviations for the lingula with 6.85HU (2.15HU), r^2=0.94, slope=0.98, and intercept=-13.0HU (r^2=0.9, slope=0.86, intercept=-100.0HU). Airway wall percentages (WP) were significantly increased by 2.59% (1.04%), r^2=0.92, slope=0.89, and intercept=7.98% (r^2=0.93, slope=0.89, intercept=7.16%).
Conclusion: There are significant differences between QCT parameters in LDCT and ULDCT, however, they are strongly correlated. The accuracy of QCT parameters decreases for the lobes and for higher airway generations. Regarding these findings, ULDCT may be an alternative to LDCT. ADMIRE strength 4/5 generally delivered preferable results.
Limitations: Results are influenced by inspiration level.
Ethics committee approval: Study under Mayo Clinic IRB approval: #14-002156.
Funding: Dr. Fletcher received a research grant from Siemens Healthcare.

Reducing artefacts from contrast media in the thorax in dual-layer spectral detector CT: using virtual monoenergetic image reconstructions and orthopaedic metal-artefact-reduction algorithms
N. N. Pan[1], S. Wang[1], X. Lu[2]; [1]Tianjin/CN, [2]Shenyang/CN (pannannan1018@163.com)

Purpose: To assess the artefacts reduction caused by contrast media in the subclavian vein and axillary vein in patients with thoracic tumour in dual-layer spectral detector CT (DLCT) by virtual monoenergetic image (VMI) reconstructions and orthopaedic metal-artefact-reduction (MAR) algorithms.
Methods and materials: A total of 61 consecutive patients with a thoracic tumour who underwent enhanced chest CT examination were included. We reconstructed the same arterial CT dataset into conventional images (CI), VMI, CI with MAR algorithms (CI+MAR), and VMI with MAR algorithms (VMI+MAR). VMI and VMI+MAR were reconstructed at 100, 130, and 160 keV. Noise (SD), artefact index (AI), and attenuation in Hounsfield Units (HU) with a difference of the four reconstructed images were compared. Subjective image quality was compared in terms of diagnostic image quality and degree of artefact reduction using the Likert-scale.
Results: Attenuation difference and AI were decreased in VMI+MAR images at 100, 130, and 160 keV, compared with VMI images or CI+MAR images ($p < 0.05$), and they were all lower than CI images ($p < 0.05$). Furthermore, noise was reduced in VMI+MAR and VMI as compared to CI images ($p < 0.05$). In addition, soft tissue adjacent to contrast media showed better artefacts reduction and better assessment in VMI+MAR images than VMI images or CI+MAR images, and they were all better than CI images. ($p < 0.05$).
Conclusion: The combination of MAR and VMI showed significant reduction of artefacts caused by contrast media than each technique alone, and provided improved diagnostic confidence.
Limitations: We only analysed images obtained at three energy levels (100, 130, and 160keV). Individual patient characteristics such as circulation and anatomical differences could have also impacted the extent of artefact.

MR CLEAN-MED - The effect of periprocedural medication in acute ischemic stroke treatment: acetylsalicylic acid, unfractionated heparin, both or neither? Interim results and protocol amendment
R. van de Graaf[1], B. Roozenbeek[1], V. Chalos[1], A. C. G. M. van Es[1], H. Lingsma[1], D. W. J. Dippel[1], A. van der Lugt[1], M. Clean Med Investigators[2]; [1]Rotterdam/NL, [2]Na/NL (r.a.vandegraaf@erasmusmc.nl)

Purpose: A considerable proportion of ischemic stroke patients do not recover despite fast and complete recanalisation after endovascular therapy (EVT). It is unknown whether periprocedural antithrombotic therapy can improve clinical outcome. This study assesses the effect of acetylsalicylic acid (ASA) and unfractionated heparin (UFH), alone, or in combination, in patients who undergo EVT.
Methods and materials: MR CLEAN-MED is a multicenter, prospective, randomised, open-label, blinded-endpoint trial using a 2x3 factorial design. We aim to enroll 1500 patients. Study interventions are intravenous treatment with ASA (300 mg) and/or UFH in a low-dose (5000 IU bolus, followed by 500 IU/hour x 6 hours) or moderate-dose (5000 IU bolus, followed by 1250 IU/hour x 6 hours). Primary outcome is the score on the modified Rankin Scale at 90 days. Safety endpoints include the occurrence of symptomatic intracerebral hemorrhage (sICH) and mortality.
Results: Sixteen Dutch and five French sites participated in the study. By October 2019, 270 patients were randomised. Following on receipt of the 4th safety report in April 2019, after inclusion of 132 patients, the data safety monitoring board recommended to stop enrollment in the moderate-dose UFH arm based on an increased sICH risk compared to the other treatment arms (22.7% vs. 5.7%; OR 4.88 95%CI 1.55-15.55[Table]). No patients were included in the moderate-dose UFH arm after receipt of this recommendation.
Conclusion: In MRCLEAN MED the effect of ASA and/or UFH during EVT on functional outcome will be evaluated further and the inclusion of patients in the ASA and low-dose UFH arms continues. Periprocedural treatment with moderate-dose UFH (5000 IU bolus, followed by 1250 IU/hour during 6 hours) is associated with increased sICH risks and should be avoided.

The effect of density on recall, detection, and interval cancer rates in tomosynthesis plus digital mammography or digital mammography breast cancer screening: preliminary results from RETomo trial
V. Iotti[1], P. Giorgi Rossi[1], A. Nitrosi[1], V. Helin[2], E. Gauthier[2], C. Campari[1], V. Marchesi[1], R. Vacondio[1], P. Pattacini[1]; [1]Reggio Emilia/IT, [2]Villejuif/FR (valentina.iotti@ausl.re.it)

Purpose: The RETomo trial was a two-arm test-and-treat randomised controlled trial comparing tomosynthesis (DBT) plus digital mammography (DM) versus DM alone for breast cancer screening. We investigate interim analysis on recall, detection, interval cancer rate in the first round by breast density.
Methods and materials: Women (45-70yo) presenting for a screening mammography in ReggioEmilia, and previously screened with DM, were randomised to the experimental arm (DBT+DM) or to the control arm (DM), both with two projections and double reading (NCT02698202). Density was automatically assessed with DenSeeMammo software on the 4 DM projections. Recall, detection, and interval cancer rates were reported. All women were followed up to 24 months from recruitment or up to the second round.
Results: From March 2014-2016, 19566 women were recruited. Density assessment was available for 8651 women in the DM+DBT-arm and 8544 in the DM-arm. Recall rate was similar in both arms and increased with density from 1.9% in BI-RADS A to 4.2% in BI-RADS D. Detection rate, including ductal carcinoma in situ (DCIS), was 9.1/1000(79) and 4.7/1000(40) respectively. DBT+DM detected about two fold more cancers in all BI-RADS classes except A, but interaction could be due to chance (p=0.65). Interval cancers rate was similar in both arms (2.0/1000[17] and 1.9/1000[16] in DBT+DM and DM arm, respectively). Interval cancer rate increases with density in both arms (OR for the increase of one BI-RADS class 1.6, 95%CI 1.0-2.5).

Conclusion: DBT+DM detected more cancers independently from density, but without impact on interval cancer rate. Density increased recall rate and interval cancer rate in both arms.
Limitations: Interval cancers are only one of the outcomes to assess the efficacy of DBT in screening.
Ethics committee approval: ProvincialEthical Committee.

Whole-body MRI versus an FDG-PET/CT-based reference standard for staging of paediatric Hodgkin lymphoma: a prospective multicentre study
S. Spijkers[1], A. S. Littooij[1], A. Beishuizen[1], S. G. Elias[1], B. de Keizer[1], T. Kwee[2], N. Tolboom[1], R. A. J. Nievelstein[1]; *[1]Utrecht/NL, [2]Groningen/NL (suzannespijkers@outlook.com)*

Purpose: To assess the concordance of WB-MRI and FDG-PET/CT for staging in children with Hodgkin lymphoma (HL) in order to contribute to the development of evidence-based 'radiation reduced' imaging protocols in paediatric HL in the future.
Methods and materials: A total of 68 children with HL were included in this prospective, multicenter, international study. All participants underwent WB-MRI and FDG-PET/CT at staging. Two radiologist independently evaluated all WB-MR images in two separate readings: with and without DWI. The FDG-PET/CT examinations were evaluated by a nuclear medicine physician. An expert panel assessed all discrepancies between WB-MRI and FDG-PET/CT to derive the FDG-PET/CT-based reference standard. Concordance for correct classification of all disease sites between WB-MRI (both with and without DWI) and the reference standard was calculated, as well as PPV, NPV and Cohen's kappa statistics. Inter-observer agreement for the WB-MRI including DWI reading was calculated using kappa statistics.
Results: WB-MRI including DWI was concordant with the FDG-PET/CT-based reference standard for determining disease stage in 97% of the patients (66/68). Agreement between WB-MRI and the reference standard was very good for both nodal (κ=0.97, 95%CI 0.94-0.99) and extra-nodal (κ 1.00) staging. Kappa values for correct disease stage increased significantly with the addition of DWI (p=0.04). Inter-observer agreement between WB-MRI readers was good (κ=0.74, 95%CI 0.58-0.91).
Conclusion: WB-MRI with DWI showed excellent agreement with the FDG-PET/CT-based reference standard, but did not reach complete concordance for stage. The addition of DWI to the WB-MRI protocol in staging of paediatric HL was shown to improve staging agreement with the FDG-PET/CT-based reference standard.
Limitations: Main limitation: lack of a true gold standard.
Ethics committee approval: The local institutional review boards approved the study. Written informed consent was obtained.
Funding: Financially supported by Kinderen Kankervrij (projectnumber 87).

Pivotal study of MRI-guided transurethral ultrasound ablation (TULSA) in men with localised prostate cancer
J. J. Futterer[1], D. Bonekamp[2], S. Arora[3], S. Raman[4], T. Tirkes[5], K. J. Macura[6], J. Chin[7], L. Klotz[8], S. Eggener[9]; *[1]Nijmegen/NL, [2]Hirschberg/DE, [3]Nashville/US, [4]Los Angeles/US, [5]Indianapolis, IN/US, [6]Baltimore, MD/US, [7]London, ON/CA, [8]Toronto, ON/CA, [9]Chicago/US (jurgenfutterer@gmail.com)*

Purpose: MRI-guided transurethral ultrasound ablation (TULSA) is an incision-free procedure for customised prostate ablation. We report one-year outcomes from the TULSA-PRO Ablation Clinical Trial (TACT).
Methods and materials: TACT enrolled 115 men with organ-confined prostate cancer (≤T2b, PSA ≤15 ng/ml, Gleason Grade Group 1-2) from 13 centers in five countries. TULSA was used for whole-gland ablation, sparing the urethra and urinary sphincter. Primary endpoints were adverse events and proportion of men with PSA reduction ≥75%. Secondary endpoints included one-year 10-core biopsy, mpMRI, prostate volume reduction, and quality-of-life.
Results: Median (IQR) age was 65 (59-69) years and PSA 6.3 (4.6-7.9) ng/ml. Pre-treatment, 72/115 (63%) men had Grade Group 2 (GG2) disease, and 98/115 (85%) had PI-RADSv2 score ≥3 MRI lesions. Ablation time was 51 (39-66) min for targeted prostate volumes of 40 (32-50) cc, with ablation coverage 98% (95-99%) on MRI thermometry.
Grade 3 adverse events occurred in 8% of men, all resolved, with no rectal injuries or Grade ≥4 events. At one year, 1% were incontinent (>1 pad/day), while 69/92 (75%) maintained erections sufficient for penetration. PSA reduction ≥75% was achieved in 110/115 (96%), decreasing 95% (91-98%) to nadir 0.34 (0.12-0.56) ng/ml. Prostate volume decreased from 37 to 2.8 cc. On one-year biopsy, GG2 disease was eradicated in 54/68 (79%) men; 72/111 (65%) had no evidence of any cancer.
Multivariate predictors of residual GG2 included intraprostatic calcifications at screening, thermal coverage of target volume, and one-year MRI lesions ($p<0.05$).
Conclusion: The TACT pivotal study of MRI-guided TULSA met its primary endpoint of ≥75% PSA reduction in 96% of patients, with low rates of severe toxicity and residual GG2 disease.
Limitations: Short-term outcomes, single-arm study.
Ethics committee approval: Ethics approved at all sites, all patients provided written informed consent.

Adherence to PI-RADS v2 minimum technical requirements in the PRECISION trial: a new quality control scoring system for multiparametric MRI of the prostate
F. Giganti, V. Kasivisvanathan, S. Punwani, M. Emberton, C. Allen, C. M. Moore, Precision Study Group Collaborators; *London/UK (giganti.fra@gmail.com)*

Purpose: The PRECISION trial was a multi-centre randomised study showing the superiority of MRI-targeted to standard TRUS-guided biopsy in 500 biopsy-naïve men across 23 centres from 11 countries. We report the results from the quality assurance work assessing scans from each trial site.

Methods and materials: Men were scanned using either a 3T or 1.5T scanner. Three centres used an endorectal coil and 4 did not administer antiperistaltic agents before multiparametric MRI.
64 out of 252 scans were chosen randomly and included scans from each site. Two expert radiologists reviewed the images in consensus using the PI-RADS v.2.1 guidelines. The quality of each scan was assessed using a 1-to-5 Likert scale, where 1 meant no MR sequences were of diagnostic quality and 5 meant each sequence was independently of diagnostic quality (Fig. 1).
Results: Four scans (6%) had a score of 2, 16 (25%) of 3, 27 (42%) of 4, and 17 (27%) of 5. MR quality was deemed of at least sufficient diagnostic quality (scoring ≥3) for 60 (94%) scans, with 44 (69%) being of good/excellent quality (scoring ≥4).
Adherence to minimum standards was highest for T2-WI, lower for DWI (slice thickness, number of b-values and lack of dedicated long b value sequences) and lowest for DCE (temporal resolution and absence of fat saturation/subtraction).
Conclusion: MRI and targeted biopsies outperform standard biopsy when sufficient attention is paid to high-quality scan acquisition and reporting. Whilst adherence to PI-RADS v2.1 minimum technical requirements in PRECISION was good overall, the greatest variability was in the DCE sequences.
Limitations: Further assessment of the utility of DCE imaging is warranted in the diagnostic setting.

MRI in addition to mammography screening in women with extremely dense breasts: outcome of the second (incident) round of the randomised DENSE trial
M. F. Bakker, S. V. de Lange, R. M. Pijnappel, W. B. Veldhuis, C. van Gils, O. B. O. T. Dense Study Group*; Utrecht/NL*

Purpose: To evaluate the incident vs. prevalent round of supplemental MRI screening for women with extremely dense breasts within a population-based screening program.
Methods and materials: Between 2011-2015, we randomised 40,373 screening participants (aged 50-75) with a negative mammography and extremely dense breasts (assessed with Volpara software) to supplemental 3.0-T MRI (n=8,061) or mammography screening only (n=32,312). In the prevalent (first) screening round, 4,783 women underwent MRI. Here we compare the results of the incident (second) MRI screening round with those of the prevalent round (presented earlier).
Results: After the prevalent screening round, 4,308 women (90%) had again undergone mammographic screening with a negative result and were eligible for the second round. Of them, 3,389 (79%) underwent supplemental MRI screening again. Reasons for discontinuation were time constraints, other health concerns, or MRI-related (e.g. claustrophobia).
Supplemental cancer detection rate with MRI was 5.9/1000 screens [95%CI:3.6-9.1], compared to 16.5/1000 [95%CI:13.3-20.5] in the prevalent round. For this, 3.2% [95%CI:2.6%-3.8%] of women were recalled for further diagnostic work-up, compared to 9.5% [95%CI:8.7%-10.4%] in the prevalent round.
Conclusion: As expected from an incident screening round, the cancer detection rate in this second round of supplemental MRI screening of women with extremely dense breasts is lower than in the prevalent round. Still, by adding MRI, the number of cancers detected almost doubled compared to normal mammography screening only. The false-positive rate decreased to one-third of the rate of the prevalent screening round.
Limitations: The incident screening round data on interval cancers are not yet available.

Functional prediction by corrected coronary opacification (CCO) from coronary computed tomography angiography (CCTA) in the assessment of not evaluable well-calcified plaque
P. Palumbo, E. Cannizzaro, S. Torlone, A. Corridore, M. C. de Donato, F. Cobianchi Bellisari, F. Sgalambro, E. Di Cesare, C. Masciocchi*; L'Aquila/IT (palumbopierpaolo89@gmail.com)*

Purpose: Coronary computed tomography angiography (CCTA) is a reliable tool in the diagnosis of obstructive coronary artery disease. However, heavily calcified plaques often require further functional examination to assess whether flow is limited. The purpose of our study was to determine whether changes in coronary opacification (CCO) can predict abnormal myocardial perfusion alteration.
Methods and materials: 75 patients with calcified plaques not properly evaluable with CCTA and subsequently assessed with adenosine-stress MRI were retrospectively included in our study. 19 patients underwent invasive coronary angiography (ICA) in coronary arteries. Per-vessel CCO analysis and per vessel fist-pass MRI perfusion qualitative and MPRI analysis were performed. Obtained values were compared with the severity of coronary stenosis and TIMI flow grade at the time of invasive coronary angiography.
Results: CCO identified abnormal TIMI with a sensibility, specificity, PPV, and NPV respectively of 100%, 83.3%, 77.8%, and 100%, with the best cutoff of 0.178. Very good correlation between CCO and TIMI was found (r = 0,83). Based on angiographic stenosis, CCO reported a sensibility, specificity, PPV, and NPV respectively of 88.9%, 90%, 88.9%, and 90%, with the best cutoff of 0.178. The optimal correlation was found with qualitative first-pass perfusion alteration and good correlation with MPRI (r = -0.72), and very good agreement between the two exams (kappa = 0.78, 95% CI 0.51 to 1)

Conclusion: CCO differences seem to have good capability in predicting qualitative first-pass perfusion or MPR alteration in a vessel-based analysis.
Limitations: Lack of functional ICA-derived FFR does not permit a comparison with current gold standard.
Ethics committee approval: The study was conducted in accordance with the declaration of Helsinki.
Funding: No funding was received for this work.

Coronary CT angiography-derived plaque quantification for the identification of lesion-specific ischemia

N. Zhao, Y. Gao, B. Lv*; Beijing/CN (15810686235@163.com)*

Purpose: To investigate the quantitative characteristics of coronary atherosclerotic plaques with haemodynamic significance and identify risk factors for lesion-specific ischemia as compared with invasive FFR.
Methods and materials: 162 patients (56.4 ± 8.8 years, 72% male) who underwent CCTA and ICA were prospectively enrolled. All patients were evaluated for conventional risk factors. The lumen area stenosis rate, minimum inner diameter, minimum lumen area, lesion length, plaque burden and volume ratios of fibrous, and lipid and calcification of plaques were measured from CCTA using a semi-automatic software prototype (Plaque analysis prototype, Siemens Healthineers). The differences between all CT parameters were compared in FFR ≤0.8 and >0.8 groups. The correlation between routine risk factors and CT parameters and haemodynamically significant plaques were analysed.
Results: 88/197 lesions were haemodynamically significant (FFR ≤0.8). In groups with invasive FFR ≤0.8, lesion length (30.20 vs. 23.07 mm), lumen area stenosis rate (78.05 vs. 65.50%), and diameter stenosis rate (52.79 vs. 40.98%) were significantly higher than FFR >0.8 group (all p<0.001). The minimum lumen area (1.57 vs. 2.25 mm^2) and minimum inner diameter (1.40 vs. 1.70 mm) of the FFR ≤0.8 group were lower with statistically significance (all p=0.001). In a multivariate analysis, the following parameters showed predictive value for lesion-specific ischemia: lesion length (OR=1.048, p<0.001) and diameter stenosis rate (OR=1.038, p = 0.015).
Conclusion: The lesion length and diameter stenosis rate portend predictive value to identify haemodynamically significant CAD (invasive FFR ≤0.8).
Limitations: Only plaque information and routine risk factors was explored for identifying flow-limiting lesions.
Ethics committee approval: This study was approved by the Institutional Review Board. Informed consent was obtained for all patients.
Funding: No funding was received for this work.

RPS 1103-3 14:22

Coronary CT angiography derived plaque markers correlated with invasive instantaneous flow reserve for detecting haemodynamically significant coronary stenoses

D. Overhoff[1], G. Özdemir[1], U. J. Schoepf[2], I. Akin[1], D. Lossnitzer[1], M. Borggrefe[1], S. O. Schönberg[1], S. Baumann[1], S. Janssen[1]; *[1]Mannheim/DE, [2]Charleston, SC/US (daniel.overhoff@umm.de)*

Purpose: To compare morphological and anatomic plaque markers derived from coronary computed tomography angiography (cCTA) for the detection of lesion-specific ischemia with invasive instantaneous wave-free ratio (iFR®) as the reference standard.
Methods and materials: In our prospective study, we enrolled patients with suspected coronary artery disease (CAD) who had undergone cCTA using a low-dose third-generation dual-source CT and invasive coronary angiography (ICA) with iFR® measurement. Various plaque markers were assessed on cCTA. The discriminatory power of these markers for the detection of ischemia-inducing CAD was evaluated against invasive iFR®.
Results: Our study cohort included 39 patients. Among 54 vessel-specific lesions, 15 lesions (28%) were characterised as haemodynamically significant by iFR®≤0.89. The area under the curve (AUC) of lesion length/ minimal luminal diameter[4] (LL/MLD[4]) (0.84, p=0.0045) was greater than the AUC of minimal luminal area (MLA) (0.82, p=0.0085), MLD (0.81, p=0.0028), the degree of luminal diameter stenosis (0.81, p=0.0050), corrected coronary opacification (CCO) (0.79, p=0.0036), remodeling index (RI) (0.75, p=0.0073), and percentage aggregate plaque volume (%APV) (0.72, p=0.0172). LL, vessel volume (VV), total plaque volume (TPV), and calcified and non-calcified plaque volume (CPV/ NCPV) did not reach statistical significance, and were unable to discriminate between vessels with and without ischemia-inducing coronary stenosis.
Conclusion: LL/MLD[4], MLA, MLD, the degree of luminal diameter stenosis, CCO, RI, and %APV derived from cCTA can support the detection of haemodynamically significant coronary stenosis as compared with iFR®, with LL/MLD[4] showing the greatest discriminatory power.
Limitations: A small study cohort that may incur selection bias. Only a modest fraction of the assessed 54 lesions were haemodynamically relevant, which may have limited the validity in positive cases.
Ethics committee approval: Approved by IRB.
Funding: No funding was received for this work.

RPS 1103-4 14:28

Performance of a deep learning algorithm for the evaluation of CAD-RADS classification with CCTA

G. Muscogiuri[1], M. Chiesa[1], L. Fusini[1], M. Guglielmo[1], A. Baggiano[1], A. I. Guaricci[2], G. Cicala[3], M. Pepi[1], G. Pontone[1]; *[1]Milan/IT, [2]Bari/IT, [3]Parma/IT (g.muscogiuri@gmail.com)*

Purpose: To develop a deep convolutional neural network (CNN) to classify coronary computed tomography angiography (CCTA) in the correct coronary artery disease reporting and data system (CAD-RADS) category.
Methods and materials: 288 patients who underwent clinically indicated CCTA were included in this single-centre retrospective study. The CCTAs were stratified by CAD-RADS scores by expert readers and considered as a reference standard. A deep CNN was designed and tested on the CCTA dataset and compared to on-site reading. The deep CNN analysed the diagnostic accuracy of the following three models based on CADRADS classification: Model A (CADRADS 0 vs CADRADS 1-2 vs CADRADS 3,4,5), Model 1 (CADRADS 0 vs CADRADS>0), and Model 2 (CADRADS 0-2 vs CADRADS 3-5). The time of analysis for both physicians and CNN were recorded.
Results: Model A showed a sensitivity, specificity, negative predictive value, positive predictive value, and accuracy of 47%, 74%, 77%, 46%, and 60%, respectively. Model 1 showed a sensitivity, specificity, negative predictive value, positive predictive value, and accuracy of 66%, 91%, 92%, 63%, 86%, and 89%, respectively. Conversely, Model 2 demonstrated the following sensitivity, specificity, negative predictive value, positive predictive value, and accuracy: 82%, 58%, 74%, 69%, 71%, and 78%, respectively. Time of analysis was significantly lower using CNN as compared to on-site reading (530.5±179.1vs104.3±1.4 seconds, p:0.01).
Conclusion: Deep CNN yielded accurate automated classification of patients with CAD-RADS.
Limitations: A small sample size was used for the study.
Ethics committee approval: In process.
Funding: No funding was received for this work.

NETosis and cardiovascular disease in a cohort of patients with acute chest pain: correlations between coronary CT angiography and laboratory results

M. Fusaro[1], M. Rattazzi[1], G. Tessarin[2], C. Bortolanza[1], M. Tiepolo[1], C. Nardin[1], L. Tonon[1], G. Morana[1]; [1]*Treviso/IT,* [2]*Padua/IT (tessarin.giovanni@gmail.com)*

Purpose: Observational cohort study evaluating neutrophil extracellular traps (NET)-osis' activation in patients with acute coronary syndrome and in patients with and without coronary artery disease investigated with coronary CT angiography.
Methods and materials: We enrolled 27 patients with an acute coronary syndrome (ACS), 86 patients with non-complicated coronary artery disease (CAD) diagnosed with coronary computed tomography angiography, and 114 patients with no CT signs of coronary artery disease from March 2016 to October 2017. Each patient underwent blood sampling to assess circulating markers of NETosis, such as lactoferrin, proteinase PR3, PMN elastase, and neutrophil gelatinase-associated lipocalin (NGAL). The circulating levels of these markers were then compared between the three groups of patients.
Results: Increased levels of neutrophils and decreased levels of lymphocytes ($p<0.001$) were found in patients with acute coronary syndrome compared to the other two populations. Analysis of NETosis's markers showed a significant increase of NGAL and PMN-Elastase in ACS patients compared to the ones with NO-CAD (respectively, $p=0.005$ and $p=0.009$) and with CAD (respectively, $p=0.002$ and $p=0.010$). A significant increase of lactoferrin was also recorded in CAD versus NO-CAD populations ($p=0.014$). No significant differences for PR3 were found. Furthermore NGAL plasmatic levels resulted independently associated to ACS presence ($p=0.013$) also after traditional risk factors adjustment.
Conclusion: This study showed a significant increased level of some NETosis' markers in subjects with ACS compared to patients with and without CAD, suggesting a role of neutrophils activation in atherothrombotic complications of atherosclerosis.
Limitations: A limited number of patients analysed, especially patients with acute coronary syndrome.
Ethics committee approval: Approval of the ethics committee for the clinical trial of provinces of Treviso and Belluno (Italy). Written informed consent acquired.

Comparison of pericoronary fat attenuation index in patients with and without plaque on cCTA by plaque type and stenosis severity

R. Ma, M. van Assen, D. Ties, G. J. Pelgrim, G. Sidorenkov, P. M. van Ooijen, P. van der Harst, R. van Dijk, R. Vliegenthart*; Groningen/NL (ericgeminim@gmail.com)*

Purpose: To investigate differences in fat attenuation index (FAI) between coronary arteries with and without plaque and relationships with plaque morphology.
Methods and materials: We retrospectively investigated 165 patients with clinically indicated cCTA between January 2015 and November 2017 (72 patients without and 93 patients with plaque). Scanning involved 3rd generation dual-source CT (SOMATOM Force, Siemens Healthineers) at 70kV. For healthy coronary arteries, FAI was measured at the proximal coronary segment. For diseased coronary arteries, FAI was measured across the plaque-causing most luminal narrowing. The first regression model compared FAI in healthy and diseased coronary arteries. A second model, including only diseased coronary arteries, evaluated the relationship of plaque-type and stenosis severity with FAI. Plaque type was divided into non-calcified, mixed, and calcified. Stenosis severity was categorised as minimal (1-24%), mild (25-49%), moderate (50-69%), and severe (70-100%).
Results: FAI in healthy and diseased coronary arteries were -98.0±10.1HU versus -100.5±10.1HU, -93.9±8.5HU versus -91.4±11.2HU, and -96.1±9.0HU versus -93.7±10.8HU for LAD, LCX, and RCA, respectively. There was a significant difference in FAI between healthy vessels and diseased vessels ($p=0.018$). FAI of non-calcified, mixed, and calcified plaque was -90.7±12.0HU, -95.0±10.5HU, and -97.9±10.8HU, with a significant difference between FAI of non-calcified and calcified plaque ($p=0.025$) and between non-calcified and mixed plaque ($p<0.001$). FAI of minimal, mild, moderate, and severe stenosis was -94.7±10.6HU, -95.5±11.2HU, -95.8±11.9HU, and -99.1±12.0HU. FAI was significantly different between minimal/mild and severe stenosis ($p=0.011/0.016$).
Conclusion: FAI showed differences by coronary plaque composition and degree of stenosis. These results may offer insight into the development of coronary artery disease and plaque vulnerability.
Limitations: The study lacked pathology results.
Ethics committee approval: The Medical Ethical Board waived the need for informed consent.

FFR-CT in the evaluation of acute chest pain: concepts and first experiences

R. R. Bayer[1], A. M. Fischer[1], S. S. Martin[2], C. Tesche[3], A. Varga-Szemes[1], U. J. Schoepf[1]; [1]*Charleston, SC/US,* [2]*Frankfurt am Main/DE,* [3]*Munich/DE (bayer@musc.edu)*

Purpose: Fractional flow reserve derived from coronary CTA (FFR-CT) has demonstrated utility in the evaluation of coronary artery disease in stable outpatients. However, the utility of FFR-CT in the emergency department (ED) setting in patients with acute chest pain (ACP) is insufficiently studied. We evaluated 30-day clinical outcomes (major adverse cardiovascular events (MACE), revascularisation, and readmission) in patients presenting to the ED with ACP.
Methods and materials: Patients between the ages of 18-95 years who presented to our ED with ACP and underwent clinically indicated cCTA and FFR-CT were included. cCTA was acquired using 3rd generation dual-source CT and FFR-CT was performed HearFlow®. Patients were retrospectively evaluated for 30-day MACE, readmission, revascularisation, and additional testing.
Results: A total of 59 patients underwent CCTA and subsequent FFR_{CT}. 32 out of 59 patients (54%) had negative FFR_{CT} (≥0.80) out of whom 18 patients (55%) were discharged from the ED. Out of the 32 patients without functionally significant CAD by FFR_{CT}, 32 patients (100%) underwent no revascularisation and 32 patients (100%) had no MACE at the 30-day follow-up period. Conversely, there were 3 MACE in the group of 27 patients with an FFR_{CT} <0.8. The average turnaround time for FFR_{CT} results was 3.5 hrs.
Conclusion: This preliminary data demonstrates that cCTA and subsequent FFR_{CT} has the potential for accurate and safe evaluation of CAD in patients presenting to the ED with acute chest pain. In this small cohort of patients, FFR_{CT} yielded a negative predictive value of 100%.
Limitations: The limitations of the study included a small sample size at a single centre. The high disease prevalence and severe may have resulted in selection bias.
Ethics committee approval: IRB approval with waiver of consent.

Comparative-effectiveness analysis of coronary CTA in patients with stable chest pain

X. Wu[1], A. Malhotra[2], H. Mojibian[1]; [1]*New Haven, CT/US,* [2]*Stamford, CT/US (ajay.malhotra@yale.edu)*

Purpose: To evaluate the comparative-effectiveness of CCTA as initial diagnostic and as follow-up imaging modality for patients with stable chest pain.
Methods and materials: A decision-analytic model was created over a 5-year span. Input parameters were based on randomised trials and long-term follow-up studies. Base case calculations, probabilistic sensitivity analysis, and two-

way sensitivity analyses were performed. Two sets of analyses (conservative and aggressive) were performed.
Results: The base case calculation shows coronary CCTA to be the optimal diagnostic modality in both conservative and aggressive management with an expected utility of 4.56 QALYs. Among functional imaging, using CCTA as a follow-up for equivocal results is shown to yield higher benefit than using any modality alone.
CCTA was the optimal initial diagnostic modality in 97.65% of the 10,000 Monte Carlo simulations.
CCTA remains the optimal strategy throughout the ranges when varying the pre-test probability of severe and moderate CAD from 0 to 40% and 0 to 70%. When varying the sensitivity of CCTA, the results show that CCTA is replaced by PET followed by CCTA when the sensitivity of CCTA is below 86.4%. When varying the sensitivity of SPECT, PET, and stress echocardiogram from 50% to 100%, CCTA remains the optimal strategy throughout the ranges. Two-way sensitivity analyses were performed varying the sensitivity of CCTA with the sensitivity of each functional imaging modality. CCTA remained the optimal strategy when the sensitivity was at least 5% higher than the other modality in absolute values.
Conclusion: CCTA is the optimal initial diagnostic modality for patients with stable chest pain, yielding the highest health benefit. CCTA also serves as a value follow-up modality in patients with equivocal functional imaging results.
Limitations: Limitations inherent to modeling study.
Ethics committee approval: n/a

Routine early postoperative CT imaging after CABG surgery: clinical value and unexpected findings
M. G. Karolyi, T. Gloor, M. O. Schmiady, H. Alkadhi*; Zurich/CH (mihaly.karolyi@usz.ch)*

Purpose: Cardiac CT angiography (CCTA) has evolved as the preferred imaging modality to follow-up patients who have undergone coronary artery bypass surgery (CABG). Yet, its clinical value in the early postoperative setting is not established. We evaluated the benefit of adding CCTA to our routine clinical workup after CABG.
Methods and materials: 215 patients (181 male, age 66±10 years) underwent CCTA within two weeks after CABG using third-generation dual-source CT with an effective radiation dose of 4.5±2.6 mSv. Graft patency and additional findings were registered and the change in clinical patient management after CCTA was evaluated.
Results: Graft occlusion or high-grade stenosis was revealed in 6.7% (32/215) of the patients, with 5.8% (19/329) of venous and 4.0% (13/323) of arterial grafts affected (p=0.22). Pleural effusion with lung atelectasis was recognised in 24% (51/215), residual pneumothorax in 12% (25/215), infiltration in 4% (9/215), and cardiac or vascular thrombus in 1.5% (3/215) of the patients, while additional incidental findings in 5.1% (11/215) of the patients, such as pathologic lymphadenopathy, lung nodule, unknown hepatic lesion, renal aneurysm, or hiatus hernia. No adverse events related to CCTA were documented. CCTA changed further clinical management in 31.3% (10/32) of the patients with occluded or stenosed grafts, and altogether in 11.6% (25/215) of the patients after CABG.
Conclusion: Early postoperative CCTA after CABG frequently reveals persistent postoperative and unexpected findings and may change management in about 1/3 of the patients with affected grafts. This effect on clinical outcomes should be evaluated in long term follow-up studies.
Limitations: Retrospective study design. No clinical follow-up.
Ethics committee approval: Approved by the institutional review board. Due to the retrospective study design, written informed consent of the patients was waived.
Funding: No funding was received for this work.

RPS 1103-10 15:04
CAD-RADS in the era of FFR_{CT}: an observational study in an acute chest pain population
A. F. Abadia[1], D. Giovagnoli[1], U. J. Schoepf[1], R. R. Bayer[1], R. Steinbach[1], M. van Assen[2], A. Varga-Szemes[1], S. S. Martin[3]; [1]*Charleston, SC/US,* [2]*Groningen/NL,* [3]*Frankfurt am Main/DE (simartin@outlook.com)*

Purpose: Coronary artery disease reporting and data system (CAD-RADS) is a standardised classification system for coronary CT angiography (CCTA). We aimed to investigate the impact of fractional flow reserve (FFR_{CT}) derived from CCTA on CAD-RADS stratifications in patients presenting with acute chest pain (ACP).
Methods and materials: FFR_{CT} analysis was included in the diagnostic workup of 94 patients (mean age 65.7±9.6 years) who presented to the emergency department (ED) with ACP and were referred for CCTA. We evaluated the rate of CAD-RADS reclassifications from the initial interpretation of the CCTA study alone versus after FFR_{CT} results were obtained. Other reported data included downstream resource use and 90-day clinical outcomes.
Results: 3 patients were initially classified as CAD-RADS 1, 18 as CAD-RADS 2, 44 as CAD-RADS 3, and 29 as CAD-RADS 4 based on CCTA alone. No patient with an initial CAD-RADS 1, 2, or 4 classification was reclassified following the addition of FFR_{CT} results. However, in patients with CAD-RADS 3, where function testing is often recommended for further evaluation, 41% (18/44) were reclassified to CAD-RADS 2 after FFR_{CT} results were obtained. This assessment may decrease the rate of additional diagnostic testing by 64%. Additionally, no clinical events occurred in the group of patients with FFR_{CT} >0.80 at 90-day follow up.
Conclusion: Adding FFR_{CT} analysis in patients presenting with ACP substantially decreases equivocality in CCTA interpretation, drastically reduces CAD-RADS 3 classifications, and has the potential to obviate unnecessary downstream testing. One should consider an update to the CAD-RADS classification to account for the availability of FFR_{CT}.
Limitations: Single-centre, short follow-up time, small sample.
Ethics committee approval: IRB-approved. Informed consent waived.

RPS 1103-11 15:10
Effect of calcification on diagnostic performance of computational fluid dynamic based FFR-CT identifying ischemia-specific lesions in patients with suspected CAD: a preliminary study from China
N. Zhao, Y. Gao, B. Lv*; Beijing/CN (15810686235@163.com)*

Purpose: To assess the effect of calcification on the diagnostic performance of FFR-CT for haemodynamically significant CAD with invasive FFR as a standard reference.
Methods and materials: 127 patients with suspected CAD (56.9 ± 8.9 years, 75.6% male) who underwent CCTA and ICA were prospectively enrolled. The performance of FFR-CT was compared in different conditions, including the presence and absence of calcification, different CAC scores, diffusivity index of calcification, and coronary segments with calcified plaques. The calcification-related parameters were compared among true positive, true negative, false positive, and negative groups of FFR-CT. The association between the parameters and ΔFFR (ΔFFR=FFR – FFR-CT) and performance of FFR-CT were analysed.
Results: 152 vessels of 127 patients had haemodynamically relevant stenosis. The vessel-based and patient-based sensitivity, specificity, and accuracy of FFR-CT were 74.63%, 77.65%, and 75.7%, and 79.37%, 76.56%, and 77.2%. The accuracy and specificity reduced with increased CAC scores (per-patient: 86.96% to 74.04%, 100% to 72.73%; per-target-vessel: 78.05% to 74.77%, 92% to 76.47%) and diffusivity index (per-target-vessel) (75% to 71.43%, 76.32% to 71.87%). The specificity was lower in the presence of calcification (per-patient: 100% vs. 72.55%; per-vessel: 92% vs. 76.27%) and more calcification related coronary segments and arteries groups. But all the differences between groups didn't reach statistical significance. The values of all parameters were non-significantly higher in the false negative group. In regression analysis, the number of coronary segments and arteries had a predictive value for diagnostic performance of FFR-CT (OR=1.426, p = 0.039; OR=0.355, p = 0.026).
Conclusion: The diagnostic performance of FFR-CT could be potentially negatively affected by calcification.
Limitations: The sample size of study is relatively small and subjectives of some subgroups are not enough.
Ethics committee approval: This study was approved by the Institutional Review Board. Informed consent was obtained from all patients.
Funding: No funding was received for this work.

Prognostic value of coronary CT angiography-derived plaque features and clinical parameter on adverse cardiac outcome using support vector machine learning
C. Tesche[1], B. Hedels[1], F. Straube[1], S. Hartl[1], B. Brück[1], M. J. Bauer[1], U. J. Schoepf[2], E. Hoffmann[1], U. H. Ebersberger[1]; [1]*Munich/DE,* [2]*Charleston, SC/US (tesche.christian@googlemail.com)*

Purpose: To evaluate the prognostic value of coronary CT angiography-derived plaque features and clinical parameter on adverse cardiac outcome using support vector machine (SVM).
Methods and materials: Data of 361 patients (61.9±10.3 years, 65% male) with suspected coronary artery disease (CAD) who underwent cCTA were retrospectively analysed. The occurrence of major adverse cardiac events (MACE) more than 90 days after cCTA was recorded. Several cCTA-derived plaque characteristics and conventional CT risk scores together with cardiovascular risk factors were provided to the supervised SVM learning algorithm to predict MACE. Performance of SVM was compared against conventional regression analysis.
Results: MACE was observed in 31 patients (8.6%) after a median follow-up of 4.5 years. Patients suffering MACE had significantly more obstructive CAD with a higher segment stenosis score, segment involvement score, and number of high-risk plaque features compared to controls (all p<0.05). Likewise, patients with MACE had a higher Framingham risk score, reflecting the clinical risk for cardiovascular events. The SVM algorithm showed a sensitivity and specificity of 0.94 and 0.87 for the prediction of MACE. The area under the curve (AUC) was 0.97 (95%CI 0.95-0.98) and showed significantly higher performance compared to regression analysis incorporating all available information (AUC 0.92, p<0.05).
Conclusion: A deep-learning SVM algorithm utilising cCTA-derived plaque information and clinical data improves the prediction of MACE when compared to regression analysis. A SVM based algorithm may improve the integration of patient's information to improve risk stratification.
Limitations: Retrospective single-centre study. Patient follow-up was performed using electronic medical records of the hospitals, therefore, we might have missed events occurring outside the hospital.
Ethics committee approval: Approved by the local ethical board with a waiver of informed consent.
Funding: No funding was received for this work.

Prognostic value of cCTA derived morphological and functional quantitative plaque markers using semi-automated plaque software
D. Overhoff[1], S. Baumann[1], F. Kaeder[1], U. J. Schoepf[2], S. O. Schönberg[1], M. Borggrefe[1], I. Akin[1], D. Lossnitzer[1], S. Janssen[1]; [1]*Mannheim/DE,* [2]*Charleston, SC/US (daniel.overhoff@umm.de)*

Purpose: In this study we analysed the prognostic value of coronary computed tomography angiography (cCTA) derived morphological and functional quantitative plaque markers and plaque scores for major adverse cardiovascular events (MACE).
Methods and materials: We analysed data of patients with suspected coronary artery disease (CAD). Various plaque markers were obtained using a semi-automated software prototype or derived from the results of the software analysis. Several risk scores were calculated and follow-up data concerning MACE was collected from all patients.
Results: A total of 131 patients (64±11 years, 73% male) were included in our study. MACE occurred in 11 patients within the follow-up period of 34±25 months. CAD-RADS score (OR=11.62), Syntax score (SS) (OR=1.11), Leiden-risk-score (OR=1.37), Duke jeopardy score (DJS) (OR=1.57), the index DJS/minimal luminal diameter (MLD) (OR=1.40), segment involvement score (SIS) (OR=1.76), total plaque volume (TPV) (OR=1.20), lipid-rich plaque volume (OR=1.23), and percentage aggregated plaque volume (%APV) (OR=1.32) were significant predictors for MACE (all p≤0.05). Also, the corrected coronary opacification (CCO) correlated significantly with the occurrence of MACE (p<0.0001). The CAD-RADS score, SS, and Leiden-risk score showed substantial sensitivity for predicting MACE (90.9%). The SS and Leiden-risk score displayed high specificities of 80.8% and 77.5%, respectively. These plaque markers and risk scores all provided high negative predictive value (NPV >90%).
Conclusion: The cCTA derived plaque markers of SIS, TPV, lipid-rich plaque volume, %APV, CCO, and the risk scores exhibited a predictive value for the occurrence of MACE and can likely aid in identifying patients at risk for future cardiac events.
Limitations: Since only patients with CAD were selected, the validity regarding individual CVRF may be affected. Also, the MACE/non-MACE groups were not matched for baseline characteristics.
Ethics committee approval: IRB approved study.
Funding: No funding was received for this work.

Variability in non-contrast head CT image quality in Ireland: opportunities for tarameter optimisation and standardisation to improve stroke care
J. Hynes, D. Caldwell, P. Kenny, P. J. Macmahon; *Dublin/IE (johynes@tcd.ie)*

Purpose: Non-contrast computed tomography (NCCT) of the brain is a critical tool in the investigation of suspected acute ischaemic stroke. The recognition of subtle differences in attenuation values between normal brain parenchyma and regions of ischaemic tissue is crucial to accurate and timely diagnosis. Our study aims to identify which combination of CT acquisition parameters maximises the ability to detect these early changes. We also investigated the variation in imaging protocols for suspected acute stroke at different institutions in the regional hospital network.
Methods and materials: Uniformity images of the CATPHAN phantom were obtained under various combinations of kV, mAs, reconstruction kernel, slice thickness and strength of iterative reconstruction. Images were analysed by an in-house algorithm, based on the statistical method of Chao et. al., (2000) to objectively measure low contrast detectability. Data is presented as contrast-detail diagrams, i.e., the minimum separation in Hounsfield Units (HU) required to distinguish a low contrast object of a given equivalent diameter from the background. 12 CT scanners made by 3 different manufacturers across 6 hospitals were surveyed.
Results: Increasing mAs, slice thickness and utilising higher levels of iterative reconstruction objectively improve low contrast detectability in NCCT brain. Deviations in protocols across manufacturers and hospitals were found to result in variations in image quality.
Conclusion: Variations in acquisition protocol produce differences in image quality which may contribute to missed and/or delayed findings. Optimising low contrast detectability and ensuring standardisation between linked institutions offers the potential to make a meaningful improvement in modern stroke care.

Limitations: Standardisation will inevitably be limited by the variation in manufacturers, radiologists' preferences and scanner performance.

Adrenal glands enhancement in computed tomography as a predictor of 24-hour mortality in critically ill patients

R. Winzer, J. Kühn, C.-J. Baldus, D. Seppelt, I. Platzek, R.-T. Hoffmann, D. Fedders*; Dresden/DE (robert.winzer@uniklinikum-dresden.de)*

Purpose: To assess the hyperattenuation of adrenal glands on contrast-enhanced computed tomography scans as a predictor of hospital mortality in critical care unit patients.
Methods and materials: Seventy-three patients (67.5 ±12.3 years of age) were included in this retrospective analysis. All patients underwent contrast-enhanced CT due to life-threatening indications. Attenuation of the adrenal glands in the portal venous phase was ROI-based assessed quantitatively by documenting Hounsfield units (HU) by two radiologists. From ROC analysis, Youden's J statistic was derived with death within 24 (48 and 72) hours as a classifier. Interrater agreement was assessed using intraclass correlation coefficient for measurements of the HU in adrenal glands and weighted kappa (k) after classifying patients with hyperdense adrenal enhancement (= enhancement above the threshold by ROC analysis).
Results: Fourteen patients (19%) died within 24 hours. In the portal venous phase HU means of both adrenal glands differed significantly between patients who died within 24 hours and those who survived (135.7 ± 46 HU vs 74.7 ± 24 HU; p=0.001). For portal venous phase, data ROI-based ROC analysis yielded for a Youden index of 0.79/0.85, a sensitivity of 100%/100% and a specificity of 79%/85% (p<.0001), a cut-off point of 93/95 HU for prediction of 24-hour mortality for rater 1 and 2, respectively. The AUC was 0.92/0.93. ICC of 0.99 and weighted kappa (k) of 0.84 indicated a high interrater agreement.
Conclusion: Venous hyperattenuation of adrenal glands on contrast-enhanced CT can predict 24-hour mortality quite well and can serve as a reproducible prognostic marker for the patient's outcome.
Limitations: Retrospective study.

Do emergency physicians appropriately request a head CT in patients with new-onset seizure?

I. García Tuells, J. M. Plasencia Martinez, E. Antolinos, M. N. Plasencia, J. M. M. Garcia Santos, J. Trejo Falcón*; Murcia/ES (irenegt92@gmail.com)*

Purpose: To determine how Emergency Head Computed Tomography (EHCT) is requested in patients with new-onset seizure in our environment. EHCT would be appropriate if the new-onset seizure was focal, associated with neurological deficit or in certain contexts.
Methods and materials: Physicians from 3 hospitals (H1, H2, H3), regularly involved in emergency on-call duty, answered a five-question survey on EHCT appropriateness for new-onset seizures. Fisher's test was used to compare the answers (A) among hospitals, resident/staff physician, residence year and medical specialty.
Results: We obtained 39 surveys [H1 12 (20.77%), H2 18 (46.15%), H3 6 (23.08%)] from 31 residents (79.49%) [14 (45.16%) ≥3 years of training] and 8 staff physicians (20.51%). 31/39 (79.49%) were Family and Community Medicine Specialists (FCMS). 32/39 (82%) would request (A4+A5) EHCT whatever the kind of seizure (Q1). That was the most common response in FCMS (27/31 -87.1%- vs 5/8 -62%-, P=0.043) and in staff physicians (8/8 -100%- vs 24/31 -77.4%- P=0.042). 9/39 (23.07%) and 8/39 (20.51%) requested an EHCT (A4+A5) according to Radiology and Emergency Departments guidelines (Q4) or Emergency Department guidelines (Q5). Residents ≤2nd year (15/17 -88.23 - vs 6/14 -42.86%- P = 0.029) were not aware (A2+A3) of those guidelines (Q5). For 31/39 (79.45%) of the participants, the EHCT results did not modify (A2+A3) the clinical attitude (Q2) and 27/39 (69.20%) were not sure (A3) about EHCT detected relevant alterations in those patients (Q3). The answers were similar among hospitals.
Conclusion: On-call physicians routinely request CT scans for new-onset seizure ignoring current evidence. It is mandatory to go into quality improvement cycles promoted by radiology departments to improve current practices.
Limitations: Limitations were a potential Hawthorne effect and the small sample size.
Ethics committee approval: n/a

The performance of artificial intelligence in the detection of intracranial haemorrhage on head computed tomography with clinical workflow integration

N. Watte, K. H. Nieboer, N. Buls, J. de Mey*; Brussels/BE (ninawatte@gmail.com)*

Purpose: To evaluate the performance of an artificial intelligence (AI) tool using a deep learning algorithm for detecting intracranial haemorrhage (ICH) on head computed tomographic (CT) exams with clinical workflow integration at the emergency department.
Methods and materials: We retrospectively collected a dataset at the emergency department, containing 500 consecutive head CT exams and their clinical reports, between Sept 1, 2019, and Oct 1, 2019. All CT exams were automatically pseudo-anonymised and transferred for ICH detection by an AI tool (Aidoc, Israel). We registered the number of studies that were successfully processed by AI, and we calculated the diagnostic performance by the positive (PPV) and negative (NPV) predictive values, sensitivity, and specificity. The original clinical radiology report and consensus by independent supervision were considered as the gold standard. Concordance was assessed by Cohen's k statistic.
Results: During a one-month implementation phase, the algorithm created a report for 388 studies (77,6%) during real-time radiology workflow; 22,4% failed, due to multiple possible technical issues, not further subject to this study. From the 388 processed studies, 31 (7,9%), were labelled by AI as having ICH. The expert readers detected 37 (9,5%) ICHs. The concordance between AI and expert reading was substantial (kappa=0,65). Algorithm performance for ICH revealed a 98% NPV and 61% PPV. The false-negative and false-positive rates were 6/337 (1,7%) and 20/37 (54%), respectively. The sensitivity and specificity were 84%.
Conclusion: In a clinical emergency setting, 77% of all head CT exams could be automatically evaluated by AI. With high specificity and negative predictive value, the AI tool shows the potential to rule out ICH. The positive predictive value remains moderate.
Limitations: We currently investigated 500 cases. Further research with 3000 CT exams is ongoing.

Diagnostic accuracy of multidetector CT in colonic ischaemia in the emergency department

G. Addeo[1], M. M. Lanzetta[1], G. Grazzini[1], D. Cirone[1], M. C. Bonini[2], S. Pradella[1], V. Miele[3]*; [1]Florence/IT, [2]Colle Val d'Elsa/IT, [3]Rome/IT (gloria.addeo@gmail.com)*

Purpose: To evaluate the diagnostic accuracy of MDCT (multidetector computed tomography), performed in an acute care setting in the diagnosis of primary CI (colonic ischaemia), with laparoscopic or laparotomic evaluation or surgery as the reference standard.
Methods and materials: The abdominal MDCT scans of 277 patients with clinical-laboratory suspicion of CI were retrospectively reviewed, 46 patients were excluded for secondary CI. The final study population consisted of 231 patients. CT was classified as positive for CI when the radiologist's interpretation showed a definitive diagnosis of CI; clear absence of CI was classified as a negative result. If the radiologist missed the relevant findings and failed to suspect CI, the CT report was defined as incorrect. The MDCT findings were

true positive, true negative, false positive, and false negative considering laparoscopic or laparotomic evaluation or endoscopy as the reference standard.
Results: In 41% of 231 patients included, CI was pathologically confirmed on the use of surgery. On the basis of the emergency radiology reports there were 30% true positive cases, 3,5% false positive, 11% false negative and 56% true negative. We calculated sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and diagnostic accuracy of MDCT obtaining: 73,4% sensitivity; 94% specificity; a PPV and a NPV of 90% and of 84%, respectively; 86% diagnostic accuracy.
Conclusion: Despite the successful CT imaging results in CI diagnosis, high colonic distention was the major cause leading to more false negative results even after intravenous administration of the contrast agent. Radiologists' experience and expertise have an important impact on their performance.
Limitations: Our investigation is in itself limited by its retrospective nature.
Ethics committee approval: The Hospital Institutional Review Board approved the study.
Funding: No funding was received for this work.

RPS 1117-5 14:40
Accuracy of Single-Pass Split-Bolus CT for detecting vascular injury in the spleen: a retrospective study in 111 patients with blunt splenic trauma
F. H. Berger[1], M. Edwards[2], T. Tromp[2], D. R. Kool[3], L. F. M. Beenen[3], B. Teunissen[3], M. Scheerder[3], M. Brink[2]; [1]*Toronto, ON/CA*, [2]*Nijmegen/NL*, [3]*Amsterdam/NL (Mobrink@hotmail.com)*

Purpose: To evaluate the diagnostic performance of Single-Pass Split-Bolus CT (SPSB-CT) for the detection of all splenic vascular injuries (SVI) and clinically relevant splenic vascular injuries in blunt trauma patients with proven splenic injury.
Methods and materials: Six-year single Level 1 trauma centre retrospective analysis of all blunt trauma patients with splenic injury on SPSB-CT. Patients were identified through electronic records. Data at the presentation and during 3 months follow-up were used. Two radiologists and one trauma surgeon, using all clinical and imaging data, defined the reference standard for the presence of SVI (AV fistula, pseudoaneurysms, active contrast extravasation) and clinically relevant SVI causing management changes or death. Four blinded radiologists evaluated initial SPSB-CT for SVI with binary (yes/no) and confidence (1-5) scores. Pooled sensitivity and specificity and observer agreement (Fleiss Kappa) statistics were calculated with 95% confidence intervals.
Results: 111 patients were included (male: 76%, mean age: 35, range 9-81) with 108 thoracoabdominal SPSB-CT (median DLP 455 mGycm), and 3 abdominopelvic SPSB-CT (mean DLP 243 mGycm). Mean aortic and hepatic enhancement was 310 HU and 109 HU. Incidence of SVI was 37/111 (33.3%), incidence of clinically relevant SVI was 27/111 (24.3%). For SVI, sensitivity was 85.8% (range 74.8% - 89.2%) and specificity was 89.9% (range 87.8% - 91.9%). For clinically relevant SVI, sensitivity was 88.9% (range 85.2% - 92.6%) and specificity was 81.9% (range 79.8% - 83.3%). Observer agreement was 88.1% with a Fleiss kappa of 0.76. At a 3 month follow-up, two patients had delayed splenic haemorrhage. No deaths related to missed SVI by SPSB-CT.
Conclusion: In blunt trauma splenic injury patients, SPSB-CT adequately detects splenic vascular injury with good inter-observer agreement.
Limitations: Retrospective, single-centre study.
Ethics committee approval: Ethics approval and informed consents was obtained.
Funding: No funding was received for this work.

Detection of CVA and TIA at the emergency department triage: developing a prediction machine learning model
E. Druskin[1], E. Zimlichman[1], S. Soffer[2], S. Bader[1], Y. Barash[1], E. Konen[1], E. Klang[1]; [1]*Ramat Gan/IL*, [2]*Tel Aviv/IL*

Purpose: Suspected cerebrovascular accident (CVA) or transient ischemic accident (TIA) patients undergo head CT. Early identification of patients with CVA/TIA at the emergency department (ED) triage can expedite evaluation. Our aim was to develop a prediction model for CVA/TIA at triage time.
Methods and materials: We retrieved data for consecutive adult patients (1/2012 to 12/2018) who performed head CT in our ED. We obtained the following triage variables: chief complaint recorded by the triage nurse, demographics, vital signs, pain score, emergency severity index (ESI), comorbidities and home medications. Previous ED visits and hospitalisations were also computed. CVA/TIA diagnoses were verified using ICD9 coding. We used a gradient boosting model to predict CVA/TIA at the triage time. Included variables were used as input for the model. We trained the model on years 2012-2017 data and tested on the year 2018 data. We evaluated the AUCs of single variables and the full model to predict CVA/TIA. We used Youden's index to find the model's optimal sensitivity and specificity.
Results: The study cohort included 93,202 patients who underwent head CT in our ED. Among those, 7,280 patients (7.8%) were finally diagnosed with CVA/TIA. Variables with higher AUC included chief complaint (0.84), pain score (0.67), age (0.63) and systolic blood pressure (0.62). The full model showed an AUC of 0.87 (95% CI: 0.86 - 0.88) for detecting CVA/TIA at triage. The model showed a sensitivity of 84.1% and specificity of 75.0% for detecting CVA/TIA.
Conclusion: Nurse staff recorded chief complaint has a high accuracy for CVA/TIA. A machine-learning model may further expedite head CT scans for CVA/TIA at the triage.
Limitations: Retrospective single-centre study.
Ethics committee approval: Sheba Medical Center IRB approval. Informed consent was waived by the committee.

Identification of lodged projectiles on CT based on their shape, caliber measurements and dual-energy material differentiation
D. Gascho[1], N. Zoelch[1], E. Deininger-Czermak[1], C. M. S. Tappero[1], A. Buehlmann[1], P. Wyss[1], M. Thali[1], S. Schaerli[2]; [1]*Zurich/CH*, [2]*Basel/CH (dominic.gascho@irm.uzh.ch)*

Purpose: The purpose of this study was to assess the visual classification of bullets and the accuracy of calibre estimations on computed tomograpy, as well as the feasibility of dual-energy-based material differentiation.
Methods and materials: This postmortem study includes fatal gunshot wounds (n=10) with a projectile or bullet fragment lodged inside the body. The decedents underwent CT with 120 kVp. Two additional scans with tube voltages of 120 and 140 kVp (CT dose index: both 9 mGy) were performed over the anatomic region where the projectile was lodged. The shape of the projectile was assessed by an expert in ballistics using volume renderings. The calibres were estimated by measuring the diameter of the projectile on aligned multi-planar reconstructions. Two radiologists (experienced / little experienced in ballistics) performed the measurements. For each projectile, the dual-energy index (DEI) was calculated. The DEI was based on CT numbers obtained from ROI measurements at 120 and 140 kVp (Fig.1C&D).
Results: Non-fragmented bullets could be identified as semi-jacketed hollow-point (SJHP) bullets or full metal jacket (FMJ) bullets. The SJHP bullets demonstrated characteristic mushrooming on CT. The experienced radiologist was close to the actual calibre according to the measurements of the diameters of non-fragmented bullets. All lead bullets, whether fragmented or not, clearly differed from a bullet made of copper/zinc in their DEI.
Conclusion: CT can provide information regarding the type of ammunition used, which is crucial for the assessment of injuries. However, visual assessments and calibre estimations are only feasible for non-fragmented projectiles. The DEI-based material differentiation is not limited to non-fragmented projectiles and allowed a clear distinction between lead and copper/zinc bullets.
Limitations: This study is limited by the small number of cases.

The accuracy of US and CT in diagnosing appendicitis with consideration of indeterminate examinations according to STARD guidelines

C. Crocker[1], M. A. Akl[2], M. Abdolell[1], M. Kamali[1], A. Costa[1]; [1]*Halifax/CA,* [2]*Makka/SA (andreufcosta@gmail.com)*

Purpose: To determine the accuracy of US and CT in diagnosing appendicitis at our institution, taking into account the number of indeterminate examinations in accordance with the Standards for Reporting Diagnostic Accuracy (STARD) guidelines.
Methods and materials: We evaluated 790 patients who underwent US, CT or both for evaluation of suspected appendicitis between May 2013-April 2015. Patient characteristics and US and CT results were recorded. The reference standard was histopathology or three months of medical record follow-up if surgery was not performed. 3x2 tables were generated, and sensitivity, specificity, overall test yield and accuracy were calculated according to STARD guidelines. For surgical cases, time to surgery (one-way ANOVA) and negative appendectomy rates (NAR, Fisher's exact test) were compared between patients who underwent US alone, CT alone, or both US and CT.
Results: There were 473/562 indeterminate US examinations (overall test yield, 15.8%); sensitivity and specificity were 98.5% and 54.2%, respectively. 13/522 CTs were indeterminate (overall test yield, 97.5%); sensitivity and specificity were 98.9% and 97.2%, respectively. Taking indeterminate studies into account, the accuracy was 13.7% for US and 95.6% for CT. Time to surgery was longer in patients who underwent US and CT (19.2±16 hours) vs. US alone (12.8±6.4, p=0.002), but not CT (15.8±8.6, p=0.07).
Conclusion: At our institution, a large proportion of US examinations are indeterminate for appendicitis. CT is the preferred first-line imaging test for evaluating appendicitis in non-pregnant adults.
Limitations: It is a single-centre and retrospective study. We did not include clinical or laboratory data, however, this also impacts patient diagnosis and management, and we did not re-interpret US and CT images.
Ethics committee approval: IRB approval was obtained and need for consent was waived.
Funding: No funding was received for this work.

Thin slices and maximum intensity projection reconstructions increase sensitivity to hyperdense artery sign in acute ischemic stroke

J. Rosskopf, B. L. Schmitz, T. Gräter*; Ulm/DE (johannes.rosskopf@uni-ulm.de)*

Purpose: To investigate the effect of different cranial nonenhanced CT (NECT) image reconstructions on correct detection of hyperdense artery sign (HAS) which is a frequently rising challenge particularly also for observers with lower practice level on NECT.
Methods and materials: Twenty-five of 100 patients' NECT image data presented with HAS. Sixteen observers with lower practice level on NECT evaluated independently and in a randomised order the three image reconstructions of each data set with thin slice 0.75 mm, thick slab 5 mm and 5 mm maximum intensity projection (MIP) and rated the likelihood of the presence of HAS in the middle cerebral artery.
Results: MIP and thin slice image reconstructions yielded significantly higher sensitivities for the correct detection of HAS than thick slab reconstructions (73%/73% vs 45%; $p < 0.05$). Sensitivity to HAS did not differ between using thin slice and MIP reconstructions (73% vs 73%). The interobserver reliability was moderate (κ, 0.4). Ranking of HAS detectability did not correlate with image reconstructions ($p > 0.05$ of ICC in a mixed model analysis).
Conclusion: MIP and thin slices reconstructions increased the sensitivity to HAS (73%) whereas thick slab reconstructions seemed to be rather less appropriate (45%). These findings might be important also in particular for observers with lower practice level on NECT.
Limitations: The observers in our study might have been biased in detecting clots by the appearance of early signs of infarction.

RPS 1117-11 15:10

Diffusion-weighted imaging can add value to emergency MRI for the diagnosis of acute appendicitis among pregnant women

Y.-C. Wong[1], L.-J. Wang[1], C.-H. Wu[2]; [1]*Taoyuan/TW,* [2]*New Taipei City/TW (ycwong@cgmh.org.tw)*

Purpose: We investigated whether or not diffusion-weighted imaging (DWI) can add value to emergency non-enhanced MRI for the correct diagnosis of acute appendicitis among pregnant women.
Methods and materials: From January 2018 to August 2019, 44 consecutive emergency MRI without contrast enhancement were performed to pregnant women for assessing acute right lower abdominal condition. Their median age was 33.0 years (IQR 27.0, 36.0) and median gestation age was 16 weeks (IQR 10.3, 24.9). All MRI examinations were retrospectively reviewed for acute appendicitis by two readers independently. The charts were reviewed for final diagnosis. The sensitivities, specificities, positive predictive value (PPV) and negative predictive value (NPV) of the variables for final diagnosis of acute appendicitis were computed.
Results: Among 44 patients, the final diagnosis of acute appendicitis was confirmed in 17 (38.6%). The final diagnosis of the other 27 patients was not acute appendicitis. They comprised 4 patients who underwent surgeries for other abdominal conditions and 23 patients who did not undergo surgery but were discharged without complications. Of 44 MRI examinations, 20 had DWI pulse sequence. Twenty four MRI did not have DWI. The final diagnosis was significantly associated with DWI ($p<0.001$), T2WI ($p<0.001$) and fat-saturated T2WI ($p<0.001$). The sensitivities, specificities, PPV and NPV of MRI overall diagnosis for acute appendicitis were 100.0% (95%CI 100.0, 100.0), 100.0% (95%CI 100.0, 100.0), 100.0%, 100.0% (with DWI) and 100.0% (95%CI 100.0, 100.0), 82.4% (95%CI 64.2, 100.5), 70.0%, 100.0% (without DWI).
Conclusion: DWI can add value to non-enhanced MRI for a correct diagnosis of acute appendicitis for pregnant women.
Limitations: Limitations were selection bias and a small number of subjects. The research was done at a single institution and discrepancies were resolved between 2 readers.
Ethics committee approval: n/a

Diagnostic accuracy of multidetector CT in primary acute mesenteric ischemia

M. Lanzetta, G. Addeo, M. C. Bonini, G. Grazzini, S. Pradella, V. Miele*; Florence/IT (monica.lanzetta@virgilio.it)*

Purpose: The purpose was to evaluate the diagnostic accuracy of multidetector CT in detecting primary acute mesenteric ischemia (AMI), considering laparoscopy, laparotomy, or other diagnoses confirmed by clinical-laboratoristic data as the reference standard.
Methods and materials: Initial MDCT scans in 231 patients with acute abdomen associated with metabolic acidosis and/or hyperlactatemia were retrospectively reviewed. CT was classified as positive or negative from the radiologist's report and considered true positive (TP) or false positive if laparoscopy/laparotomy or clinical status and serial MDCTs confirmed the diagnosis of AMI or not. A negative CT was considered true negative when laparoscopy/laparotomy excluded AMI or when CT findings oriented for another diagnosis were confirmed by clinical-instrumental data. Negative CT was considered false negative (FN) if laparoscopy/laparotomy confirmed the diagnosis of AMI. Moreover, all MDCTs were retrospectively evaluated by a skilled radiologist for the presence of vascular, bowel wall, mesenteric-peritoneal findings, and the involvement of other organs.
Results: Out of all 231 patients who underwent contrast-enhanced MDCT for acute abdomen and abnormal laboratory tests, 60 turned out to have AMI. MDCT shows a sensitivity of 82%, a specificity of 96%, a positive predictive value of 87%, a negative predictive value of 94% and a diagnostic accuracy of 92% in the diagnosis of AMI. Absent/decreased enhancement of the bowel wall was detectable in all patients with AMI; absent/decreased enhancement of the bowel wall, and colon involvement were more frequent in FN compared to TP; paper thin wall and peritoneal findings were more frequent in intestinal injury requiring resection.
Conclusion: MDCT plays a fundamental role in the diagnosis of AMI, making it possible to identify findings more correlated with ischemic damage requiring intestinal resection.
Limitations: Retrospective design from a single centre, lack of control group.
Ethics committee approval: Ethics committee approval was obtained.
Funding: No funding was received for this work.

DWI and PRECISE criteria in men on active surveillance for prostate cancer: a multicentre preliminary experience of different ADC calculations
F. Giganti[1], M. Pecoraro[2], D. Fierro[2], R. Campa[2], C. Allen[1], M. Emberton[1], C. Catalano[2], C. M. Moore[1], V. Panebianco[2]; [1]*London/UK,* [2]*Rome/IT (giganti.fra@gmail.com)*

Purpose: The PRECISE scoring system evaluates the likelihood of radiological progression in patients on active surveillance (AS) for prostate cancer (PCa) with serial multiparametric magnetic resonance imaging (mpMRI). A score of 1-2 denotes radiological regression, a score of 3 implies stability, and a score of 4-5 denotes progression. We assessed the inter-reader reproducibility of different apparent diffusion coefficient (ADC) calculations and their relationship to the PRECISE scores.
Methods and materials: Two radiologists retrospectively evaluated baseline and follow-up scans (performed on the same MR systems) in 30 patients from two different institutions. A PRECISE score was initially given in consensus. After at least 6 weeks to reduce the likelihood of being influenced by the consensus reading, each radiologist independently calculated the ADC for the lesion, non-cancerous tissue, and urine in the bladder. Normalised ADC ratios were calculated with respect to normal prostatic tissue (npADC) and urine. Spearman's correlation (ρ), intraclass correlation coefficients (ICC), differences in ADC, and ROC curves were computed.
Results: Interobserver reproducibility was very good (ρ>0.8; ICC>0.90). When considering patients with radiological regression/stability versus progression at follow-up mpMRI, lesion ADC was different between these groups (0.91 vs 0.73 × 10^{-3} mm^2/s; p=0.025). Differences between the two groups were seen in npADC ratio (0.68 vs 0.53; p=0.012). Cut-offs of 0.77 × 10^{-3} mm^2/s (lesion ADC) and 0.59 (npADC ratio) could differentiate the two groups (areas under the curve: 0.74 and 0.77, respectively).
Conclusion: The ADC correlates well with the PRECISE scores and it holds promise in the evaluation of radiological progression of PCa over time.
Limitations: A small cohort of patients and the absence of tissue verification by means of radical prostatectomy.

Interobserver reproducibility of the PRECISE scoring system for prostate MRI on active surveillance: results from a two-centre pilot study
F. Giganti[1], M. Pecoraro[2], A. Stabile[3], V. Stavrinides[1], S. Cipollari[2], M. Emberton[1], C. Catalano[2], C. M. Moore[1], V. Panebianco[2]; [1]*London/UK,* [2]*Rome/IT,* [3]*Milan/IT (giganti.fra@gmail.com)*

Purpose: To assess the interobserver reproducibility of the PRECISE score for magnetic resonance imaging (MRI) in patients on active surveillance (AS) for prostate cancer (PCa).
Methods and materials: The PRECISE scoring system assesses the radiological progression of PCa over time. A score of 1 or 2 means regression of a previously visible lesion, a score of 3 denotes stability, and 4 or 5 suggests radiological progression. We retrospectively evaluated serial MRI scans in 80 men on AS from two different academic centres (40 from each centre) with biopsy-confirmed low- or intermediate-risk PCa (i.e. ≤ Gleason 3+4 and a prostate specific antigen ≤ 20 ng/ml) and ≥ 2 MR scans. Two radiologists reported all scans independently and gave a PRECISE score from the second scan onwards. Cohen's κ coefficients and percent agreement were computed.
Results: The agreement was substantial, both at a per-patient and a per-scan level (κ=0.71 and 0.61; percent agreement=79% and 81%, respectively) for each PRECISE score. The agreement was greater (κ=0.83 and 0.67; percent agreement=90% and 91%, respectively) when the PRECISE scores were grouped according to the absence/presence of radiological progression (PRECISE 1-3 vs 4-5). A higher inter-reader agreement was observed for the scans performed at one centre (κ=0.81 vs 0.55 on a per-patient level, and κ=0.70 vs 0.48 on a per-scan level, respectively). The discrepancies between institutions were less evident for percent agreement (80% vs 78% and 86% vs 75%, respectively).
Conclusion: We observed substantial reproducibility for PRECISE scoring of radiological change in men on AS, particularly when the clinical cut off a PRECISE score ≥ 4 for MRI-directed biopsy was used.
Limitations: Not all men underwent targeted rebiopsy during follow-up.

Clinical and economic impact of transperineal laser ablation (TPLA) in the treatment of benign prostatic hyperplasia (BPH)
G. Manenti, T. Perretta, S. Marsico, C. P. Ryan, D. D'amato, A. Turbanti, E. Finazzi Agrò, R. Floris; *Rome/IT*

Purpose: To assess the efficacy, safety, and economic impact of transperineal laser ablation (TPLA) in the treatment of benign prostatic hyperplasia (BPH).
Methods and materials: 30 patients (age 73.4 ± 8.4 years) with lower urinary tract symptoms underwent TPLA under local anaesthesia. Under ultrasound guidance by US/MRI fusion software, up to four 21G applicators were inserted into the prostatic tissue. The primary endpoint was the absence of relevant complications intra- and early (15 days) post-intervention. Secondary endpoints included the evaluation of total intervention time, ablation time, energy deployed, observation time, catheterisation time, IPSS, quality of life (QoL), peak urinary flow rates, post-void residual (PVR), and prostatic morphology and volume, evaluated with 3T mpMRI at 3, 6, and 12 months.
Results: No complications occurred intra- or early post-intervention. The mean ablation time was 33.3 minutes (range 25.3 min-max 42.4), the mean energy deployed was 12,137 J (range 7,204.4-max 14,3483 J), the mean hospital stay was 113 minutes, and the mean catheterisation time was 7.1 days (range 1.1-max 9.3 days). At 3 months, the mean IPSS improved from 22.3 to 7.4 (P < 0.001), the mean QoL from 3.4 to 1.7 (P < 0.001), the mean Q max from 5.1 to 12.5 mL/s, the mean PVR from 148.3 to 87.1, and the mean prostate volume from 54.9 to 42.3 mL.

Conclusion: TPLA is feasible, safe, and economical in the treatment of BPH. Our preliminary data demonstrates significant clinical results at 6 and 12 months.
Limitations: A small number of treated patients, short follow-up, and our first expierence with this technique.
Ethics committee approval: Protocol approved by the ethical committee of the Tor Vergata Hospital.
Funding: No funding was received for this work.

RPS 1107-4 14:18

Intra-reader comparison of PI-RADS 2 versus PI-RADS 2.1 in a large cohort: stable cancer detection performance with few changes in scoring

M. Rudolph[1], A. Baur[1], M. Haas[1], P. Asbach[1], S. Mahjoub[2], H. Cash[1], B. Hamm[1], T. Penzkofer[1]; [1]*Berlin/DE,* [2]*Cologne/DE*
(madhuri-monique.rudolph@charite.de)

Purpose: To evaluate the PI-RADS 2.1 scoring system in a lesion-based intra-reader comparison to the previous version 2, analysing cancer detection performance and intra-reader variability.
Methods and materials: 342 datasets (3.0T) of patients who received an MRI/TRUS biopsy (10-core systematic and targeted biopsies) were evaluated in a blinded/randomised setting. Lesions were marked and scored according to PI-RADS v2 and v2.1 by one of three experienced radiologists >6 months between the sessions. Histopathology was used as a reference and correlated with location and scoring of the readers' assessments.
Results: 366 lesions were found and 193 (53.76%) lesions harboured PCa. Significant cancer (csPCA, Gleason≥3+4) was detected in 135 (37.6%) lesions. 216 (60.17%) lesions were in the PZ with prevalence of csPCA at 87 (40.82%), 143 lesions (39.83%) in the TZ with prevalence of 48 (33.57%). Distribution of PI-RADS-scores and csPCa detection rates were: (PZ, PI-RADS 2/2.1) 1) 14.3%/15.4%, 2) 8.1%/13.0%, 3) 13.0%/10.0%, 4) 42.4%/42.9%, and 5) 72.1%/68.3%, and (TZ, PI-RADS 2/2.1) 1) 0.0%/6.3%, 2) 4.3%/7.4%, 3) 18.8%/8.3%, 4) 57.1%/40.0%, and 5) 59.3%/61.7% (all p>0.05). Cohen's kappa for PI-RADS 2 versus 2.1 was 0.59 and the weighted kappa was 0.77. PI-RADS v2/v2.1 AUC-ROC for significant cancer detection was 0.776/0.733 for PZ and 0.793/0.800 for TZ (p>0.05). The new segments (Left/Right Base PZm) were used in 31 of the lesions (9.06%).
Conclusion: The comparison of PI-RADS 2 versus 2.1 revealed slight changes with respect to cancer detection rate and scoring, with no detectable statistical significance in a large cohort. Intra-reader variability was moderate to good. ROC-performance was stable at a high level. The newly added segments are used in few instances.
Limitations: A retrospective design and MRI/TRUS gold standard (although less bias than prostatectomy cohort).
Ethics committee approval: IRB approved the study.
Funding: Berlin Institute of Health.

Do we practice what we preach? A systematic review of compliance to PI-RADSv2 acquisition protocol

A. Ponsiglione[1], R. Cuocolo[1], A. Stanzione[1], F. Verde[1], A. Ventimiglia[2], V. Romeo[1], M. Petretta[3], M. Imbriaco[1]; [1]*Naples/IT,* [2]*Castellamare di Stabia/IT,* [3]*Avellino/IT (andreaponsiglione@hotmail.it)*

Purpose: To assess the adherence in literature to technical parameters required by PI-RADSv2 guidelines.
Methods and materials: Multiple medical literature databases were systematically assessed by 3 investigators. Original studies regarding prostate magnetic resonance imaging (MRI) published after January 2016 were retrieved using an appropriate search string. Information about technical acquisition protocols and patient enrolment were collected from full text and/or supplemental materials for the analysis. Technical parameters were dichotomised in relation to their adherence to PI-RADSv2 guidelines.
Results: A total of 150 studies were included in the analysis. Of all papers, 15% reported protocol details regarding all technical specifications requested for T2-weighted (T2w) sequences, only 8% for diffusion-weighted imaging (DWI) and apparent diffusion coefficient (ADC) maps, whereas 10% did the same for dynamic contrast-enhanced (DCE) sequences. Overall, only 5% of all studies reported every technical parameter requested by PI-RADSv2, none of which completely met guidelines specifications.
Only 19% of studies were in line with PI-RADSv2 for all reported technical parameters. In particular, the adherence was lowest for T2w frequency in-plane resolution (12%), ADC maps low-b value (27%), and DCE imaging temporal resolution (43%). Furthermore, only 59% of studies reporting DWI high-b value followed recommendations.
Conclusion: Compliance to PI-RADSv2 in literature is greatly heterogeneous. Our results point out the need for a better diffusion of protocol standardisation and for less stringent indications of some technical parameters.
Limitations: Our analysis was limited to a relatively short period of time (34 months), even if it included exams from a wider range (2006–2018). The number of studies collected was high, while there was heterogeneous reporting of imaging protocol details.

MRI-derived PRECISE scores for predicting radiological progression in prostate cancer patients on active surveillance

I. Caglič, N. Sushentsev, E. Sala, N. Shaida, B. Koo, A. Warren, C. Kastner, V. Gnanapragasam, T. Barrett*; Cambridge/UK*
(iztokcaglic@gmail.com)

Purpose: To validate the predictive value of the prostate cancer radiological estimation of change in sequential evaluation (PRECISE) MRI system in the follow-up of prostate cancer (PCa) patients on active surveillance (AS) and its correlation to disease progression on AS.
Methods and materials: 305 men enrolled in an AS programme between 2011 and 2018 were included. Disease progression on AS was defined as the end-point. Receiver operating characteristic curve analysis was performed, with the area under the curve (AUC) for PRECISE scores estimated for detection of progression. Kaplan–Meier curves compared progression-free survival (PFS) between PRECISE scores.
Results: Progression rate for the cohort was 16.7% (51/305) over a median follow-up of 52 months. The AUC, specificity, sensitivity, PPV, and NPV of the PRECISE system were 0.83, 0.77, 0.89, 0.57, and 0.95, respectively. PSA-Density and the Likert lesion-probability score were the only significant baseline parameters predictive of progression in multivariate analysis (OR=5575.0, p=0.008 and 1.7, p<0.001, respectively). Diagnostic performance of PRECISE was increased to AUC=0.92 (PPV=0.69 and NPV=0.94) when combined with the significant baseline predictors. Kaplan-Meier curves showed a significant difference in PFS between PRECISE scores 1-3 (94%) versus scores 4-5 (35.5%) at 5 years; p<0.001.
Conclusion: PRECISE MRI scoring has a good predictive value for men with PCa on AS. The high NPV of PRECISE can reduce the need for re-biopsy, whilst the moderate PPV for progression should trigger either closer monitoring or re-biopsy.
Limitations: A retrospective design. In 8 cases, PRECISE score 5 (i.e. T3a/T3b disease) triggered a direct switch to treatment, with pathological progression not definitively being confirmed.
Ethics committee approval: The Local Ethics Committee waived the need for informed consent.
Funding: No funding was received for this work.

Inter-reader agreement in multiparametric MRI reporting using prostate imaging reporting and data system version 2.1

G. Brembilla, P. Dell'oglio, A. Stabile, A. Damascelli, L. Brunetti, G. Cristel, A. Esposito, F. Montorsi, F. de Cobelli*; Milan/IT (brembilla.giorgio@hsr.it)*

Purpose: To evaluate the agreement among readers with different expertise in detecting suspicious lesions at prostate multiparametric MRI using prostate imaging reporting and data system version 2.1.
Methods and materials: We evaluated 200 consecutive biopsy naïve or previous negative biopsied men who underwent MRI for clinically suspicious prostate cancer (PCa) between May and September 2017. Of them, 132 patients underwent prostate biopsy. 7 radiologists (4 dedicated uro-radiologists and 3 non-dedicated abdominal radiologists) reviewed and scored all MRI examinations according to PI-RADS v2.1. Agreement on index lesion detection was evaluated with Conger's k coefficient, AC1 coefficient, percentage of agreement (PA), and indexes of specific positive and negative agreement. Clinical and radiological features that may influence variability were evaluated.
Results:
Agreement in index lesion detection among all readers was substantial (AC1: 0.738; 95%CI: 0.695-0.782). Dedicated radiologists showed higher agreement compared to non-dedicated readers. Clinical and radiological parameters that positively influenced agreement were PSA density ≥0.15 ng/ml/cc, pre-MRI high risk for PCa, positivity threshold of PI-RADS score >3, PZ lesions, the homogeneous signal intensity of the PZ, and subjectively easy interpretation of MRI. The positive specific agreement was significantly higher among dedicated readers, up to 93.4% (95%CI: 90.7-95.4) in patients harbouring csPCa. Agreement on absence of lesions was excellent for both dedicated and non-dedicated readers (respectively: 85.1% [95%CI 78.4-92.3]; and 82.0% [95%CI 77.2-90.1]).
Conclusion:
Agreement on index lesion detection among radiologists of various experience is substantial to excellent when using PI-RADS v2.1. Concordance on the absence of lesions is excellent across the readers' experience.
Limitations: A retrospective study, limited to a single-tertiary-care referral centre.
Ethics committee approval: This study was approved by our Institutional Review Board and written informed consent was obtained.
Funding: No funding was received for this work.

Diagnostic value of combining PI-RADS v2.1 with prostate-specific antigen density in prostate cancer

X. Wei, J. Zou, S. Zhong, G. Hu, J. Xu*; Shenzhen/CN (502498022@qq.com)*

Purpose: To investigate the diagnostic value of the prostate imaging reporting and data system version 2.1 (PI-RADS v2.1) and PSA-derived indicators, aiming at improving the diagnostic value of prostate cancer to guide clinical biopsy decision-making.
Methods and materials: 180 patients were analysed, with the biopsy results being benign prostatic hyperplasia (BPH) and prostate cancer (PCa) in 111 (61.67%) and 69 (38.33%) patients, respectively. The PI-RADS v2.1 was used to describe the MRI findings. The age, PSA, fPSA, and fPSA/tPSA of the patients were collected. PSAD was divided into three groups with cut-off points of 0.150 and 0.350. Univariate and multivariate analyses were performed to determine significant predictors of prostate cancer.
Results: The differences of the PI-RADS v2.1 score, age, PSA, fPSA/tPSA, PSAD, and PV between the PCa group and BPH group were statistically significant. The multivariate analysis revealed that the PI-RADS v2.1 score and PSAD were independent predictors for prostate cancer. Combining the PI-RADS v2.1 score and PSAD, when the PI-RADS v2.1 score ≤2 and PSAD ≤0.350 ng/mL/mL, or the PI-RADS v2.1 score was 3 and PSAD≤0.150 ng/mL/mL, the prostate cancer detection rate was low (9.10%), and prostate cancer cases in this range were all low-risk cancer (the Gleason score was 6). In contrast, a PI-RADS v2.1 score of 3 and PSAD>0.350 ng/mL/mL or a PI-RADS v2.1 score ≥4, was associated with the highest prostate cancer detection rate (76.00%), and most of the cases were high-risk cancer.
Conclusion: Patients with a PI-RADS v2.1 score ≤2 and PSAD ≤0.350 ng/mL/mL, or a PI-RADS v2.1 score of 3 and PSAD ≤0.150 ng/mL/mL might avoid unnecessary biopsies. The combination of PI-RADS v2.1 and PSAD did improve the diagnostic value of prostate cancer and assist in clinical guidance biopsy decision-making.
Limitations: A bias may exist.

RPS 1107-9 14:48

Safe reduction of MRI-targeted biopsies in men with PI-RADSv2 category 3 lesions: cross-institutional validation of a multivariate risk model based on clinical parameters

D. Deniffel[1], K. Namdar[1], I. Gujrathi[2], E. Salinas-Miranda[1], A. Toi[1], N. Perlis[1], A. Finelli[1], F. Khalvati[1], M. A. Haider[1]; *[1]Toronto/CA, [2]Boston/US (ddeniffel@lunenfeld.ca)*

Purpose: To assess whether a risk model solely based on clinical parameters can reduce MRI-targeted biopsies of PI-RADSv2 category 3 index lesions without missing clinically significant (cs) prostate cancer (PCa) (ISUP≥grade 2).
Methods and materials: We retrospectively analysed 278 patients without a prior PCa diagnosis who underwent multiparametric MRI and MRI-targeted biopsy at 2 institutions. A multivariate model was fitted to the training cohort (institution 1; n=202), using the following clinical parameters: prostate volume, prior biopsy status, PSA density (PSAd), and age. Decision thresholds to rule out csPCa were determined within the PI-RADSv2 3 subgroup of the training cohort (n=115). The validation cohort (institution 2) consisted of 76 men with PI-RADSv2 3 index lesions. Using the area under the ROC curve (AUC), the performance of our model in the validation cohort was compared to PSAd, normalised ADC (nADC), lesion volume, and the MRI European randomised study of screening for PCa risk calculator (MRI-ERSPC-RC).
Results: Our model (AUC=0.80) outperformed PSAd (AUC=0.60; p=0.01), lesion volume (AUC=0.45; p=0.03), and the MRI-ERSPC-RC (AUC=0.39; p=0.0002), and was not inferior to nADC (AUC=0.68; p=0.13). Predefined thresholds for nADC and lesion volume resulted in a minor biopsy reduction by 5% (4/76) and 4% (3/76), respectively; the published threshold for the MRI-ERSPC-RC would have reduced biopsies by 93% (71/76), however, missing 83% (5/6) of csPCas. At a PSAd ≥0.083 ng/ml/ml and a risk threshold ≥0.082 for the multivariate model, the percentage of men who may have avoided biopsy was 21% (16/76) and 33% (25/76), respectively, without missing any csPCa (0/6).
Conclusion: Applying a risk model based on clinical parameters in men with PI-RADSv2 3 index lesions could result in 33% fewer biopsies being performed without missing any csPCa.
Limitations: A retrospective study.
Ethics committee approval: IRB-approved study.
Funding: OICR; DFG-fellowship [DE 3207/1-1].

MpMRI-targeted prostate biopsy only: does systematic biopsy belong in the past?

M. Klingebiel, T. Ullrich, C. Arsov, M. Quentin, D. Mally, P. Albers, G. Antoch, L. Schimmöller*; Düsseldorf/DE (Maximilian.Klingebiel@med.uni-duesseldorf.de)*

Purpose: To evaluate the prostate cancer (PCa) detection of targeted MRI/ultrasound fusion-guided biopsy (TB) and systematic transrectal ultrasound-guided biopsy (SB) in a large patient collective.
Methods and materials: Consecutive patients with 3T multi-parametric MRI of the prostate and subsequent TB plus SB from 01/2014 to 04/2019 were included in this study. Study endpoints were PCa detection of TB versus SB, and analyses of cases with only positive SB or Gleason upgrade by SB. Histopathological positive cores of TB and SB were retrospectively correlated with the MRI data.
Results: In total, 785 patients (65±9 years; median 8.1ng/ml) met the inclusion criteria. In 461 patients a PCa and in 342 patients a clinically significant PCa (csPCa; Gleason score ≥3+4=7) were verified. In 75 patients (16%), only SB detected a PCa, including 30 patients with csPCa (6.5%). In 50 of these cases

(26 csPCa), SB targeted the MRI index lesion missed by TB. 19 of 44 non-significant PCa (nsPCa) were not visible on MRI (43%). In 42 patients, SB resulted in a Gleason upgrade compared to TB. In 31 of these cases, TB missed the MRI centre of the PCa. In 12 patients, SB resulted in csPCa, whereas TB showed nsPCa (2.6%). In 175 patients, TB and SB showed equal results (38%). In 69 patients, TB resulted in a Gleason upgrade including 28 more csPCa (6%). In 101 patients, only TB detected the PCa, including 67 csPCa (15%).
Conclusion: Additional SB detected 9% more csPCa, which in the majority were correctly described on MRI, but missed by TB. Furthermore, SB over-detected 10% additional insignificant PCa. Thus, SB might be unnecessary and provide no benefit through the optimisation of TB.

Preoperative MRI risk estimation and predictors of positive surgical margins in patients with prostate cancer undergoing radical prostatectomy

L. Schimmöller, M. Quentin, T. Ullrich, S. Dörfler, C. Arsov, P. Albers, G. Antoch*; Düsseldorf/DE (lars.schimmoeller@med.uni-duesseldorf.de)*

Purpose: To analyse multiparametric prostate MRI (mpMRI) examinations of patients with positive surgical margins (PSM) of the prostate cancer (PCa) after robotic assisted radical prostatectomy (RPE).
Methods and materials: Consecutive patients with PSM in one or more localisations after RPE and prior mpMRI for PCa detection from 01/2016 to 12/2018 were retrospectively included in this study. MpMRIs were analysed by two experienced readers in consensus regarding PCa visibility, capsule contact length (CCL), extracapsular extension (ECE), and location of PSM in relation to the histopathologic examination of the prostatectomy specimens.
Results: 44 patients with a postoperative tumour stage of 34% T2c, 25% T3a, and 41% T3b were included. PSM occurred at the posterior capsule in 14 patients, anterior in 13 patients, basal at the seminal vesicles (SV) in 7 patients, and in 16 patients apical at the membranous urethra. The PCa was visible on MRI in 97% of cases (n=41). An MRI correlate of ECE was seen in 56% (19/34), the contact to the urethra in 88% (13/16), and to the SV in 100% (7/7). Measurable ECE on MRI was found in 57% (mean 5.1±2.7mm) with a mean CCL was 21±13 mm.
Conclusion: PSM occurred mostly apical at the urethra, anterior, or posterior at the capsule margin or basal at the SV. MpMRI has a high ability to visualise PCa and determine cases with a risk of PSM. Measurable ECE, CCL, and distance to the membranous urethra should always be reported.

Feasibility of a 2nd generation MR-compatible remote-controlled manipulator for transrectal focal laser ablation in patients with prostate cancer

S. P. Hoogendoorn, J. G. R. Bomers, J. P. M. Sedelaar, J. J. Futterer*; Nijmegen/NL (Stefan.Hoogendoorn@radboudumc.nl)*

Purpose: To assess the feasibility of a 2nd generation MR-compatible remote-controlled manipulator (RCM) as an aid to perform transrectal MRI-guided focal laser ablation in men with histologically proven prostate cancer (PCa).
Methods and materials: Between March 2016 and May 2018, 17 consecutive patients with at least one focus of histologically proven PCa (Gleason ≥7) underwent transrectal MRI-guided focal laser ablation. An MR-compatible RCM (Soteria Medical) was used to steer the needle guide. Depending on the size of the lesion, several ablations were performed. For the evaluation of the workflow, the procedure times, the manipulation times, and the number of ablations were recorded. Complications were registered according to the clinical practice guidelines proposed by the Society of Interventional Radiology (SIR).
Results: All lesions were reachable with the MR-compatible RCM. The median procedure time was 125 minutes (range, 77-169 minutes) and the median manipulation time for laser-fibre movement was 34 minutes (range, 8-60 minutes). Per lesion, a median number of 5 ablations was performed (range, 2–7). One SIR grade B (urine-retention) and one grade C/D (urosepsis) complication were reported.
Conclusion: It is safe and feasible to perform transrectal MRI-guided focal laser ablation using a MR-compatible RCM.
Limitations: n/a

Multiparametric MRI and targeted prostate biopsy: a comparison between In-Bore and TRUS-MRI fusion techniques performed by the same operator

S. Cipollari, R. Campa, M. Pecoraro, V. Salvo, M. Del Monte, C. Catalano, V. Panebianco*; Rome/IT (stefanocipollari@gmail.com)*

Purpose: To compare in-bore and of TRUS-MRI fusion MR targeted prostate biopsies performed by the same operator.
Methods and materials: A cohort of 820 patients with elevated PSA level and no previous positive biopsy who underwent prostate mpMRI were retrospectively reviewed. Patients underwent diagnostic high-field (3T and 1.5T) mpMRI (T2WI on axial and coronal planes, DWI with six b values up to 2000 s/mm2, DCE images). Two expert radiologists retrospectively evaluated the exams according to PI-RADS v2 and inter-reader agreement was calculated using K statistics. Targeted biopsy was performed in 223 patients; 106 underwent in-bore biopsy and the remaining 117 patients underwent TRUS-MRI fusion biopsy. MRI data was compared to histopathology data. Detection rates were calculated to evaluate the performance of the two different techniques.
Results: In-bore and fusion techniques did not significantly differ in overall prostate cancer detection (0.68 vs. 0.66, p=0.07). The in-bore biopsy was in the subgroup of lesions smaller than 0.3cc (mean diameter 8.3 mm) and in detection of clinically significant PCa (0.60 vs. 0.56, $p < 0.05$). A statistically significant difference in favour of the in-bore technique was found in terms of a higher per-core cancer detection (0.56, 95% CI 0.54–0.58 vs 0.4, 95% CI 0.38– 0.42) and a lower number of cores per-patient (3.22, 95% CI 3.02–3.42 vs 6.52, 95% CI 4.82–8.22)
Conclusion: In-bore and TRUS-MRI fusion techniques were comparable in terms of overall detection rate. The in-bore technique was superior in the detection of smaller lesions, in the PI-RADS 3 lesions, and in the per-core detection rate.
Limitations: Relatively small size and possible bias due to different scans.

RPS 1107-14 15:18

MRI-directed high frequency (29MHz) TRUS-guided biopsies: an alternative to TRUS-MRI image fusion?

F. Cornud[1], A. Lefevre[1], P. Camparo[2], P. Soyer[1], M. Barral[1]; *[1]Paris/FR, [2]Amiens/FR (francois.cornud@imagerietourville.com)*

Purpose: Significant prostate cancer (sPCa) detection rate is increased by pre-biopsy MRI. However, MRI/ultrasound fusion biopsy entails targeting errors. In-bore MR-guided biopsy is precise, but not widely available. Very high frequency transrectal ultrasound (micro-ultrasound), as a second look examination after MRI, may localise tumour foci of sPCa.
Methods and materials: A total of 117 consecutive patients, mean age 64 ± 12yo, biopsy-naïve in 67% (79/117) of cases, non-suspicious rectal examination in 85% of cases (102/117), with a median PSA level of 8 ng/mL (range: 2-200ng/ml) and at least one focal lesion (MRI+) with a score>2 on biparametric-MRI (bp-MRI), were included. Transrectal biopsy of all lesions visible on micro-ultrasound (MUS+) was performed using a 29MHz transducer. MUS+/MRI+ and

MUS+/MRI- lesions were targeted without image fusion, which was only used for MUS-/MRI+ lesions. Tumours with a Gleason score ≥7 or a maximum cancer core length >3 mm were considered significant.
Results: A total of 144 focal lesions were analysed. Of them, 131 (131/144, 91%) were MUS+, including 114 (114/144, 79%) MUS+/MRI+ and 17 (17/144, 12%) MUS+/MRI- lesions. Significant cancer was detected in 70 lesions (70/114, 56%) in the MUS+/MRI+ group and in 4 lesions (4/17, 23.5%) in the MUS+/MRI- group. The 13 remaining lesions were MUS-/MRI+ without sPCa. The sensitivity and specificity of micro-ultrasound were 100 and 18%.
Conclusion: Micro-ultrasound, as a second look imaging modality, can localise tumour foci detected by bp-MRI and represents an attractive alternative to MRI-TRUS image-fusion.
Limitations: A single-centre study.

Soractelite™ transperineal laser ablation (TPLA) for the treatment of benign prostatic hyperplasia: results at 6 and 12 months
G. Patelli[1], G. Mauri[2], G. Iapicca[3], G. Manenti[4], T. Perretta[1], C. Ryan[4], R. Esposito[5], C. M. Pacella[6]; [1]*Seriate/IT,* [2]*Milan/IT,* [3]*Avellino/IT,* [4]*Rome/IT,* [5]*Cosenza/IT,* [6]*Albano Laziale Roma/IT (patellig@yahoo.it)*

Purpose: To investigate the safety and effectiveness of TPLA in patients with symptomatic benign prostatic hyperplasia (BPH).
Methods and materials: Under US guidance, up to 4 21G applicators were inserted in the prostatic tissue. A diode laser operating at 1064 nm was used. Change in IPSS, PVR, Qmax, QoL, and prostatic volume at 6 and 12 months, and any complications, were recorded.
Results: Data of 160 patients with at least 6 months follow-up and 83 patients with at least 12 months follow-up were analysed.
At 6 months, IPSS improved from 22.5 ± 5.1 to 7.7 ± 3.3 (P<0.001), PVR from 89.5 ± 84.6 to 27.2± 44.5 ml (P<0.001), Qmax from 8.0 ± 3.8 to 14.3 ± 3.9 ml/s (P<0.001), QoL from 4.5 ± 1.1 to 1.8 ± 1.0 (P< 0.001), and volume from 75.0 ± 32.4 to 60.3 ± 24.5 ml (P< 0.001).
At 12 months, IPSS improved from 22.5 ± 4.5 to 7.0 ± 2.9 (P<0.001), PVR from 71.7 ± 93.9 to 17.8 ± 51.0 ml (P<0.001), Qmax from 8.6 ± 5.2 to 15.0 ± 4.0 ml/s (P<0.001), QoL from 4.2 ± 0.6 to 1.6 ± 0.9 (P< 0.001), and volume from 87.9 ± 31.6 to 58.8 ± 22.9 ml (P< 0.001).
7/160 (4.3%) grade I and 1/160 (0.6%) grade III complication occurred.
Conclusion: SoracteLite™ TPLA allows significant improvement of IPSS, Qol, Qmax, PVR, and reduction of prostatic volume at 6 and 12 months
Limitations: A retrospective design.
Ethics committee approval: IRB approval was obtained.

Associations between cardiovascular function, brain volumes, and white matter hyperintensities
M. van Hout, I. Dekkers, J. J. M. Westenberg, A. Scholte, H. J. Lamb; *Leiden/NL (i.a.dekkers@lumc.nl)*

Purpose: To study whether vascular and left ventricular (LV) function is associated with total brain volume, grey and white matter volumes, and white matter hyperintensities (WMH) in the middle-aged general population.
Methods and materials: 4,366 participants of the UK-biobank underwent magnetic resonance imaging (MRI) to assess LV (ejection fraction (EF) and cardiac index (CI)) and brain parameters (total, grey, and white matter volumes and volume of WMH). The augmentation index (AIx) was used as a measure of arterial stiffness. An analysis of variance was used to test whether multivariate linear regression or polynomial splines should be performed using the cardiovascular function as determinants, brain volumes normalised for head size, and WMH as outcome variables, adjusting for known confounders. WMH were log-transformed to adjust for skewed distribution.
Results: EF was non-linearly associated with total brain volume and grey matter volume, with an optimal volume for an EF between 55 and 60% (P<0.001), but not associated with white matter volume. EF showed a negative linear association with WMH (β=1.005 mm^3 [-1.003; -1.008], P=0.03). In contrast, CI was not associated with total brain volume, grey matter volume, or WMH. CI did show a significant positive linear association with white matter volume (β=3.194 mm^3 [760; 5,627], P=0.01). AIx was not significantly associated with brain volumes or WMH.
Conclusion: A complex association exists between LV ejection fraction and brain structure, with an optimal grey matter volume for an EF between 55 and 60%. EF is negatively associated with WMH.
Limitations: Our observational cross-sectional design precludes causal inference and did not assess cognitive functioning.
Ethics committee approval: The study was approved by the National Research Ethics Service Committee (11/NW/0382).
Funding: No funding was received for this work.

RPS 1111-2 14:06
Vascular hyperintensities on a post-contrast 3D fast-spin-echo T1-weighted sequence: a sign of poor collateral pathways in sickle-cell disease cerebral vasculopathy?
C. Y. Provost[1], W. Ben Hassen[1], J. Benzakoun[1], L. Legrand[1], D. Calvet[1], P. Bartolucci[2], O. Naggara[1], C. Oppenheim[1], M. Edjlali-Goujon[1]; [1]*Paris/FR,* [2]*Créteil/FR (cyprovost@gmail.com)*

Purpose: Sickle cell disease (SCD) cerebral vasculopathy is characterised by progressive occlusion of cerebral arteries with the development of extensive collateral pathways to compensate. We aimed to evaluate the prevalence and meaning of post-contrast vascular hyperintensities (PCVH) on a 3D fast-spin-echo T1-weighted sequence in SCD.
Methods and materials: We included 19 SCD patients with cerebral artery occlusion and 50 SCD patients without occlusion, as detected on MR angiography at 3-Tesla. Two neuroradiologists blinded to clinical data and the other MRI sequences looked for PCVH on a post-contrast 3D fast-spin-echo T1-weighted sequence. We evaluated the concordance between the arterial distribution of occlusions and PCVH. Dynamic susceptibility contrast perfusion imaging was performed to measure Tmax values in the occluded arterial territory.
Results: Inter and intraobserver agreements for the detection of PCVH were excellent. PCVH was found in 14 of 19 patients (74%), with cerebral artery occlusion and only 1 of 50 patients (2%) without occlusion (p<0.001). This latter patient had bilateral severe stenosis of the cervical internal carotid arteries. The concordance between the arterial distribution of occlusions and that of PCVH was good to excellent (κ=0.73, 0.76, and 0.80 for the anterior, middle, and posterior cerebral arteries, respectively). Tmax values in the occluded arterial territory were higher in PCVH-positive patients compared to PCVH-negative patients (3 seconds versus 2 seconds, p<0.001).
Conclusion: PCVH in sickle cell disease is a sign of severe cerebral vasculopathy and is associated with marked hypoperfusion. It may represent poor collateral pathways.
Limitations:
The 3D fast-spin-echo T1-weighted sequence was only performed at 3-Tesla, thus limiting the generalisability of the findings.
Ethics committee approval: This study received ethics committee (Comité de Protection des Personnes Île-de-France Saint-Louis) approval.
Funding: No funding was received for this work.

White matter lesion volume in subjects with prediabetes, subjects with diabetes, and normoglycemic control subjects

S. Grosu[1], R. Lorbeer[1], F. Bamberg[2], C. L. Schlett[2], A. Peters[3], M. Heier[1], S. Rospleszcz[1], B. B. Ertl-Wagner[1], S. Stöcklein[1]; [1]*Munich/DE,* [2]*Freiburg/DE,* [3]*Neuherberg/DE*

Purpose: As white matter lesions (WML) of the brain are associated with an increased risk of stroke, cognitive decline, and depression, elucidating the associated risk factors is important. In addition to age and hypertension, prediabetes and diabetes may play important roles in the development of WML. Previous studies have, however, shown conflicting results. We aimed to evaluate the association between WML volume and prediabetes/diabetes.
Methods and materials: 400 subjects of the epidemiological KORA study cohort underwent 3T-MRI. WML were manually segmented on 3D-FLAIR images. An oral glucose tolerance test (OGTT) was administered to all participants without previously diagnosed type 2 diabetes. Linear and logistic regression analyses of WML volume and measures of diabetes and diabetes status were conducted while controlling for cardiovascular risk factors.
Results: The final study population consisted of 388 participants (57% male; age: 56.3±9.2 years). WML were found in 249 participants with a mean volume of 1755±5920 mm^3. 98 subjects had prediabetes and 51 established diabetes. Serum glucose concentration determined by OGTT, but not fasting glucose or HbA1c levels, showed a significant association with WML volume after adjustment (p=0.004). WML volume was significantly higher in subjects with prediabetes (p=0.023) and diabetes (p=0.003) compared to normoglycemic control subjects. However, these associations became insignificant after adjustment.
Conclusion: In this population without prior cardiovascular disease, we identified serum glucose concentration assessed by OGTT as a quantitative determinant of WML volume. Our data suggests that the effect of diabetes, and particularly prediabetes, on WML volume might be driven by impaired glucose tolerance.
Limitations: The limited sample size. Unmeasured confounding variables cannot be fully ruled out.
Ethics committee approval: Approved by the ethics committee of Ludwig-Maximilian-University Hospital, Munich.
Funding: German Research Center for Environmental Health and the German Research Foundation (DFG).

Acute symptomatic lacunar ischaemic stroke as the first presentation of small vessel disease: how common is it?

A. Guarnera[1], C. Barbato[2], L. Ulivi[2], S. Browning[3], D. Werring[3], R. Simister[3], R. Jager[3]; [1]*Rome/IT,* [2]*Florence/IT,* [3]*London/UK (guarneraalessia@gmail.com)*

Purpose: To investigate the prevalence of cerebral small vessel disease (SVD) in a consecutive cohort of patients presenting with acute symptomatic lacunar ischaemic strokes (ASLIS) and to ascertain how frequently an ASLIS represents the initial radiological manifestation of SVD.
Methods and materials: In a hospital trust, a database of 831 patients undergoing MRI for acute stroke from May 2018-February 2019 was retrospectively reviewed to identify patients with DWI+ASLIS. Patients with a history of trauma or cancer, haemorrhagic strokes, and large vessel disease were excluded. Patients were split into those with and without SVD by using established scoring systems. Subjects with evidence of SVD were assigned to three categories: arteriolosclerosis, probable/possible cerebral amyloid angiopathy (CAA), and mixed disease. Potential risk factors were evaluated by Fisher's and Student's tests, and calculating the odds ratio, between the groups of patients with and without evidence of SVD and among the subgroups of patients with SVD.
Results: Of 104 subjects included, 29 (28%) showed no evidence of SVD, while of the remaining 75 (72%), 59 (57%) had evidence of arteriolosclerosis, 4 (4%) of CAA, and 12 (11%) of mixed disease. Among the markers of SVD, white matter hyperintensity was the most common. Subjects with evidence of SVD were significantly more prone to be older, smokers, and affected by diabetes, hypercholesterolemia, and hypertension (OR:2.1).
Conclusion: In 2/3 of patients with ASLIS and a co-existing burden of SVD, arteriolosclerosis was predominant and subjects were likely to present cardiovascular risk factors. DWI+ASLIS was the first imaging manifestation of SVD in about 1\3 of subjects. These patients may have different pathophysiology, different risk of stroke recurrence, and need tailored therapy.
Limitations: The relative small cohort analysed.
Ethics committee approval: The study was approved by the institutional ethics committee.
Funding: No funding was received for this work.

Dynamic computed tomography angiography (dCTA) for determining infarct size and collaterals in order to predict the clinical outcome after recanalisation of acute ischaemic stroke

E. Puglielli, P. Pierluigi, A. Bernardini, S. Roiati, N. Caputo*; Teramo/IT (edopug@hotmail.com)*

Purpose: To investigate the impact of dCTA weighting on the evaluation of collateral circulation using classic methods and their ability to predict infarct size and clinical outcome. The visualisation of pial collaterals may vary depending on whether the CTA is arterial (A), arterio-venous (AV), or venous (V) weighted.
Methods and materials: 190 consecutive patients (mean age=47 years, April 2009-September 2019) with classical onset underwent endovascular therapy in a single-centre using predominantly stent retrievers, neurotrombectomy devices, or thromboaspiration. Basal CT and dCTA were used for imaging. Two readers studied infarct volume on imaging of the collateral scores stratified by dCTA weighing with age, gender, occlusion aetiology, symptoms, national institutes of health stroke scale (NIHSS) median score at presentation, clot burden score (CBS), and modified Rankin scale (mRS) correlation.
Results: The median NIHSS score at presentation was 18 (range 3-36) and the onset to treatment time was 123 (76-187) minutes. dCTA scans were A-weighted in 135/190 (71.05%), AV in 25/190 (13.15%), and v-weighted in 30/190 (15.78%). Poor collateralisation (OR 12.50; 95% CI (3.9, 43); p<0.0001) and longer time to peak of maximum arterial enhancement (OR 3.1; 95% CI (1.93, 6.1); p <0.0001) were positively associated with a late venous phase cortical vein filling. All collateral scores were related to infarct volume irrespective of dCTA weighting (p<0.005). No association was shown between dCTA weighting, collateral grade, and clinical outcome.
Conclusion: dCTA weighting did not significantly impact collateral grade analysis with the three common collateral scores and there is a lack of evidence of their ability to predict final infarct size after recanalisation
Limitations: The possible error due to a small series.

The arterial remodelling ratio and normalised wall index of the middle cerebral artery are associated with leptomeningeal collateral status: a study of high-resolution vessel wall imaging

R. Tang[1], S. Liu[2], S. Xia[2], Z. Wang[1]; [1]*Beijing/CN,* [2]*Tianjin/CN (vickney1993@163.com)*

Purpose: Arterial stenosis is not sufficient for stratifying stroke risk. In this study, we evaluated atherosclerotic plaque features of the middle cerebral artery (MCA) using high-resolution vessel wall imaging (HR-VWI) and explored the correlation between plaque features and leptomeningeal collateral (LMC) status.
Methods and materials: 61 patients with intracranial atherosclerotic disease who underwent HR-VWI scans (September 2016-December 2018) were

retrospectively included. All patients presented with symptoms of ischaemic stroke or transient ischaemic attack with confirmed stenosis >30% in M1-2 segments. Plaque features were measured at the cross-section with most lumen narrowing (MLN) on HR-VWI. LMC was graded per patient on strategically acquired gradient echo (STAGE) derived magnetic resonance angiography (MRA) images using an established five-point collateral score (CS) system. Patients were divided into a poor (CS=0-2) or good (CS=3-4) LMC group. Independent two-sample t-tests, Mann-Whitney U-tests, or one-way analysis of variance was used as appropriate. Univariate and multivariate logistic regressions were conducted to identify the plaque features correlated with LMC status.
Results: Larger outer wall area (OWA), lumen area (LA_{MLN}), wall area, less stenosis percent (S%), M1 segment, and inferior wall distribution were found in the good LMC group compared with the poor LMC group (all p<0.05). Significant associations between the arterial remodelling ratio (ARR, odds ratio [OR] 3488.108, 95% confidence interval [CI] 1.198-2.637, p=0.004) and normalised wall index (NWI, OR 132.686, 95% CI 0.693-0.978, p=0.027) with LMC status were found.
Conclusion: Plaques in the poor or good LMC group exhibit different morphology and distribution features, among which ARR and NWI are associated with LMC status, which may help determine therapeutic decision-making in the clinical setting.

The role of diffusion-weighted brain MR imaging in predicting outcomes after comatose cardiac arrest

K. Coursier[1], S. Vanden Berghe[2], S. A. Cappelle[3], K. Ameloot[4], F. de Keyzer[5], R. Peeters[4], S. van Cauter[4], S. Janssens[4], P. Demaerel[4]; *[1]Genk/BE, [2]Heule/BE, [3]Ypres/BE, [4]Leuven/BE, [5]Brussels/BE*
(kristof_coursier@hotmail.com)

Purpose: To assess a qualitative and quantitative approach to diffusion-weighted brain MR imaging (DWI) in order to investigate its role in predicting clinical outcomes after cardiac arrest.
Methods and materials: 75 patients underwent brain MR imaging within 5±2 days after a cardiac arrest. Two observers independently used a four-point Likert scale scoring template per assessed brain area on high b-value diffusion-weighted images (DWI). Intra and interobserver variability were tested using the intraclass correlation coefficient. ROC/AUC analysis was used for the outcome correlation with the clinical outcome defined by the cerebral performance category status at 180 days. Quantitative parameters on DWI were the percentage of voxels with apparent diffusion coefficient (ADC) <0.650 x 10^{-3} mm^2/s and the mean whole-brain ADC value.
Results: Intraobserver variability was excellent for the total cerebral cortex (TCC) score and for the total grey nuclei (TGN) score. Interobserver variability was excellent for the TCC and good to excellent for the TGN score. ROC analysis of the qualitative DWI showed a good correlation with the outcome for the TCC and for the TGN (AUC=0.83) score, whereas the quantitative DWI parameters correlated very poorly with the outcome (AUC 0.57-0.60).
Conclusion: Qualitative assessment of DWI acquired early after cardiac arrest provides valuable information to predict the outcome after cardiac arrest, while the correlation of the quantitative ADC assessment with the outcome was poor.
Limitations: n/a
Ethics committee approval: Study is based on a clinical trial that was approved by the ethics committee of UZ Leuven K.U.L., s58017.
Funding: Study is based on a clinical trial that was funded by a non-commercial TBM grant from the Flemish Government (IWT Flanders, Belgium).

Homogeneity of the mean transit time allows for the discrimination of the functional outcome after aneurysmal subarachnoid haemorrhage

K. Jannusch, K. Beseoglu, M. Kaschner, N. A. Teichert, H. Nasri, A. K. Petridis, B. Turowski, J. Caspers, C. Rubbert; *Düsseldorf/DE*
(christian.rubbert@med.uni-duesseldorf.de)

Purpose: The pathogenesis leading to poor functional outcome after aneurysmal subarachnoid haemorrhage (aSAH) is multifactorial. CT perfusion imaging (CTP), especially the mean transit time (MTT), is increasingly used to monitor for delayed cerebral ischaemia. We hypothesise that the homogeneity (i.e. the standard deviation) of the MTT across the cortex on patient admission is predictive of the functional outcome.
Methods and materials: 147/630 consecutive subarachnoid haemorrhage patients (2008-2015) were retrospectively analysed (mean age 54.5, 66.7% female. Inclusion: aSAH, admission within 24h of ictus, CTP within 24h of admission, documented functional outcome after six months (modified Rankin scale grades; mRS). Exclusion: previous aSAH, CTP not evaluable).
MTT was recorded over 360° along the cortex in a 10 mm wide ribbon using a sliding window approach spanning 10° in 2° increments.
MTT standard deviation across the cortical ribbon (MTT_{SD}) was compared between mRS-dichotomised patient groups (≤2;>2) using a t-test. A logistic regression model (LRM) with stepwise regression using MTT_{mean}, MTT_{max}, MTT_{SD}, patient age, sex, world federation of neurosurgical societies and modified Fisher score, was assessed.
Results: F1 shows MTT_{SD}/mRS. MTT_{SD} was significantly different between patient groups (mRS ≤2;>2, p<0.001). After stepwise regression, the LRM retained MTT_{SD} (p=0.021), age (p=0.003), and Fisher score (p=0.0004). McFadden R^2=0.22 indicated a good to excellent model fit. The model's area under the receiver operating characteristics curve was 0.81.
Conclusion: Along with the Fisher score and patient age, the MTT_{SD} is predictive of functional outcome 6 month after aSAH ictus. MTT_{SD}, as a measurement of homogeneity, should be further evaluated for monitoring and prognostic assessments.
Limitations: Patients with detrimental pre-aSAH-mRS might have been included (unlikely at mean age of 54.5).
Ethics committee approval: The study was approved by the local ethics committee. The requirement for written informed consent was waived.
Funding: No funding was received for this work.

Feasibility study of 4D flow MRI to evaluate haemodynamics in patients with intracranial aneurysms

J.-G. Zhang, Z. Li; *Chengdu/CN (zjgscuhx@126.com)*

Purpose: To study the relationship between aneurysm morphology and haemodynamics in patients with intracranial aneurysms by using 4D flow technology. This study aims to explore its feasibility and value.
Methods and materials: In this study, clinical and imaging data of 25 patients with intracranial aneurysms were collected before surgery. After post-processing of 4D flow original phase images, the dynamic 3D images of blood flow velocity, wall shear stress (WSS), and velocity vector were created by the CVI42 software. The haemodynamic indexes including WSS, WSS ratio, shear concentration index (SCI), mean and maximum blood flow velocity, and mean and maximum instantaneous blood flow were measured and calculated. Meanwhile, the morphological parameters of aneurysms (including neck diameter, height, aneurysm width, parent diameter, neck diameter/parent diameter, aneurysm angle, etc.) were measured on digital subtraction angiography (DSA) images. Pearson's correlation was used to analyse the correlation between haemodynamic parameters (WSS, WSS ratio, and SCI) and other parameters.
Results: The WSS and WSS ratio was positively correlated with the ratio of neck diameter and parent diameter (r=0.578, 0.637, P<0.05), and SCI values were positively correlated with the aneurysm angle (r=0.395, P<0.05).
Conclusion: The haemodynamics of intracranial aneurysms is closely related to their morphology and the 4D flow MRI technique can dynamically and quantitatively evaluate the haemodynamic indicators of aneurysms, which has application value in exploring the mechanism of aneurysms and assessing the risk of aneurysm rupture.

Limitations: The small sample size.
Ethics committee approval: This study was approved by the ethics committee of West China Hospital and written informed consent was obtained.

Imaging of endovascularly treated intracranial aneurysms: comparing the novel technique of ASL-based silent-MR angiogram with 3D TOF-MR angiogram and digital subtraction angiogram

A. Rajendran[1], K. Chandrasekharan[2], D. K. Santhosh[2]; [1]*Chennai/IN,* [2]*Trivandrum/IN (adhithyan40@gmail.com)*

Purpose: To compare silent-MRA and 3D TOF-MRA in the evaluation of follow-up imaging of endovascularly treated intracranial aneurysms in comparison with DSA as the criterion standard for the assessment of the residual aneurysms and stent patency.
Methods and materials: A prospective analysis of consecutive patients with endovascularly treated aneurysms either by coiling or flow diverter who had follow-up imaging with TOF, silent-MRA, and DSA. The results were analysed by two neuro-radiologists independently. 3D TOF-MRA, silent-MRA, and DSA were evaluated for the size of the residual aneurysms and graded by the Raymond–Roy scale. The patency of the stent was also analysed. Images were analysed for the quality and graded on a 5-point scale. Kappa parameters were used to look for the agreement between the two methods. Scores were averaged and compared between techniques by using a Wilcoxon signed-rank test.
Results: 19 patients (4=stent-assisted coiling, 6=flow-diverters, and 9=simple or balloon-assisted coiling) were included.
The mean image quality score for residual aneurysm evaluation was 3.89+/-0.6 for TOF-MRA and 4.68+/-0.46 for silent-MRA. Scores of silent-MRA and 3D TOF-MRA differed significantly (P<0.05) according to the Wilcoxon signed-rank test.
The mean image quality score for the assessment of the stent or flow-diverter patency was 2.8+/-1.07 for TOF-MRA and 4.2+/-0.6 for silent-MRA. Scores of silent-MRA and 3D TOF-MRA differed significantly (P<0.05) for evaluating the stent or flow diverter patency.
Intermodality agreement values of 0.90 and 0.40 were obtained for DSA/silent-MRA and DSA/3D TOF-MRA, respectively.
Conclusion: Silent-MRA provides more accurate imaging information and better image quality than conventional TOF-MRA in the evaluation of residual aneurysms and stent patency by reducing the magnetic susceptibility artefacts.
Limitations: The limited number of cases.
Ethics committee approval: Ethics committee approval obtained.
Funding: No funding was received for this work.

Follow-up of intracranial aneurysms treated with endovascular techniques: a comparison of the different methods with a review of the literature

E. Puglielli, G. Lanni, L. Conti, A. Gennarelli, N. Caputo; *Teramo/IT (edopug@hotmail.com)*

Purpose: To compare time-of-flight 3D-TOF magnetic resonance angiography (MRA), contrast-enhanced CE-MRA at 1.5-Tesla, computed tomography angiography (CTA), and digital subtraction angiography (DSA) for evaluating aneurysm occlusion and parent artery patency after coiling or stent-assisted coiling with a review of the recent literature.
Methods and materials: in this retrospective single-centre study, 427 patients were included if they had an intracranial aneurysm treated by coiling/stent-assisted coiling (April 2009-June 2019) followed by MRA (3D-TOF-MRA and CE-MRA), CTA or DSA, performed in an interval of 6, 12, or 24 months. Pooled sensitivity and specificity were calculated using the aneurysm occlusion status as defined by the Raymond-Roy occlusion grading scale.
Results: Vessels visualisation in the vicinity of the treated aneurysm was better in CTA, while regarding aneurysm occlusion, evaluation of the agreement with DSA was better for CE-MRA (K=0.51) than 3D-TOF-MRA (K=0.25). Diagnostic accuracies for the aneurysm remnant depiction were similar for 3D-TOF-MRA and CE-MRA (P=1). For TOF-MRA, the sensitivity and specificity of all aneurysms undergoing endovascular therapy were 87% and 93%, respectively, in accordance to the recent literature.
Conclusion: After coiling or stent-assisted coiling treatment, 3D-TOF-MRA and CE-MRA demonstrated good accuracy in detecting the aneurysm remnant, although it tends to overestimate. Vessels visualisation in the vicinity of treated aneurysm was better in CTA. Despite CE-MRA, agreement with DSA was better; there was no statistical difference between 3D-TOF-MRA and CE-MRA accuracies. Both MRAs were unable to provide a precise evaluation of the in-stent status but could detect the parent vessel occlusion. While digital subtraction angiography (DSA) remains the gold standard, magnetic resonance angiography (MRA) is attractive as a non-invasive follow-up technique.
Limitations: The small series.

Concordance between the simplified Edinburgh CT criteria and the modified Boston MRI criteria for cerebral amyloid angiopathy-associated (CAA) intracerebral haemorrhages (ICH)

F. Bruno, E. Tommasino, F. Cobianchi Bellisari, A. Barile, E. Di Cesare, C. Masciocchi, A. Splendiani; *L'Aquila/IT (federico.bruno.1988@gmail.com)*

Purpose: To evaluate the reproducibility of the Edinburgh CT criteria for cerebral amyloid angiopathy-associated (CAA) lobar intracerebral haemorrhage (ICH) in comparison to the modified Boston MRI criteria.
Methods and materials: We retrieved the images of 132 patients, with first-ever intracerebral hemorrhage diagnosed by non-contrast CT, in our Emergency department. The same patients underwent also MRI examination, to assess brain complications and were confirmed clinically with the diagnosis of cerebral amyloid angiopathy. Two blinded expert neuroradiologists independently evaluated CT images for the presence of the described CT signs for CAA ICH (finger-like projections, subarachnoid haemorrhage, lobar distribution).
Results: Using the simplified Edinburgh CT criteria, CAA-ICH was found in 89/100 patients (89%). The Boston criteria categorised 92 patients as having CAA-ICH. The concordance between the different diagnostic method was 92% (k= 0.82). Among CT signs, the presence of all CT signs resulted to have the highest specificity, while the highest diagnostic performance was recorded for SAH alone.
Conclusion: The concordance between the simplified Edinburgh criteria and the modified Boston criteria is high. Therefore, CT scores can be safely used in cases where MR is unsuitable, be it for contraindications or patient medical conditions.
Limitations: No histological confirmation.
Ethics committee approval: All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki declaration.
Funding: No funding was received for this work.

Clinical radiomics nomogram for the risk estimation of haematoma expansion after intracerebral haemorrhage

Y. Yang, Q. Chen, D. Zhu, J. Liu, M. Zhang, H. Xu, S. Huang; *Wenzhou/CN*

Purpose: Early haematoma expansion (HE) following intracerebral haemorrhage (ICH) is strongly associated with a poor outcome. The purpose of this study was to develop and validate a clinical radiomics nomogram for predicting HE in patients with acute spontaneous ICH.
Methods and materials: In total, 1,153 eligible patients were enrolled, of whom 864 (75%) were assigned to the derivation cohort and 289 (25%) to the validation cohort. Based on the LASSO algorithm or multivariate analysis, three models (the clinical model, the radiomics model, and the hybrid model incorporating both clinical and radiomics predictors) were constructed to predict HE. The Akaike information criterion (AIC) and likelihood ratio test (LRT) were used for comparing the goodness of fit of the three models, and the AUC was used to evaluate their discrimination ability for HE.
Results: The hybrid model (AIC=681.426; χ^2=128.779) was determined as the optimal model with the lowest AIC and highest Chi-square values compared with the radiomics model (AIC=767.979; χ^2=110.234) or clinical model (AIC=753.757; χ^2=56.448). The radiomics model had better discrimination ability for HE than

the clinical model in both derivation (p=0.009) and validation (p=0.022) cohorts. In both datasets, the clinical radiomics nomogram showed satisfactory discrimination and calibration in predicting HE (AUC=0.771, sensitivity=87.0%; AUC=0.820, sensitivity=88.1%; respectively).
Conclusion: Integrating CT-based radiomic signatures with clinical risk factors could optimise the predictive performance for HE. In the absence of CT angiography, the clinical-radiomics nomogram can offer an individualised tool for the risk stratification of HE with good sensitivity and may help select more ICH patients for anti-expansion clinical trials.
Limitations: The nomogram is derived from a single-centre analysis, thus lacking external validation.

RPS 1111-14 15:18
Quantification of carotid intraplaque haemorrhage: a comparison with manual segmentation and semi-automatic segmentation on magnetisation-prepared rapid acquisition with gradient-echo sequence
Y. J. Song[1], H.-S. Kwak[2]; [1]*Jeonju-si Jeollabuk-do/KR,* [2]*Jeonju/KR*
(twinklinglena@gmail.com)

Purpose: Carotid intraplaque haemorrhage (IPH) increases the risk of territorial cerebral ischaemic events but different sequences or criteria are used to diagnose and quantify carotid IPH. The purpose of this study was to compare manual segmentation and semi-automatic segmentation for the quantification of carotid IPH on magnetisation-prepared rapid acquisition with the gradient-echo (MPRAGE) sequence.
Methods and materials: 40 patients with 16-79% carotid stenosis and IPH on MPRAGE sequence were reviewed by 2 trained radiologists with more than 5 years of specialised experience in carotid plaque characterisation. Initially, the radiologists manually read the IPH based on the MPRAGE sequence. The IPH volume was then measured by 3 different semi-automatic methods: high signal intensity above 150%, 175%, and 200% than that of the adjacent muscle on MPRAGE sequence. The agreement on measurements between manual segmentation and semi-automatic segmentation was assessed using the intraclass correlation coefficient (ICC).
Results: There was good agreement between manual segmentation and the 3 criteria of semi-automatic segmentation for the quantification of IPH volume. ICC of each semi-automatic segmentation were as follows: 150% criteria: 0.87-0.96, 175% criteria: 0.85-0.96, and 200% criteria: 0.69-0.90. The agreement of total IPH length was good in all criteria of semi-automatic segmentation (ICC=150% criteria: 0.80-0.94, 175% criteria: 0.71-0.91, and 200% criteria: 0.60-0.87). ICC of 150% and 175% criteria were significantly better than that of 200% criteria (p<0.05).
Conclusion: ICC of 150% and 175% criteria for semi-automatic segmentation are more reliable for quantification of IPH volume. Semi-automatic classification tools may be beneficial in large-scale multicentre studies by reducing the image analysis time and avoiding bias between human reviewers.
Limitations: There was no histological confirmation. The relatively small number of patients.
Ethics committee approval: This study was conducted with institutional review board approval.
Funding: No funding was received for this work.

Accelerated time-of-flight magnetic resonance angiography using spiral imaging improves the conspicuity of intracranial arterial branches whilst reducing scan time
N. Sollmann, T. Greve, A. Hock, C. Zimmer, J. S. Kirschke*; Munich/DE*
(nico.sollmann@tum.de)

Purpose: To compare time-of-flight magnetic resonance angiography (TOF-MRA) acquired with compressed SENSE (TOF-CS) to spiral imaging (TOF-Spiral) for the imaging of brain-feeding arteries.
Methods and materials: 71 patients (60.2±19.5 years, 28.2% with pathology) who underwent TOF-MRA after the implementation of new scanner software enabling spiral imaging were analysed retrospectively. TOF-CS (standard sequence; duration: ~4 min) and the new TOF-Spiral (duration: ~3 min) were acquired. Image evaluation (vessel image quality and detectability, diagnostic confidence [1: diagnosis very uncertain-5: diagnosis very certain], quantitative measurement of aneurysm diameter, or degree of stenosis according to NASCET criteria) was performed by two readers. Quantitative assessments of pathology were compared to computed tomography angiography (CTA) or digital subtraction angiography (DSA).
Results: TOF-CS showed higher image quality for intraosseous and intradural segments of the internal carotid artery, while TOF-Spiral better depicted small intracranial vessels like the anterior choroidal artery. All vessel pathologies were correctly identified by both readers for TOF-CS and TOF-Spiral with high confidence (TOF-CS: 4.4±0.6 and 4.3±0.7; TOF-Spiral: 4.3±0.8 and 4.3±0.8) and good inter-reader agreement (Cohen's kappa: >0.8). Quantitative assessments of the aneurysm size or stenosis did not significantly differ between TOF-CS or TOF-Spiral and CTA or DSA (p>0.05), with excellent correlations between the measurements of both readers (ICC>0.95).
Conclusion: TOF-Spiral for the imaging of brain-feeding arteries enables reductions in scan time without drawbacks in diagnostic confidence. A combination of spiral imaging and CS may help to overcome the shortcomings of both sequences alone and could further reduce acquisition times.
Limitations: The retrospective design and comparatively low number of vessel pathologies observed among the enrolled patients.
Ethics committee approval: This retrospective study was approved by the IRB.

Comparison study between published contrast administration protocols for enhanced liver CT examination in adults
F. Zanca[1], B. Rizk[2], D. Racine[3], P. Pujadas[4], D. Fournier[5], H. Brat[5];
[1]*Leuven/BE,* [2]*Villars-sur-Glane/CH,* [3]*Lausanne/CH,* [4]*Paris/FR,* [5]*Sion/CH*
(federica.zanca@palindromo.consulting)

Purpose: To compare hepatic enhancement level and uniformity across adult patients, using different personalised contrast administration protocols proposed in literature.
Methods and materials: 623 patients undergoing a three-phase liver CT examination were prospectively included, using a standardised CT protocol (100 or 120 kV in the function of patient BMI, 5 ml/sec contrast media (CM) injection rate, 80 sec portal phase delay, Iopamidol 370mg Iodine/ml).
Patients were prospectively assigned to one of three specific CM administration protocol group: G1 (100ml fixed CM volume, n = 297); G2 (600mgI/kg of body weight, n = 98,); G3 (750mgI/kg of measured fat free mass (FFM), n=228). Impact of kV settings was accounted through measured liver parenchymal enhancement (CEI) scaling factors for each scanner.
The mean injected CM volume, iodine dose, and median CEI at 100kV were compared across groups (one-way ANOVA or Kruskall-Wallis, p<0.005). The variance of the distributions was assessed and CEI compared to a diagnostically appropriate level of 30-50HU.
Results: G3 mean contrast volume and iodine dose (93.1 ml, 34.4 mgI respectively) were significantly lower than G1 (100ml, 37.0 mgI) and G2 (109.5 ml, 40.5 mgI) (p<0.0001 for both). 87-94% of patients were over-enhanced with a significantly lower median CEI for G3 (65.6HU) than G2 (70.7HU) and G1 (77.5HU) (p<0.0001 for both). Only 8% (G1), 6% (G2), and 13% (G3) reached target enhancement. Variance decreased from 520 (G1) to 403 (G2) to 247 (G3).
Conclusion: The FFM-based protocol improved patient-to-patient liver enhancement uniformity, while significantly reducing the iodine load, although still overestimated for a large group of patients. Our kV scaling factors suggest that 600mgI/FFM@100kV would significantly reduce over-enhancement and target a homogeneous diagnostic value of 50 HU.

Standardisation of dual-energy CT iodine uptake of the abdomen: defining reference values in a big data cohort
I. Yel, C. Booz, S. S. Martin, L. Lenga, B. Kaltenbach, T. J. Vogl, M. H. Albrecht; *Frankfurt am Main/DE (Dr.IbrahimYel@gmail.com)*

Purpose: Despite a wealth of literature on dual-energy CT (DECT) iodine uptake in various pathologies, physiologic reference values for this technique for a confident clinical application have not been defined to date. Therefore, we investigated the iodine uptake of healthy abdominal and pelvic organs in a big data cohort.
Methods and materials: Consecutive portal-venous abdominal DECTs were reviewed and unremarkable exams were included (n=520; white/asian=489; mean age=59±15,5 years; 265w/255m). ROI-measurements were performed in the following anatomical regions (number of ROIs): liver (9), pancreas (3), spleen (3), adrenal glands (2), kidneys (6), prostate (4), uterus (2), urinary bladder wall (1), and lymph nodes (3). Iodine uptake was compared among different organs and subgroup analysis was performed (young vs old/male vs female).
Results: Overall mean iodine uptake values were as follows (mg/ml): liver=1.93±0.54, pancreas=2.06±0.57, spleen=2.55±0.65, adrenal glands=1.66±0.43, kidneys=6.28±1.36, prostate=1.11±0.52, uterus=1.07±0.74, bladder=0.69±0.29, and lymph nodes=0.75±0.21. Iodine uptake was comparable between liver/pancreas and liver/adrenal glands (p>=0.119). Women showed higher iodine uptake for liver (2.07±0.58vs1.79±0.45mg/ml), pancreas (2.29±0.57vs1.83±0.47mg/ml), spleen (2.81±0.65vs2.30±0.53mg/ml), adrenal glands (1.76±0.49vs1.56±0.33mg/ml), and kidneys (6.74±1.36vs5.83±1.20mg/ml) than men (p<0.001). In older patients, iodine uptake increased for liver (1.98±0.52vs1.87±0.54mg/ml), spleen (2.48±0.65vs2.63±0.64mg/ml), and kidneys (6.11±1.24vs6.45±1.45mg/ml) compared to younger subjects (p<=0.040). Only the uterus showed lower values in older women (0.77±0.45vs1.35±0.84mg/ml,p<0.001).
Conclusion: Physiologic iodine uptake values show age- and gender-related differences for the liver, spleen, and kidneys. Pancreas and adrenal glands show higher iodine perfusion in women. While prostate parenchyma seems unaffected throughout a lifetime, iodine supply of the uterus decreases in elderly women. Lymph nodes and bladder are unaffected by demographic influences.
Limitations: Monocentric study. Single device (Somatom Force).
Ethics committee approval: Approval by local IRB.

Comparison of established dual-energy CT reconstructions with a novel virtual non-calcium based method to detect radiolucent gallstones
A. Almutairi, A. Alzahrani, A. Alosaimi, F. Azzumeea, M. F. A. Mohammed; *Riyadh/SA (mohammed.f.mohammed@gmail.com)*

Purpose: Cholelithiasis affects up to 15% of the population with recurrent ED visits. CT is often the first investigation for abdominal pain and offers higher sensitivity and specificity for the diagnosis of acute cholecystitis. However, up to 80% of gallstones are radiolucent. We hypothesise that a new dual-energy CT technique improves detection of stones compared to previously reported VMI techniques.
Methods and materials: Consecutive patients who received a dsDECT scan in the ED and an MRI or US study within 6 months of the dsDECT were included. An optimised VNCa algorithm was used to detect gallstones alongside 40 keV and 190 keV reconstructions by 2 abdominal radiologists. Sensitivity, specificity, PPV, NPV, and interobserver agreement were calculated and reported with 95% confidence intervals. US or MRI were considered the reference standard.
Results: 85 patients met the inclusion criteria. Modified VNCa correctly detected all 14 radiolucent stones with a sensitivity, specificity, PPV, NPV, and agreement of 100% [78% - 100%], 98.6% [92.4% - 99.9%], 93.3% [70.2% - 99.7], 100% [94.8% - 100%], and k = 0.88 respectively. Performance of 40 keV reconstructions was 35% [16.3% - 46.1%], 98.6% [92.4% - 99.9%], 83.3% [43.7% - 99.2%], and 88.6% [79.8% - 93.9%] and 50% [26.8% - 73.2%], 90.1% [81% - 95.1%], 50% [26.8% - 73.2%], and 90.1[81% - 95.1%] for 190 keV reconstructions.
Conclusion: A modified VNCa-based algorithm provides a highly sensitive and specific tool for detection of radiolucent gallstones, providing accurate and rapid diagnosis in the acute setting.
Limitations: A reterospective study. A small number of stones.
Ethics committee approval: IRB approved.

Diagnose negative gallstones with dual-layer spectral detector CT
J. Liu[1], X. Lu[2]; [1]*Tianjin/CN,* [2]*Shanghai/CN (18522587288@163.com)*

Purpose: To investigate the clinical application of dual-layer spectral detector CT (DLCT) in the diagnosis of negative gallstones.
Methods and materials: Between March 2019 to September 2019, we retrospectively enrolled 17 patients (6 men; mean age, 46 years; age range, 28–65 years) with gallstones who were detected by the magnetic resonance cholangiopancreatography (MRCP) and were not detected by conventional CT imaging. All patients underwent unenhanced abdomenal CT scanning with DLCT. The 40 keV to 200 keV virtual monoenergetic images (VMI), effective atomic number (Z_{eff}), spectral HU curve of negative gallstoness, and bile were analysed.
Results: All negative gallstones were clearly diagnosed by DLCT. The attenuation of negative stones showed lower than bile on the VMIs. The difference of attenuation between gallstones and bile was the largest in $VMI_{40\ keV}$ (gallstones -55.26±12.54 HU, bile 19.56±11.91HU). The Z_{eff} also showed the significant difference (gallstones 6.01±0.19, bile 7.17±0.08). The slope of the spectral curve of the negative stones was positive, the spectral curve of bile was approximately straight, and the slope was almost zero.
Conclusion: DLCT can confirm the negative gallstones, which has high diagnostic value.
Limitations: There was a small sample size in our study. Some stones were too small, which may have led to measurement errors.

RPS 1101-5 14:24
Contrast media reduction in abdominal dual-energy CT: low keV virtual monoenergetic images restore diagnostic assessment and image quality
S. Lennartz[1], N. Grosse Hokamp[1], C. Zäske[1], D. Zopfs[1], G. Bratke[1], A. Glauner[1], D. Maintz[1], D.-H. Chang[2], T. Hickethier[1]; [1]*Cologne/DE,* [2]*Heidelberg/DE (simon.lennartz@uk-koeln.de)*

Purpose: Abdominal CT with reduced contrast media (CM) application would be beneficial for patients at risk for contrast-induced nephropathy yet may imply inferior assessability. The study evaluated if low-keV virtual monoenergetic images from abdominal spectral-detector CT (SDCT) with reduced contrast media ($RCM\text{-}VMI_{40keV}$) provide similar image quality as conventional scans with standard contrast media dose (SCM).
Methods and materials: 78 patients with abdominal SDCT were included: 41 patients at risk for adverse reactions who received 44 RCM scans with 50ml of CM and 37 patients who received 44 SCM scans with 100ml of CM. Both groups were matched for effective body diameter. $RCM\text{-}VMI_{40keV}$, conventional RCM, and SCM images were reconstructed. Attenuation and SNR of liver, pancreas, kidneys, lymph nodes, aorta, and portal vein were assessed ROI-based. CNR of lymph nodes vs aorta/portal vein were calculated. Two readers blinded against patients/reconstructions assessed organ/vessel contrast, lymph node delineation, image noise, and overall assessability using 4-point Likert scales.
Results: Lymph node attenuation was similar between $RCM\text{-}VMI_{40keV}$ and SCM images (p=0.83), while for all other ROIs, $RCM\text{-}VMI_{40keV}$ was superior (p<0.05). SNR was equal between $RCM\text{-}VMI_{40keV}$ and SCM images for all ROIs (p-range 0.23-0.99). CNR of lymph nodes vs aorta/portal vein was highest in $RCM\text{-}VMI_{40keV}$ (p<0.05). Qualitatively, $RCM\text{-}VMI_{40keV}$ received equivalent or higher scores than SCM in all criteria except for organ contrast, overall assessability, and subjective image noise for which SCM was superior. However, in these three categories, $RCM\text{-}VMI_{40keV}$ received proper or excellent scores in

88.6%/94.2%/95.4% of all cases. Conventional RCM were inferior in all quantitative/qualitative parameters.
Conclusion: VMI_{40keV} effectively antagonises contrast deterioration in CM-reduced abdominal SDCT, facilitating diagnostic assessment.
Limitations: The study did not investigate lesion detection.
Ethics committee approval: Waived due to retrospective study characteristics.

Optimised virtual monoenergetic image for liver fibrosis staging using dual-layer spectral CT
R. Li, L. Wang, Y. Yang, F. Yan, Q. Han, X. Chen*; Shanghai/CN (lrk12113@rjh.com.cn)*

Purpose: To investigate the value of an optimised virtual monoenergetic image (VMI) for liver fibrosis staging using dual-layer spectral CT.
Methods and materials: 26 rabbit models of CCl_4-induced liver fibrosis were established and 4 untreated rabbits served as controls. Dynamic contrast-enhanced CT was performed including arterial phase [AP] and venous phase [VP] using dual-layer spectral CT. CT attenuation on VMI (40kev, 50kev, 60kev, 70kev) and conventional polyenergetic images (CPI) were measured by whole-liver volumetric ROI drawing on precontrast and enhancement images. $\Delta CT_{40\text{-}70kev}$ were calculated and correlated with the histopathological fibrosis stage to determine the optimised VMI.
Receiver operating characteristic (ROC) analysis was performed for assessing the diagnostic performance of the optimised VMI for fibrosis stage.
Results: On arterial phase, no significant correlation was identified between $\Delta CT_{40\text{-}70kev}$ and fibrosis stage or CPA ($P > 0.05$). On portal venous phase, ΔCT_{CPI}, $\Delta CT_{VMI\ 40}$, $\Delta CT_{VMI\ 50}$, $\Delta CT_{VMI\ 60}$, and $\Delta CT_{VMI\ 70}$ showed moderate correlation (r=0.453, P=0.012; r=0.595, P=0.001; r=0.543, P=0.002; r=0.498, P=0.005; and r=0.449, P=0.013; respectively) with fibrosis. $\Delta CT_{VMI\ 50}$ showed the highest correlation with fibrosis stage. $\Delta CT_{VMI\ 50}$ areas under ROC (AUROCs) were 0.861, 0.790, 0.831, and 0.740 for diagnosing fibrosis with ≥F1, ≥F2, ≥F3, and F4 stage, respectively.
Conclusion: $\Delta CT_{VMI\ 50}$ on portal venous phase may be a potential biomarker for liver fibrosis staging.
Limitations: This is an anmial study. The study should be further confirmed in patients.

Virtual monoenergetic images for diagnosing small hepatocellular carcinoma using dual-layer spectral CT: optimal energy level and added value
Z. Fu[1], C. Xu[1], D. Li[1], Y. Tian[1], X. Chen[2], C. Du[1]; [1]Nanjing/CN, [2]Shanghai/CN (xingbiao.chen@hotmail.com)

Purpose: To determine the optimal keV setting for virtual monoenergetic images (VMI) derived from dual-layer spectral CT (DLCT) and added value for diagnosing small hepatocellular carcinoma (sHCC) in comparison with conventional 120 kVp polyenergetic images (PI).
Methods and materials: 64 patients with sHCC who underwent upper abdomen enhanced scan using DLCT were retrospectively enrolled and were diagnosed by pathology within one week before or after CT examination. PI and VMIs (40–100 keV with an interval of 10 keV) were reconstructed from the same acquisition. CT value of sHCC lesions and liver parenchyma at the same slice and image noise for PI and VMIs were recorded. The contrast-to-noise ratios (CNR) and signal-to-noise ratios (SNR) were calculated and compared with PI and VMIs. PI and VMIs were reviewed by 2 radiologists independently for the sHCC diagnosis using a 3-point scale and compared.
Results: Image noise from VMI_s had no significant difference with PI. With energy levels from 60keV to 40 keV, SNR of VMIs increased from 7.07±2.48 to 9.09±4.21 and all were significantly higher than PI (5.36, all P<0.05). CNR of VMI_{40keV} and VMI_{50keV} were 4.09±2.34 and 2.70±1.61, and both were significantly higher than PI (0.96±0.82, both P<0.05). The subject score for VMIs increased from 2.78±0.42 to 2.90±0.25 as the energy level increased from 60keV to 40keV. All subject scores for VMIs were significantly greater than for PI (2.53±0.51, all P<0.05).
Conclusion: The lowest energy level VMI_{40keV} provided the best SNR, CNR, subject score, and equivalent noise as PI on DLCT. Moreover, VMI_{40keV} improved the sHCC lesion conspicuity and increased the diagnostic confidence.
Limitations: Small population. VMI energy level interval was large.

Iodine accumulation in the liver in patients treated with amiodarone can be unmasked using material decomposition from multiphase spectral-detector CT
K. R. Laukamp[1], A. Hashmi[2], N. Grosse Hokamp[1], A. Gupta[2], S. Lennartz[1], P. F. Graner[2], T. Persigehl[1], R. Gilkeson[2], N. Ramaiya[2]; [1]Cologne/DE, [2]Cleveland, OH/US (kai.laukamp@uk-koeln.de)

Purpose: Amiodarone accumulates in the liver where it increases x-ray attenuation by its iodine-content. Liver damage indicated by steatohepatitis and a decrease of attenuation can thereby be masked. Therefore we evaluated liver-attenuation in patients treated and not treated with amiodarone using true-non-contrast (TNC) and virtual-non-contrast (VNC) images acquired with spectral-detector-CT (SDCT).
Methods and materials: 142 patients, of which 21 have been treated with amiodarone, receiving SDCT-examinations (unenhanced-chest [TNC], CT-angiography of chest and abdomen [CTA-Chest, CTA-Abdomen]) for transcatheter-aortic-valve-replacement (TAVR)-planning were included. TNC, CTA-Chest, CTA-Abdomen, and corresponding VNC-images (VNC-Chest, VNC-Abdomen) were reconstructed. Image-analysis was conducted using ROI-based measurements of mean-attenuation (HU). The liver-attenuation-index (LAI) was calculated as the difference between liver- and spleen-attenuation.
Results: Liver-attenuation and LAI derived from TNC-images of patients receiving amiodarone were higher (63.1±9.8HU versus 58.1±8.6HU, p=0.04; 16.8±7.9HU versus 9.7±8.1HU, p<0.001). Contrary to TNC, liver-attenuation and LAI were not higher in amiodarone patients in VNC-Chest (liver-attenuation, 56.3±8.3HU versus 55.3±5.8HU, p=0.35; LAI, 7.5±8.5HU versus 7.5±6.9HU, p=0.50) and in VNC-Abdomen (liver-attenuation, 59.2±6.4HU versus 58.7±5.8HU, p=0.62; LAI, 8.5±6.5HU versus 6.5±6.7HU, p=0.10). In patients untreated with amiodarone, VNC accurately subtracted iodine and depicted similar attenuation compared to TNC.
Conclusion: Patients treated with amiodarone showed higher liver-attenuation in TNC. In contrast, VNC revealed comparable liver-attenuation in patients treated and untreated with amiodarone, indicating that VNC accurately subtracted hepatic amiodarone-deposits in line to contrast-agent related iodine-uptake.
Limitations: Spectral imaging data for the unenhanced chest acquisition (TNC) was not routinely saved at our institution, therefore creation of VNC images was only possible for CTA-Chest and CTA-Abdomen. A ROI-based measurement of mean attenuation was conducted and not a volumetric assessment of the entire liver.
Ethics committee approval: This study was apporved by the institutional review board.

Metal implants on abdominal CT: can split-filter dual-energy CT provide additional value over iterative metal artefact reduction?

H. M. Wichtmann[1], S. Yang[1], K. R. Laukamp[2], S. Manneck[1], K. Appelt[1], D. Boll[1], T. Heye[1], M. Benz[1], M. M. Obmann[1]; [1]*Basel/CH,* [2]*Cologne/DE*

Purpose: To assess metal artefact reduction in split-filter dual-energy CT (tbDECT) using virtual monoenergetic images (VMI) compared to 120kVp-equivalent mixed images (MIX) and iterative metal artefact reduction algorithm (iMAR).
Methods and materials: Abdominal tbDECT of 30 patients with total hip replacements (15 uni-, 15 bilateral) were included. Images were reconstructed as MIX and VMI (40 to 190 keV, 10 keV increments), with and without iMAR. Quantitative image quality was assessed using ROI-analysis of corrected attenuation-values [HU] and standard deviation (SD) for hypo- and hyperdense artefact on all reconstructions. Qualitative image quality was rated for overall image quality and vascular contrast on a 5-point Likert-scale (1: no artefact/contrast to 5: most artefact/contrast).
Results: Lowest artefact (both hypo- and hyperdense) was observed on MIX_{iMAR} (-10.6 and -0.6 HU), which was significantly lower compared to the standard MIX (p=0.006 and p<0.001). Comparison between MIX and VMI_{40keV} showed more artefact on VMI_{40keV} (p<0.001). Low keV $VMI_{iMAR-40keV}$ did not show more artefact than MIX_{iMAR} or MIX (p≥0.08). Image noise was highest for conventional low VMI_{40keV} (46.1 HU). Yet, $VMI_{iMAR-40keV}$ showed similar image noise compared to MIX (10.9 vs 12.4 HU, p=0.608). Qualitative image quality was rated best for VMI_{iMAR} at 140 keV (2.43), which was significantly better than MIX (4.07, p<0.001), but not MIX_{iMAR} (2.70, p=0.176). Low keV VMI_{iMAR} showed both improved image quality and vascular contrast compared to MIX (2.93 vs 4.07, p<0.001, 4.17 vs 2.70, p<0.001).
Conclusion: Abdominal tbDECT MIX_{iMAR} reconstructions provide the best image quality in patients with total hip replacements. High keV VMI_{iMAR} does not further decrease artefact. However, iMAR enables the use of low keV VMI_{iMAR} to boost iodine-based contrast with acceptable image quality.

Improved image quality in abdominal CT: promising results from a novel deep learning image reconstruction (DLIR) technique

T. Njølstad[1], A. Schulz[1], G. Pace[2], H. K. Andersen[1], A. C. T. Martinsen[1]; [1]*Oslo/NO,* [2]*Ancona/IT (tormund.njolstad@gmail.com)*

Purpose: To assess image quality in abdominal CT reconstructed with a novel deep learning image reconstruction (DLIR) technique in thin slices and compare with standardly applied hybrid iterative reconstruction (IR) technique in thick slices.
Methods and materials: 10 abdominal CT scans, performed on a GE Revolution CT scanner, were reconstructed with standardly applied IR technique (50% ASiR) for 2.5mm slices and a novel DLIR technique (TrueFidelity) for 0.625mm slices. Image contrast, noise, and contrast-to-noise ratio (CNR) were calculated for quantitative image quality analyses. Qualitative image quality was assessed independently by 3 radiologists, blinded to reconstruction method applied, along 9 visual grading image criteria on a five-point scale in a side-by-side comparative setting. Each patient was presented twice to evaluate intraobserver agreement and images were randomly selected to the right or left monitor to avoid situation bias. Odds ratios (OR) were evaluated using logistic regression.
Results: For quantitative analyses, CNR between the portal vein and liver parenchyma was significantly higher for images reconstructed with DLIR compared to IR (p=0.005). For visual grading, DLIR image quality was more frequently perceived as slightly better or clearly better across all visual grading criteria compared to IR. OR for DLIR perceived as better than IR was highly significant for visual reproduction of liver parenchyma, overall impression of image noise, texture, and contrast (p<0.001). OR for DLIR perceived as equal or better than IR was highly significant for all visual grading criteria (p<0.001).
Conclusion: Abdominal CT reconstructed in 0.625 mm slices using a novel DLIR technique shows markedly improved image quality when compared to 2.5 mm slices, with standardly applied IR across a variety of clinical image quality criteria.
Limitations: Pilot study.

Optimisation of abdominal CT using a new iterative reconstruction technique

G. Pace[1], M. Afadzi[2], A. Schulz[2], T. M. Aalokken[2], A. C. T. Martinsen[2], A. Giovagnoni[1]; [1]*Ancona/IT,* [2]*Oslo/NO (pacegenny@gmail.com)*

Purpose: To investigate the potential of a new statistical iterative reconstruction technique (ASIR-V) to balance the deterioration of image quality in abdominal computed tomography (CT) using thinner slice reconstructions (<2.5 mm).
Methods and materials: 10 patients underwent contrast-enhanced CT for oncological follow-up on a GE revolution CT (GE Healthcare, Milwaukee, WI), noise-index 29.0, automatic current modulation at 120kV. Reconstructions at 2.5, 1.25, and 0.625mm slice thickness with ASIR-V 0, 30, 50, 70, and 90%. Quantitative (contrast-to-noise ratio in the liver, portal vein, muscle, and abdominal aorta; image noise in spleen) and qualitative analyses (5-point scale, 10 criteria) of image quality were conducted. Comparison of median CNRs and image noise between the fourteen series and the 2.5 mm/ASiR-V 50% reconstructions was done using Dunnett's multiple comparison testing with 2.5 mm/ASiR-V 50% as the control group. The qualitative evaluation was analysed with visual grading regression (VGR).
Results: No reconstructed data set provided significantly better CNR than the control group. The 1.25 mm slices in combination with ASiR-V 70%-90%, and 0.625 mm with ASiR-V 90% showed statistically equal CNR in liver parenchyma, portal vein, muscle, and aorta (all p=1), and statistically lower image noise (all p<0.05) compared to the control group. The 1.25 mm data sets with ASIR-V 70% showed equal image quality in comparison to the control group in all criteria evaluated. Image was scored superior to the control group with 1.25 mm and ASIR-V 90% (p<0.02).
Conclusion: Abdominal CT images reconstructed at 1.25 mm slices with ASIR-V 70% provided an image quality equivalent to the standard protocol (2.5 mm slices, ASiR-V 50%) and might have the potential to demonstrate more subtle abnormalities and avoid partial volume effect.
Limitations: Few patients, few readers.
Ethics committee approval: Approved by an institutional review board. Written informed consent was waived.

A randomised controlled trial proposing a straight forward 10-to-10 rule for individualised liver imaging based on tube voltage and body weight

B. Martens, J. E. Wildberger, B. M. F. Hendriks, S. M. van Kuijk, N. H. G. M. Peters, J. de Vos-Geelen, C. Mihl; *Maastricht/NL (bibi.martens@mumc.nl)*

Purpose: To optimise the CT liver protocol based on both body weight (BW) and tube voltage (TV). The rule of thumb was that 10kV TV reduction would lead to a 10% decrease in CM dose.
Methods and materials: 256 patients referred for a portal-venous-phase CT were randomly allocated to one of four groups. Group 1 (n=64): 120kV; 0.521gI/kg. In group 2 (n=63), TV was reduced (90kV), whereas the dosing factor remained unaltered: 0.521gI/kg. In group 3 (n=63), TV was reduced by 20kV with a subsequent 20% reduction in dosing factor (e.g. 100kV; 0.415gI/kg). Group 4 (n=66): 30 kV decrease with a 30% CM reduction: 90kV; 0.365gI/kg. Objective image quality (IQ) was evaluated by measuring the attenuation in Hounsfield units (HU), signal-to-noise ratio (SNR), and contrast-to-noise ratio (CNR). Subjective IQ was assessed by using a 5-point Likert scale regarding overall IQ. Statistical analysis was performed using SPSS (IBM, version 24.0).
Results: Mean attenuation values in group 1, 3, and 4 were comparable: 118.2±10.0; 117.6±13.9; 117.3±21.6 (p>0.90). Attenuation in group 2 was significantly higher, 141.0±18.2, in comparison to all other groups (p=<0.01). Patients were divided into two weight categories: 80kg and >80kg. No significant difference in attenuation was found between weight categories. CNR was

significantly higher in group 2 compared to the other three groups (p=<0.01). No significant differences in subjective IQ were found (p=0.383).
Conclusion: The proposed 10-to-10 rule is an easy to reproduce method leading to homogeneous enhancement of the liver, regardless of BW and TV.
Limitations: This is a single-centre study.
Ethics committee approval: Approved by the local ethics committee. Registered on ClinicalTrials.gov (NCT03735706). Written informed consent was obtained from all 256 patients.
Funding: No funding was received for this work.

3D-segmentation of visceral and subcutaneous adipose tissue on CT: influence of contrast-medium and -phase
R. F. Gohmann, P. Seitz, B. Temiz, S. Gottschling, C. D. Krieghoff, C. Lücke, M. Gutberlet*; Leipzig/DE (robin.gohmann@gmx.de)*

Purpose: To analyse the influence of contrast-medium and phase on the segmentation of adipose tissue.
Methods and materials: Exams of 31 patients undergoing routine multi-phasic CT containing a native scan at identical kV were retrospectively included. In addition to the native scan (n=31), patients had received an arterial (n=23), portal-venous (n=10), and/or venous scan (n=31) after intravenous injection of 90 ml iodinated contrast-medium. The volume of adipose tissue was quantified semi-automatically with a threshold between -190HU and -30HU. Absolute volumes of visceral and subcutaneous compartments were recorded separately and the relative difference between the native scan and contrast-phases ($[Vol_{contrast\text{-}phase}\text{-}Vol_{native\text{-}scan}]/Vol_{native\text{-}scan}$) was computed.
Results: Segmented volume of adipose tissue for subgroups on native, arterial, portal-venous, and venous scans was 4,79±2,21, 4,86±2,21, 4,29±2,09, and 4,49±2,35 dm^3 in the visceral and 5,90±3,44, 6,02±3,64, 6,71±3,35, and 5,72±3,22 dm^3 in the subcutaneous compartment, respectively.
Relative difference of volumes within patients between native and arterial, portal-venous, and venous phase was -4,7±3,0%, -8,6±5,8%, and -9,6±9,7% for the visceral and -0,4±4,6%, -1,0±6,5%, and -2,6±8,1% for the subcutaneous compartment, respectively.
Total and visceral volumes were significantly different between native scans and all contrast-phases (p<0,001); no significant isolated differences were observed for the subcutaneous compartment.
Conclusion: Segmented volumes of adipose tissue on CT decrease after injection of contrast-medium. This decrease in volume is less pronounced in early contrast-phases (e.g. arterial) and mainly takes place in the visceral compartment. This fact must be considered when utilising contrast-enhanced CTs for risk-stratification or evaluation of therapy-response as frequently practised in oncology.
Limitations: This study was retrospective in design, including patients with different indications for CT and underlying diseases, which might have influenced the observed changes of segmented adipose tissue after contrast injection.
Ethics committee approval: This study was approved by the local ethics committee.
Funding: No funding was received for this work.

Dynamic segmental CT liver perfusion data analysis after portosystemic shunt procedure in patients with liver cirrhosis
N. Djuraeva[1], F. Nazirov[1], A. Babadjanov[1], A. Amirkhamzaev[1], U. R. Salimov[2], N. Vakhidova[1], A. Sultanov[1]; [1]*Tashkent/UZ,* [2]*Ghandy/AF (nika.kt@rambler.ru)*

Purpose: To study the dynamics of parameters of the CT liver perfusion in patients with liver cirrhosis after portosystemic shunting.
Methods and materials: Study included 50 patients (average age 43±1.5 years). The control group consisted of 10 healthy volunteers of comparable age. All patients underwent volumetric low-dose liver perfusion with a tube rotation speed of 0.275 sec, the amount of contrast medium 40 ml, Kv 100/80, MA 200/150, and effective dose (E) 17±1,2 mSv.
Results: In the group with liver cirrhosis (LC), there was an increase in global and regional changes in hepatic perfusion towards an increase in hepatic arterial blood flow (BF) and a decrease in portal BF with a decrease in the hepatic perfusion index (HPI). After portosystemic shunting, there was a positive shift in the portal BF by 87,44±6,1 (mL/100 mL/min) and HPI improvement by 31,4 % (p<0.05). There was also a decrease in the width of the portal and splenic veins by 17.1% and 16.5% (p<0.05), respectively.
Segmental analysis of HPI showed that the most pronounced improvement in hepatic blood flow was observed in I, IV, VII, VIII segments (17.4%).
Conclusion: Low-dose CT liver perfusion revealed significant positive shifts (p<0.05) after portosystemic shunting of the HPI index, more pronounced in central segments in patients with LC, restoring the balance between hepatic and portal blood flow, and reducing the pressure in the portal and splenic veins.

The importance of being minocycline chlorhydrate. Sclerosant acting antibiotic versus corticosteroids to treat symptomatic Baker cysts: a prospective study
I. Percivale[1], A. Paladini[1], M. Spinetta[1], A. Borzelli[2], F. Pane[2], D. Negroni[1], M. Cernigliaro[1], A. Carriero[1], G. Guzzardi[1]; [1]*Novara/IT,* [2]*Naples/IT (ilaperci@gmail.com)*

Purpose: A prospective study about the efficiency and safety on the use of a sclerosant antibiotic (minocycline chlorhydrate) versus steroids (triamcinolone acetonide) to treat patients with symptomatic Baker cysts.
Methods and materials: We prospectively enrolled 66 patients, randomised into two cohorts; cyst drainage followed by antibiotic injection and cyst drainage followed by steroids injection. 58 patients underwent 6 month clinical and radiologic follow-up. The primary end-point was a volume reduction of more than 40% with respect to the cyst native volume. Secondary end-points were duration, pain reduction (VAS), and cyst permanence (volume reduction less than 40%).
Results: The primary end-point has been reached in the 66.7 % of patients treated with antibiotics (mean volume reduction: 54%) and in the 35.7% of patients treated with steroids (mean volume reduction: 69%). Cyst permanence was seen in the 65% of cases treated with steroids and in the 34% of cases treated with antibiotics. We achieved a mean pain reduction (VAS) of 3.2 points. The procedural duration was higher in patients treated with antibiotics (15.5 min) compared to corticosteroids (8.6 min).
Conclusion: Both treatments are safe (no major or minor adverse events) but antibiotic injection is more efficient considering the primary end-point. Despite

an increased procedural time, patients with antibiotic treatment have a lower rate of cyst permanence.
Limitations: The limited number of patients and short follow-up.
Ethics committee approval: n/a
Funding: No funding was received for this work.

RPS 1110-2 14:16
The correlation between the anatomical variations of the knee joint and fat-pad pathologies and patellar tilt
A. H. Çilengir, Y. K. K. Çetinoğlu, M. F. Gelal, B. Dirim Mete, F. Elmalı, C. Kazimoglu, Ö. Tosun*; Izmir/TR (acilengir@gmail.com)*

Purpose: The correlation between patellar tilt, oedema in the superolateral portion of the infrapatellar fat pad, and chondromalacia was described in the literature. However, there is not enough information about other variations that may cause knee joint pathologies. A correlation with quadriceps patellar tendon angle (QPA) was not described. Our aim was to describe the correlation between knee joint variations and analyse accompanying fat-pad, cartilage, and tendon pathologies.
Methods and materials: A retrospective analysis of age, gender, side, femoral sulcus angle (SA), tibial tubercule-trochlear groove distance (TTTG), patellar tendon length (PTL), patellar height (PH), Insall-Salvati ratio (ISR), lateral trochlear inclination angle (LTI), trochlear facet asymmetry (TFA), trochlear depth (TD), trochlear dysplasia (TDis), suprapatellar-infrapatellar-prefemoral fat-pad oedema (SPE-IPE-PFE), suprapatellar effusion (SE), patellar and femoral chondromalacia (PC and FC), and quadriceps and patellar tendinopathy (QT and PT) on 406 knee MRIs with patellar tilt (PTi) was performed. The relationship between PTi, QPA, and other parameters were evaluated. 40 knee MRIs without PTi were selected as a control group.
Results: The presence of SPE-IPE-PFE, SE, PC, and FC was more frequent in the PTi group; SA, TT-TG, PTL, ISR, LTI, TFA, and TD values were significantly different between the two groups. The distribution of PTi was significantly related to TDis, PC, QT, SA, TT-TG, LTI, and TD in the PTi group. The distribution of QPA was significantly associated with TDis, IPE, PFE, QT, SA, and LTI in the PTi group. We calculated 10 degrees of PTi as a cut-off value for a superolateral portion of the infrapatellar fat-pad oedema.
Conclusion: Many anatomical variations of the knee joint, including QPA, are associated with fat-pad, cartilage, and tendon pathologies.
Limitations: The restrospective design.
Ethics committee approval: This study has approval from an institutional review board.
Funding: No funding was received for this work.

RPS 1110-3 14:22
The assessment of medial meniscus extrusion on ultrasound using MRI as a reference standard
R. A. Zeitoun[1], H. Hossam El-Din[1], N. Eesa[1], S. F. Ismail[2]; *[1]Cairo/EG, [2]Giza/EG (raniazeitoun@gmail.com)*

Purpose: To assess medial meniscus extrusion using US on supine and standing (weight-bearing) positions as a sign of the presence of underlying meniscal tears. The study was done using MRI as a reference standard for the detection of tears.
Methods and materials: This observational analytic prospective study included 103 patients (48 females and 55 males), aged between 18-70 years. The US measured values of the medial meniscal extrusion on supine and standing positions were correlated to the MRI diagnosis of tears. The included patients were classified into two groups according to the presence or abscence of meniscal tears on MRI. Statistical analysis was performed for the obtained measurements for both groups and P<0.05 was considered significant. ROC curve was done to reach a cut-off value for extrusion as a sign of medial meniscus tear.
Results: 45 patients (43.68%) had medial meniscal tears (horizontal, vertical, branching, radial, root, and bucket-handle tears). The measured extrusion on supine and standing positions, as well as the difference between them in the two groups, all showed a significant P=0.001. The extrusion on standing position with a cutoff value of >3.3 mm showed a specificity (96.55%), positive predictive value (93.8%), and accuracy (83.5%) for the detection of a medial meniscus tear.
Conclusion: Measuring medial meniscus extrusion using ultrasonography, especially in a standing position, is a good sign to predict tears.
Limitations: The sample size and the number of patients with different subtypes of tears were not large enough for a powerful conclusion to correlate the value of extrusion and the subtype of tear.
Ethics committee approval: The study has been approved by the Ethical Committee of Faculty of Medicine, Cairo University, in compliance with the Helsinki declaration.
Funding: No funding was received for this work.

RPS 1110-4 14:28
Evaluation of medial meniscal extrusion using weight-bearing ultrasound: correlation with MRI and meniscal tears
A. L. Falkowski[1], J. A. Jacobson[1], M. Cresswell[2], A. Bedi[1], V. Kalia[1]; *[1]Ann Arbor, MI/US, [2]Vancouver, BC/CA*

Purpose: To compare medial meniscal extrusion as seen on weight-bearing ultrasound compared with MRI and meniscal tears.
Methods and materials: Patients obtaining a routine knee MRI were prospectively evaluated with supine and weight-bearing ultrasound (US) of the medial meniscus. The position of the outer boundary of the medial meniscus on US images and MRI was measured relative to the tibia by a fellowship-trained musculoskeletal radiologist. A correlation was made to the presence or absence of a meniscal tear and statistical significance was calculated via a Student t-test.
Results: 50 knees from 49 subjects (23 male, 26 female; mean age 44±15 years) were included (18 right, 32 left; one bilateral). The mean medial meniscal extrusion on supine US was 1.3 mm (range -1.5-3.6 mm), with no significant difference compared with MRI (p=0.21), which increased to 2.1 mm on weight-bearing US. In the 38% (19/50) of subjects with meniscal tears on MRI, the mean medial meniscal extrusion on weight-bearing US was 2.13 mm (range 0-4.4 mm) with a change between supine and weight-bearing of 0.63 mm (range -1.8-2.7 mm). In the 62% (31/50) of subjects with no meniscal tear, the mean medial meniscal extrusion on weight-bearing US was 2.05 mm (range 0-3.8 mm) with a change between supine and weight-bearing of 0.87 mm (range -0.1-2.2 mm) and no significant difference between subjects with and without tear (p=0.805 and p=0.413).
Conclusion: Supine US was comparable with supine MRI for the assessment of medial meniscal extrusion. The presence of a meniscal tear did not result in increased medial meniscal extrusion on weight-bearing US compared with no meniscal tear.
Limitations: The reading of the images was performed by one reader.
Ethics committee approval: IRB-approved study with informed consent.
Funding: No funding was received for this work.

RPS 1110-5 14:34
Agreement between cartilage morphology on MRI and weight-bearing CT and radiographs respectively for visualising patellofemoral OA features in the MOST study
N. Segal[1], B. Everist[1], K. Brown[1], J. He[1], J. Lynch[2], M. Nevitt[2]; *[1]Kansas City, KS/US, [2]San Francisco, CA/US (segal-research@kumc.edu)*

Purpose: The patellofemoral joint is frequently affected by osteoarthritis (PFOA) and is incompletely imaged on radiographs. Weight-bearing CT (WBCT) could offer advantages for visualisation. This study determined the agreement between the detection of cartilage damage on MRI and PFOA on WBCT and radiographs.
Methods and materials: The right knees of 60 people who did not have findings of PFOA at a prior clinic visit were randomly selected. WBCT and radiographs were read for an OARSI JSN score (0=none, 1=minimal, 2=moderate, and 3=total joint-space loss), and MRI was read for a MOAKS cartilage score (size and % of full-thickness) by 2 musculoskeletal radiologists, each with more than

10 years experience, who were blinded to the subject. Weighted kappa coefficients were calculated for agreement between modalities. Inter-reader reliability was assessed with weighted kappa statistics.
Results: The mean±SD age and BMI for the 60 participants (66.7% women) were 67.6±9.8 years and 30.0±5.3 kg/m2, respectively. There was a fair-to-moderate agreement between PFOA findings on WBCT and semi-quantitative scores of PF cartilage on MRI, while an agreement was none-to-slight between radiographic PFOA readings and MRI readings. Inter-rater reliability for the WBCT JSW {kappa=0.60 (0.48, 0.72)} and MRI MOAKS-CM {kappa=0.70 (0.61, 0.79)} readings were good.
Conclusion: PFOA scoring on WBCT agrees with MRI substantially better than does scoring on XR. At the same relative radiation level as radiographs (<0.10 mSv), WBCT imaging holds the potential to improve understanding of the weight-bearing patellofemoral joints beyond what is possible with radiographs.
Limitations: Radiologists were provided with written instructions, but no in-person training in the scoring systems used and no consensus readings were completed, potentially attenuating inter-rater agreement.
Ethics committee approval: Following an IRB-approved informed consent process, all participants provided written informed consent.
Funding: NIH R01AR071648, U01AG18832, and U01AG19069.

The efficacy of the anterior translation of the tibia in anterior cruciate ligament mucoid degeneration: an observational study
A. I. Saad, D. Waldron, A. Iqbal, S. Evans, S. L. James, R. Botchu*; Birmingham/UK (aisaad@hotmail.co.uk)*

Purpose: Mucoid degeneration (MD) of the ACL is a well-known pathological entity diagnosed on MRI. However, it can be confused with complete or partial tears of the ACL. Radiologists focus on the posterior femoral translation as a reliable secondary sign.
We encountered several patients with MD of the ACL who have a posterior translation exceeding 5 mm with an intact ACL. We investigated the likely cause of this with the means to abolish confusion and misdiagnosis of ACL tears.
Methods and materials: A retrospective search of our department's radiology system for knee MR imaging over 10 years. All patients had MD within the substance of the ACL and an intact ACL. We evaluated the measurement of the degree of posterior translation of the femur (PTF) in relation to the tibia. The data was categorised according to the length of the PTF (PTFM).
Results: We identified 464 consecutive cases with MD. The mean age was 52 years. There was a male predominance of 261 to 203 females. The average PTFM was 2.4 mm with a range of 0-20 mm. 85.6% of patients had a PTFM of <5 mm. 205 patients had no PTF. 192 cases had a PTFM range between 1-5 mm.
14.4% of patients had a PTFM >5 mm. Of them, 32.8% had a PTFM of 6 mm, 53.7% had a PTFM range between 7-9 mm, with the remaining 13.4% >9 mm.
Conclusion: It is essential to look for other secondary signs of ACL tears and not only focus on the PTFL and correlate this with clinical findings.
Limitations: This study was retrospective and no arthroscopic correlation has been assessed, as the diagnosis of MD was solely a radiological diagnosis.

RPS 1110-7 14:46
Attachment type of the posterior meniscofemoral ligament and clinical significance
H. J. Park, S. Ham*; Seoul/KR (sooyoun.ham@samsung.com)*

Purpose: To investigate the correlation between the attachment type of the posterior meniscofemoral ligament (pMFL) and the incidence of lateral meniscal tears.
Methods and materials: We retrospectively evaluated 191 patients who underwent knee MRIs. We assessed the attachment type of the pMFL (high vs low) and measured the thickness of the pMFL. Then we evaluated the presence of a meniscal tear or discoid meniscus. We assessed if there was a significant relationship between the mean thickness of the pMFL and the incidence of meniscal tears or a discoid meniscus according to the type of pMFL using independent t-tests. We also assessed the significance of the relationship between the mean thickness of the pMFL and the presence or absence of a meniscal tear or discoid meniscus using Pearson's Chi-square test.
Results: High type pMFLs were significantly thicker than low type pMFLs ($p<0.001$). There was no significant difference in the incidence of meniscal tears according to the type of pMFL. There was also no significant difference in pMFL thickness between patients with meniscal tears and those without meniscal tears.
Conclusion: High type pMFLs tend to be thicker than low type pMFLs, but the thickness is irrelevant to the incidence of meniscus injury.
Limitations: We could not completely exclude the possibility of selection bias and confounding factors because this was a retrospective study. We only included symptomatic patients who had knee MRI data, which could also contribute to a selection bias. We did not correlate pMFL results to the clinical outcomes.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Chondrocalcinosis is associated with increased knee joint degeneration over 4 years: data from the osteoarthritis initiative
S. Foreman[1], A. S. Gersing[1], C. von Schacky[1], G. Joseph[2], J. Neumann[1], N. E. Lane[3], C. McCulloch[2], M. Nevitt[2], T. M. M. Link[2]; *[1]Munich/DE, [2]San Francisco, CA/US, [3]Sacramento, CA/US*

Purpose: To determine if the presence of calcium-containing crystals (CaC) is associated with increased knee joint degeneration over 4 years and to assess if the total number of CaCs deposited is a useful measure of disease burden.
Methods and materials: 70 subjects with CaCs in right knees at baseline were selected from the osteoarthritis initiative and matched to 70 subjects without evidence of CaCs. T1-weighted gradient-echo sequences were used to confirm the presence of CaCs and count the numbers of distinct circumscribed CaCs. Morphological abnormalities were assessed at baseline and 4-year follow-ups using the modified semi-quantitative whole-organ magnetic resonance imaging score (WORMS). Linear regression models were used to analyse the associations between the presence of CaCs at baseline and changes in WORMS and to analyse the associations between the numbers of circumscribed CaCs at baseline and changes in WORMS.
Results: Presence of CaCs was associated with increased cartilage degeneration in the patella (coefficient: 0.33; 95% confidence interval (CI): 0.04-0.63), the medial femur (coefficient: 0.51; 95% CI: 0.18-0.83), the lateral tibia (coefficient: 0.36; 95% CI: 0.01-0.71), and the medial and lateral meniscus (coefficient: 0.38; 95% CI: 0.00-0.75 and coefficient: 0.72; 95% CI: 0.12-1.32). Knees with higher numbers of CaCs had increased cartilage degeneration in the patella and medial femur (coefficient: 0.09; 95% CI: 0.05-0.14; $p<0.001$ and coefficient: 0.08; 95% CI: 0.02-0.14; $p=0.005$).
Conclusion: CaCs were associated with increased cartilage and meniscus degeneration over a period of 4 years. Assessing the number of CaC depositions may be useful to evaluate the risk of onset and worsening of degenerative disease.
Limitations: No synovial fluid was available for analysis.
Ethics committee approval: IRB approval (all centres).
Funding: NIAMS-R01AR064771.

Quantitative analysis of knee joint cartilage by using T2* and T1rho relaxation times in professional female volleyball players and a healthy control group

K.-J. J. Maas[1], F. O. Henes[1], M. Regier[2], M. L. Warncke[3], M. Kaul[1], G. Schön[1], G. Adam[1], C. Behzadi[1]; *[1]Hamburg/DE, [2]Munich/DE, [3]Hamburg, HAMBURG/DE (k.maas@uke.de)*

Purpose: To analyse the effects of repetitive physical activity on T2* as well as T1rho relation time measurements of knee joint cartilage in professional female volleyball players and healthy controls.
Methods and materials: 24 professional female volleyball players (mean age: 25.5 years±3.6; BMI 21.1±1.3) and 24 female individuals (mean age: 27.5 years±2.9; BMI 21.3±1.9) underwent MRI including two separate quantitative techniques (T2* and T1rho) at 3T. 11 segments for medial and lateral knee compartments were defined and in each segment a horizontal segmentation into a deep and a superficial layer was performed. Arithmetic means from relaxation times were computed. Due to the cluster structure of the data, a random intercept model was estimated, if necessary.
Results: For female volleyball players, mean relaxation times were noted with 27.1 ms (CI: 26.7-27.5 ms) for T2* and 46.4 ms (CI: 45.8-47 ms) for T1rho. For the healthy control group, mean relaxation times were calculated with 23.5 ms (CI: 23.1-23.9 ms) for T2* and 41.5 ms (CI: 40.9-42.1 ms) for T1rho. T2* as well as T1rho relaxation times were generally prolonged in female volleyball players in comparison to healthy individuals. Significantly differences comparing T2* relaxation times were detected in 11 deep and 16 superficial cartilage layers, as well as 9 deep and 22 superficial layers for T1rho.
Conclusion: There is a tendency towards prolonged T2* and T1rho relaxation times in knee joint cartilage of professional female volleyball players compared to controls. For both imaging markers, more distinct results were detected for the superficial cartilage layer. These findings might be considered as initial stages of osteoarthritis in physically active female individuals.
Limitations: The population size.

Assessment of patellofemoral maltracking using 3.0T kinematic MRI

K.-J. J. Maas, J. Frings, M. L. Warncke, T. Dust, K.-H. Frosch, G. Adam, F. O. Henes; *Hamburg/DE (k.maas@uke.de)*

Purpose: Patellar maltracking is routinely described with subjective clinical tests, but until now remains challenging to be assessed objectively and standardised with a reproducible measurement technique. Kinematic MRI allows dynamic assessment of the patellofemoral joint with real-time muscle contraction. We aimed to implement kinematic MRI as a standardised and objective measurement technique to quantify patellar maltracking.
Methods and materials: 10 knees of patients with clinical patellar maltracking and 10 knees of healthy volunteers were evaluated. All participants underwent knee MRI at 3T in real-time by a radial 2-dimensional GRE sequence in sagittal and axial orientation at the patellar level through a range of flexion-extension (approximately 0-50°). Lateral maltracking as well as the patella tilt were measured. Maltracking was defined as the "delta" of the isometric centre of the patellar at the maximum point of flexion and extension compared to the perpendicular line from the posterior margins of the femoral condyles drawn through the centre of the trochlear sulcus.
Results: Lateral maltracking, as well as patella tilt, was significantly higher in symptomatic patients (maltracking mean: 1.03±0.55 mm, patella tilt mean: 21.8±10.58°) than in the volunteer group (maltracking mean: 0.13±0.11 mm, patella tilt mean: 3.8±2.78°) with p=0.0001. There was no lateral tracking within healthy volunteers greater than 27 mm. Lateralisation within symptomatic patients ranged from 0.54 to 2.64 mm. Lateral maltracking significantly correlated with increased patella tilt with r=0.9358 (p<0.0001).
Conclusion: Dynamic radial 2-dimensional GRE sequence allows exact dynamic assessment of patellar maltracking in symptomatic patients, providing kinematic MRI as a standardised and objective measurement technique.
Limitations: The size of the population included in this study.
Ethics committee approval: Ethics committee approval obtained.

Distal femoral cortical irregularity (DFCI): increased prevalence in competitive young alpine skiers

C. Stern, J. Galley, S. Fröhlich, L. Peterhans, J. Spörri, R. Sutter; *Zurich/CH (christoph.stern@gmx.de)*

Purpose: Tumour-like cortical irregularities at the posterior distal femur are common incidental findings in adolescents, but their origin is still debated. The purpose was to investigate the prevalence of irregularities at the tendinous attachment of the medial/lateral head of the gastrocnemius (MHG/LHG) and of the adductor magnus (AM) muscle in competitive young alpine skiers compared to young adults of the same age.
Methods and materials: Knee MRI examinations of 105 competitive young alpine skiers (age 13-16 years) and a control group (matched for gender, age, and extremity) of 105 adolescent patients were evaluated by two radiologists for the presence of cortical lesions at the femoral attachment site of the MHG, LHG, and AM tendon. Lesion diameters were measured on sagittal fat-suppressed MR images. Statistical analysis included Person's Chi-square, Student's t-test, and kappa statistics.
Results: Cortical lesions were found in 58.1% of competitive alpine skiers (61/105) compared to 26.7% in the control group (28/105)(p<0.001). In 2 skiers, more than one lesion per individual was found versus none for the control. Lesion distribution for competitive athletes and the control group were 60/63 (95%) and 26/28 (93%) lesions at the MHG, 3/63 (5%) and 1/28 (3.5%) at the LHG, and 0/63 (0%) and 1/28 (3.5%) at the AM attachment site, respectively. Inter-reader agreement was almost perfect (k=0.87). No substantial difference was observed for the average size of MHG lesions in athletes (3.7 mm) versus the control group (3.4 mm) (p=0.321).
Conclusion: A cortical irregularity of the distal femur at the tendon attachment sites is a frequent incidental finding on MRI, with a significantly increased prevalence in competitive young alpine skiers, supporting the theory of a stress-related origin. These irregularities should not be mistaken for malignancy.
Limitations: A retrospective control group.

Volume and quantitative dynamic contrast-enhanced MR blood perfusion parameters of the infrapatellar fat-pad and their relationship with oedema and effusion in patients with patellofemoral pain

R. van der Heijden, B. A. de Vries, D. Poot, M. van Middelkoop, G. P. Krestin, E. Oei; *Rotterdam/NL (r.a.vanderheijden@erasmusmc.nl)*

Purpose: The infrapatellar fat-pad (IPFP) is implied as a source of pain in knee osteoarthritis (OA) and patellofemoral pain (PFP), a supposed precursor of OA. Inflammation or increased IPFP volume may have causative effects. The aim of this study was to quantitatively evaluate dynamic contrast-enhanced (DCE) MRI parameters as a surrogate measure of inflammation and volume of the IPFP, and explore their relationship with IPFP oedema and joint effusion in PFP patients.
Methods and materials: PFP patients and healthy control subjects underwent 3T MRI comprising non-fat saturated FSPGR and DCE-MRI. Motion was corrected by image registration. The IPFP was delineated on the FSPGR sequence using Horos software. Volume was calculated and quantitative perfusion parameters (Ktrans, Kep, Ve, and Vp) were extracted by fitting the extended Tofts' pharmacokinetic model. Differences in volume and DCE-MRI parameters between patients and controls were tested by linear regression analyses adjusted for confounders of sex, age, BMI, and sports participation. The same applied to IPFP oedema and effusion.
Results: 43 controls and 35 PFP patients were included. Volume and perfusion parameters were not statistically significantly different between groups. Knees with effusion showed a higher perfusion of the IPFP.
Conclusion: The IPFP has been implied as a possible source of knee pain, but its blood perfusion as a surrogate measure of inflammation and volume do not seem to play a role in patellofemoral pain. PFP patients with effusion showed higher perfusion, indicating inflammation, in contrast to controls.

Limitations: Due to the large intersubject variability, small differences in perfusion or volume could have been undetected. But given the small effect sizes, these would not be clinically relevant.
Ethics committee approval: Approved by the institutional review board and written informed consent obtained.
Funding: Partly funded by ESSR, RSNA, Erasmus University, and Dutch Artritis Foundation.

Collective intelligence has increased diagnostic performance compared to expert radiologists in the evaluation of knee MRI
A. Campagner, C. Messina, D. Albano, S. Gitto, F. Cabitza, L. M. M. Sconfienza*; Milan/IT (carmelomessina.md@gmail.com)*

Purpose: As is widely known, the traditional diagnostic approach, which involves a single physician, can result in worrying error rates. Collective intelligence has recently been considered as a possible strategy to pool individual physicians' diagnoses and reduce misdiagnosis. Our aim is to present an investigation about the accuracy of these techniques on a real-world experiment of MR assessment.
Methods and materials: We asked 13 radiologists from a tertiary orthopaedic institution to identify abnormal exams among 417 knee MR images from the Standford MRNet dataset1 (which is a low-resolution imaging dataset used to train machine-learning predictive models). Radiologists were also asked to assess their confidence on their decisions and the perceived complexity of each case. We assessed each radiologist's accuracy in comparison with the accuracy rates obtained by leveraging collective intelligence techniques.
Results: The radiologists' panel obtained an average accuracy of 0.82-0.01 (95% confidence interval). Taking the majority annotation for each exam as the gold standard, we obtained an accuracy of 0.86. Weighing the annotations of the radiologists' by their confidence resulted in an accuracy of 0.87; considering only the most accurate raters, or selecting the most surprisingly popular annotation, we obtained an accuracy of 0.88, in either case. All collective intelligence techniques increased diagnostic accuracy in the cases for which the radiologists exhibited a greater misdiagnoses rate, on low-confidence and high-complexity cases.
Conclusion: Collective intelligence techniques were associated with increased diagnostic accuracy compared with the average of the individual radiologists and the most accurate ones. These promising results suggest that these techniques merit further consideration for applications in the ground-truthing of machine-learning models and, potentially, in clinical settings to reduce diagnostic error.

Are pixel-level annotations necessary? Evaluation of their importance in detecting abnormalities in chest x-rays
T. R. Nimmada, P. Putha, M. Tadepalli, B. Reddy, A. M. Jagirdar, P. Rao, P. Warier*; Mumbai/IN (tarun.raj@qure.ai)*

Purpose: Pixel-level annotations are commonly used to segment and localise abnormalities in chest x-rays (CXRs), but they can also be used to improve the performance of classification models. In this study, we analyse the performance of models trained with and without pixel-level supervision to detect pulmonary consolidation in chest x-rays.
Methods and materials: A dataset of 2.5 million chest x-rays (D) along with their radiologist reports were used for this experiment. Labels were extracted using natural language processing techniques from reports. Pixel-level annotations were obtained for 5,000 consolidation positive cases with the help of 5 radiologists. Three training subsets were created: D1) 1 million CXRs (20,000 consolidation positives) sampled randomly from D without any pixel-level annotations, D2) 100,000 CXRs (5,000 consolidation positives) sampled randomly from D1 without pixel-level annotations, D3) D2 with pixel-level annotations. Classification models were trained using deep learning on D1 (M1) and D2 (M2) with labels extracted from reports. Models were trained on D3 (M3) using a hybrid of labels and annotations. An independent test set of 50,000 CXRs was used to assess the performance of M1, M2, and M3.
Results: The area under the receiver operating characteristic was used to compare the performance of models. AUC of M1, M2, and M3 were observed to be 0.90, 0.85, and 0.87 respectively. AUC of M3 is higher than that of M2 but lesser than M1.
Conclusion: While models trained with pixel-level supervision performed better than those without it, models trained on more labelled data showed the best performance. The influx of more labelled data into training improved the performance of more than pixel-level annotations.
Limitations: This method should be further evaluated on more abnormalities.

Sensitivity to user input in deep learning-based vertebral segmentation from lateral cervical spine x-rays
J. Spencer[1], J. Tabak[1], J. R. Meakin[1], G. Slabaugh[2], S. M. M. R. Al Arif[3], K. Knapp[1]; *[1]Exeter/UK, [2]London/UK, [3]Veldhoven/NL (K.M.Knapp@exeter.ac.uk)*

Purpose: Cervical spine injuries (CSIs) occur in approximately 4.3% of trauma patients in the UK. We investigate the sensitivity to user input on computer-aided detection software (CAD) designed to aid clinicians with CSI diagnosis.
Methods and materials: We collected 137 lateral cervical spine radiographs. Injury diagnosis is dependent on the results of a deep learning segmentation algorithm, which requires vertebrae centres as input. The data was expertly-annotated to define ground truth outlines of the C3–C7 vertebrae.
We used the Unet architecture with a modified loss function to account for vertebrae shape, training the network using 124 images. We defined a 'true centre' for each of the 13 test images and randomly varied the input centres from this point, measuring the resulting effect on segmentation performance.

Results: Segmentation accuracy relates to the ground truth outline. Consistency relates to the result using the 'true centre' as input (both using Jaccard index). With 100 pseudo-random variations of the input centres for 13 test images, with a mean accuracy of 0.85 and consistency of 0.92. With 'radius around true centre: percentage of tests, mean consistency, mean accuracy' we have '<=1 mm: 34%, 0.97, 0.88', '(1-2) mm: 26%, 0.94, 0.87', '(2-3) mm: 15%, 0.90, 0.85', '(3-4) mm: 8%, 0.85, 0.82'. We observed a crucial drop-off in performance outside a 2 mm radius of the true centres.
Conclusion: Sensitivity to user input is vital in assessing the role of CAD in the clinical pathway for CSIs. The results indicate that guidance for user selection should be to target within 2 mm of the vertebrae centre and clinician training should account for this.
Limitations: This is a develomental version of CSPINECAD.

Is a deep learning algorithm equivalent to the radiologist in fracture detection on conventional x-rays?
G. H. Reichert[1], E. Zerbib-Attal[2], B. A. Naipeanu[1], A. Altar[1], M. Fontaine[1], R. Radjabaly[1], A. Bellamine[1], N. Javaud[1], N. Siauve[1]; *[1]Colombes/FR, [2]Paris/FR (guillaumereichert@hotmail.fr)*

Purpose: The increasing need for emergency imaging has led to a multiplication of conventional x-rays, especially in traumatic injury. At the same time, artificial intelligence (AI) programs are in development and deep learning algorithms could help the radiologist and the emergency room (ER) to screen for patients with fractures.
To determine the accuracy of a deep learning algorithm for the detection of fractures on conventional x-rays in ER patients.
Methods and materials: We use an algorithm (Rayvolve®) developed by Azmed® for fracture detection in the appendicular skeleton. The study was divided into 2 steps.
In step 1, 2,000 X-rays were selected from the ER of our hospital as the training population and were annotated for the status of fracture or not fractured, to train the algorithm.
In step 2, 126 patients were randomly selected by an emergency doctor as a test set. These x-rays were extracted and annotated by both a radiologist and the algorithm. The results of the algorithm were compared to those of the radiologist.
Results: In step 1, about 15% of the patients had a fracture.
In step 2, 26 x-rays with fractures were identified. Only 21/26 fractures were detected by the algorithm, which makes a sensitivity rate of 80.7%. Among the 100 patients with no fracture, 35/100 patients were annotated by the algorithm as fractured, which makes a sensibility rate of 35%. The positive predictive value was 37.5% and the negative predictive value was 92.9%.
Conclusion: This study shows that an algorithm like Rayvolve® could be a valuable computer-aided diagnostic tool for detecting fractures in ER. However, more fractures have to be annotated to improve the accuracy of the algorithm.

Adapting state-of-the-art deep learning detectors for diagnosing bone lesions in musculoskeletal x-rays
A. Attia, A. Joseph, E. Zerbib-Attal, L. Combaldieu, G. Fradet, N. Upendra*; Paris/FR*

Purpose: The explosion of usable data and compute power over the past decade saw deep learning (DL) transform traditional internet businesses. As of today, DL is enabling new products and services across a wavelength of sectors, of which healthcare (with a focus on assisted diagnosis on medical images) is poised to be one of the most impacted sectors. With an ever-increasing demand for medical image diagnosis and insufficient specialists to commensurate with this demand, DL seeks to turn the tables around and aide specialists with the diagnosing procedure by reducing time and ameliorating accuracy.
This paper documents how we at AZmed adapted a state-of-the-art DL detector for fracture detection, with the mission of augmenting a doctor's workflow. Our adaption involved experimenting with pre-processing techniques, pre-training datasets, backbones, and hyper-parameters tuning. The paper details the insights obtained from rigorous experimentation and astute training strategies realised as a result. Additionally, light is thrown on research conducted on feature map outputs of the network in an effort to better grasp the functioning and behaviour of our fracture detector.
Methods and materials: Train, validation, and test dataset.
Results: Yet to be published.
Conclusion: The performance of the detectors allows doctors to save time and to reduce medical errors.
Limitations: A retrospective study.
Ethics committee approval: n/a

RPS 1205-6 16:24
The effect of hard attention on abnormality detection in chest x-rays
T. R. Nimmada, B. Reddy, P. Putha, M. Tadepalli, A. M. Jagirdar, P. Rao, P. Warier*; Mumbai/IN (tarun.raj@qure.ai)*

Purpose: Visual attention in image classification allows models to focus on the region of interest effectively. In this study, we describe the effect of hard attention, achieved by explicitly cropping the region of interest (ROI) in detecting 2 abnormalities (tracheal shift and scoliosis) in chest x-rays. We also compare the performance of models trained with and without attention.
Methods and materials: Deep learning models were trained on a dataset of 2.5 million chest x-rays to detect scoliosis and tracheal shift. To incorporate hard attention, we trained a deep neural network model to localise the mediastinum from chest x-rays. This model took an input image (of size HxW) and output a binary mask (M) of size HxW with a rectangular ROI (size hxw) encompassing the mediastinum. The ROI was dilated to the left and right to obtain a binary mask (M1) of ROI size hx2w. The ROI in mask M1 was eroded to get a new mask (M2) of ROI size (h/2)x2w. M1 and M2 were used as attention masks to crop the region of interest for scoliosis and tracheal shift, respectively. This served as input data on which classification models with attention were trained.
Results: We measured the area under the receiver operating characteristic (AUC) to compare the models trained with (m_a) and without attention (m_wa). For tracheal shift, AUC of m_a and m_wa were 0.95 and 0.92, respectively. For scoliosis, AUC of m_a and m_wa were found to be 0.95 and 0.88, repsectively.
Conclusion: We have shown that performance of classification models to detect tracheal shift and scoliosis can be improved with hard attention. Attention helps us incorporate domain knowledge while training.
Limitations: Metrics other than AUC should be measured for further evaluation.

Artificial intelligence in standard radiology: automatic x-ray diagnostic algorithm
M.-M. Benta, F. Birsasteanu, S. Dunarintu, S. Iarca, B. Bercean, C. Avramescu, A. Tenescu*; Timisoara/RO (marius.benta@yahoo.com)*

Purpose: To develop a performant chest x-ray pathology classification machine learning model for the "Pius Brînzeu" Emergency County Hospital, using publicly available datasets (CheXNet and CheXPert) as its backbone.
Methods and materials: The convolutional neural network algorithm trained on CheXNet and CheXPert was underperforming when tested on cases from the "Pius Brînzeu" Hospital. We extracted 48,000 anonymised radiographs of consenting patients from the hospital's PACS system. We labelled them by transforming their associated radiological reports into labels and retrain the

algorithm with the initial model used as pretraining. Three radiologists hand labelled 2,000 x-rays in the newly obtained dataset and drew class bounding boxes that indicated afflicted areas on the x-rays. We trained a third model with the adjusted dataset.
Results: AUC was used as the metric to compare model performance. We evaluated 3 models on a gold standard dataset containing 500 radiologist annotated images. The publicly trained model scored 0.809, the automatically labelled model scored 0.813, and the one that uses hand label radiographs scored 0.825.
Conclusion: Our results indicate that there is a clear benefit to adding hospital-specific images to the dataset. Hand labelling also increases performance over NLP labelling, which shows that NLP has limitations especially in languages that don't have a word stemmer, like Romanian.
We conclude that retraining a model that uses public data as its backbone with data specific to a hospital strongly increases the performance of the model in the hospital. The most important further improvements come from the quality of the new dataset.
Limitations: The of hand labelled dataset is small compared to the hospital dataset.
Ethics committee approval: The study was aproved by the local Ethical Commitee.
Funding: No funding was received for this work.

Cascading model architecture of convoluted neural networks to improve the performance of pathology detection in digital chest x-rays
A. Kharat[1], A. Ahmad[2], J. Tandale[2], R. Lokwani[2], S. Kasliwal[2], G. Naik[2], S. Kondal[2], A. Pant[2], K. Saoji[2]; [1]Maharashtra/IN, [2]Pune/IN (kharatamit75@gmail.com)

Purpose: The chest x-ray is the most commonly used diagnostic examination screening tool in radiology. Due to constrained resources and the image-driven nature of a diagnosis, we want to assess if machine learning (ML) can aid in pathology detection.
Methods and materials: The data source was a leading hospital (LH) of 800+ bed capacity. The dataset was anonymised and not publicly available. The dataset contained 26,000 x-rays and associated radiology reports but without pathology labels. Using findings in radiology reports, pathology labels were generated.
Results: We trained a Densenet-121 model. Our objective was to build a customised ML model for the detection of any of 15 different chest diseases that are trained more effectively for chest x-ray source-specific datasets. Our data was imbalanced. Training a deep learning (DL) model for these pathologies can be challenging. Solely relying on balancing techniques cannot be a reliable way to improve performance. We explored cascading models. Along with 15 pathology prediction model for improved performance, we trained the model for binary classification to check if a chest x-ray has a pathology or not using a team of two validating radiologists. We used a Densenet-121 model trained without transfer learning. This binary model is combined with 15-pathology model in a cascading way. We found that the cascading architecture was more performant than using only the 15-pathology model on the LH dataset. We found that. at a small compromise for accuracy. the sensitivity (recall) of pathologies was better using this model.
Conclusion: Using cascading architecture, we could improve Kappa, sensitivity/recall, and F1 score significantly for pathology detection in digital chest radiographs. Using the cascading model archiecture of CNN, radiologists can efficienctly manage and control the turn around time of the reporting process of digital radiographs by incorporating these techniques in workflow.

Deep learning-based architecture for detection of tuberculosis in digital chest radiography: our experience in the Indian scenario
A. Kharat[1], A. Ahmad[2], R. Lokwani[2], G. Naik[2], J. Tandale[2], K. Saoji[2], A. Jaju[2], A. Patil[2], A. Pant[2]; [1]Maharashtra/IN, [2]Pune/IN (kharatamit75@gmail.com)

Purpose: Tuberculosis (TB) has infected 1% of the global population and is a major cause of death in developing countries.
Methods and materials: Deep learning (DL) was used to classify every digital chest x-ray (DX) into 3 types: abnormal (TB likely), abnormal (TB unlikely), and normal. A model trained on a combination of publicly available 'NIH DX dataset' and private anonymised hospital data was used. Dataset for modelling: 2,050 images with train-test ratio=78:22. Training set: 1,600 images with 530 abnormal TB, 530 abnormal non-TB, and 540 normal DX and test set consisting of 450 images equally balanced in the 3 classes with 150 images each. Basis: convolutional neural networks (CNN). DX divided into 3 predefined classes. Steps: 1] conversion of DX DICOM to PNG format, image resized to 224 x 224 and fed to the DenseNet-121 model for training, and 2] learning rate scheduler to reduce the learning rate to 1/10th of its initial value after every 10 epochs.
Results: Test set: 450 images.
Conclusion: CNN scores can potentially be used for TB screening in DX with a radiologist in the loop approach. TB screening programs to assist government hospitals using DL can be a game-changer in curbing TB. Instant alert triage can enable urgent sputum checks and initiation of antitubercular treatment before the patient leaves the hospital premise.

Breast cancer screening with denoised ultra-low-dose mammography
M. Sklair-Levy[1], M. Green[1], E. Konen[1], N. Kiryati[2], A. Mayer[1]; [1]Ramat Gan/IL, [2]Tel Aviv/IL (arnmayer@gmail.com)

Purpose: To assess a novel AI-based algorithm for the denoising of ultra-low-dose (ULD) digital mammography.
Methods and materials: A retrospective dataset of 16 digital mammography studies (each: bilateral CC and MLO) was obtained from a Senographe Pristina (GE Healthcare) imager in a standard breast cancer screening protocol. ULD mammograms were simulated by adding synthetic noise to the pixels, corresponding to 90% less radiation. A neural locally-consistent non-local block which preserves fine details (e.g. micro-calcifications) was proposed to denoise the images. The network was trained on a single case (4 views) and tested on the remaining 15. Comparision is given against 4 state-of-the-art denoising algorithms ([1], [2], [3], and [4]). Peak signal-to-noise ratio (PSNR) and structural similarity index (SSIM) quantified the similarity between denoised-ULD and normal dose image pairs.
Results: The proposed method outperformed all the compared algorithms: PSNR (proposed=38.92/second-best=38.27) and SSIM (proposed= 0.987/second-best=0.979).
Conclusion: A novel AI-based denoising algorithm was proposed and validated for the enhancement of synthetic ULD mammography. The proposed algorithm showed promising results, motivating future validation on real ULD mammography.
Limitations: Simuated data was used, real ULD data will be used in future research.
Ethics committee approval: IRB was obtained from our institution.

Development and performance comparison of multi-task deep learning approaches for the severity assessment of radiographic hip osteoarthritis features

C. von Schacky[1], J. H. Sohn[2], F. Liu[3], S. C. Foreman[1], E. Ozhinsky[3], P. M. Jungmann[4], M. Nevitt[3], T. M. M. Link[3], V. Pedoia[3]; [1]Munich/DE, [2]Baltimore/US, [3]San Francisco, CA/US, [4]Freiburg/DE
(claudio.vschacky@hotmail.de)

Purpose: Radiographic features of hip osteoarthritis include joint space narrowing, osteophytes, subchondral sclerosis, and subchondral cysts. The aim was to develop, validate, and compare the performance of four multi-task deep learning approaches for grading radiographic hip osteoarthritis features.
Methods and materials: We used 15,364 hip joints (7,738 pelvic radiographs) from subjects of the Osteoarthritis Initiative. Each hip joint was graded for five osteoarthritis features and each feature for absence, mild, moderate, or severe presence. The data was split 80%/10%/10% for training/validation/ testing. The hip joint was detected with a trained RetinaNet for object detection. Then, four different approaches to solve this multi-task problem were evaluated and compared: single-model alone, single-model with classifier, multi-task learning, and fine-tuned multi-task learning. All models were based on a Densenet-161. Reliability was assessed with Cohen's Kappa.
Results: All multi-task approaches achieved higher reliability compared to single-model approaches. The highest reliability was achieved with a fine-tuned multi-task learning model with a Kappa of 0.58 for femoral osteophytes, 0.41 for acetabular osteophytes, 0.51 for joint space narrowing, 0.44 for subchondral sclerosis, and 0.53 for subchondral cysts.
Conclusion: This study shows that a variety of multi-task learning approaches can be used for grading radiographic hip osteoarthritis features and that multi-task learning might have advantages over single-model training.
Limitations: The training set only consisted of cases of one large scale dataset from a longitudinal OA study. It would increase the quality of the training set to add further samples with different demographic and imaging characteristics.
Ethics committee approval: Written informed consent was obtained from all participants. IRB approval was granted by this HIPAA-compliant study by the four participating US-based centres.
Funding: NIH-NIAMS: 5R01AR064771-05.

Defending against adversarial attacks in the detection of pneumothoraces from chest radiographs: ensuring robustness in clinical AI applications

D. Kügler[1], A. M. Bucher[2], A. Distergoft[2], A. Rajkarnikar[3], M. Uecker[3], P. D. A. Kuijper[3], T. J. Vogl[2], D. A. Mukhopadhyay[4]; [1]Bonn/DE, [2]Frankfurt am Main/DE, [3]Darmstadt/DE

Purpose: Adversarial examples are small input changes with malicious intent that are imperceptible to the human eye yet can completely change the output of a deep neural network (DNN). In this investigation, we introduce controlled Gaussian noise administration, a practical defence against adversarial attacks on the detection of pneumothoraces from chest radiographs.
Methods and materials: We trained a DNN classifier (ResNet) on 9,265 manually annotated chest radiographs for the detection of pneumothoraces. Validation was tested on a dataset of 150 images containing comparable chest radiographs (I_C) against annotation of a trained radiologist reader. Each image was then attacked (I_A) with 4 gradient-based adversarial attack methods (BIM, DF, SMA, FGSM). In the defence dataset (I_D), we introduced controlled Gaussian randomness in increasing steps on a heuristic scale (steps 1-7).
Results: Classification by the human reader did not differ significantly between I_C and I_A (p=0.325). DNN classification accuracy dropped from 83.3% (I_C) to 16.6% (I_A; p<0.001). Best overall accuracy for I_D was found in step 5 (56%±12.6%; p<0.001). Optimal corrections steps varied highly between attack types (BIM, step1: 81.1%, p<0.001). Overall true-positive rates were 0.65 (I_C), 0.35 (I_A), and 0.56 (I_D; DF/SMA, step7: 0.9), overall false-positive rates were 0.1 (I_C), 0.9 (I_A), and 0.6 (I_D; BIM, step 3: 0.09). AUC overall was 0.775 (I_C), 0.225 (I_A), and 0.48 (I_D; BIM step2: 0.761). Steps 6 and 7 did not result in further improvement of overall accuracy (48.2%; p=0.152).
Conclusion: Even highly effective adversarial attacks can be effectively counteracted by the proposed method of controlled Gaussian noise administration. Comparable defence mechanisms should be integrated when transferring DNNs to clinical application.
Limitations: Effectiveness should be validated in a larger dataset.

RPS 1205-13 17:06

On the robustness of a deep learning-based algorithm for detecting abnormalities in chest radiographs across different devices and view positions: a retrospective case-control study

S. Na, M. Kim, J. Park, C. M. Park, E. J. Hwang, S. Park; Seoul/KR
(sgpark@lunit.io)

Purpose: To validate the robustness of a deep learning-based algorithm that detects abnormal lesions in chest radiographs for a screening environment.
Methods and materials: To verify the robustness of a deep learning-based algorithm, we collected datasets from Seoul National University Hospital. 2,673 chest radiographs taken from 27 x-ray devices were collected to verify the robustness across different x-ray devices. These radiographs were then divided into two groups of which 661 cases (479 abnormal and 182 normal) were computed radiography (CR) and 2,012 cases (1,449 abnormal and 563 normal) were digital radiography (DR). 2,625 (2,028 abnormal and 597 normal) posterior-anterior (PA) images and 1,729 (1,580 abnormal and 149 normal) anterior-posterior (AP) images were collected to verify the robustness across different view positions. These two datasets were reviewed by board-certified radiologists. For the deep learning-based algorithm, we used LUNIT INSIGHT CXR 3 to predict 10 major radiologic findings in chest radiographs. This algorithm was trained with 147,823 images using various augmentation schemes such as photometric and geometric jittering for making itself more robust to radiographs taken with various settings.
Results: The algorithm achieved AUC of 96.54 and 97.09 for CR and DR, respectively. The p-value of DeLong's test for the difference between two AUCs was 0.4802. Moreover, for PA and AP images, it achieved AUC of 97.29 and 96.67 for PA and AP, respectively. The p-value was calculated to be 0.3182.
Conclusion: Chest radiographs have tremendous heterogeneity due to various devices and methods in taking chest radiographs. Our experimental results showed that a well-generalised algorithm can be robust in detecting abnormalities on chest radiographs in a screening environment.
Limitations: More validation of the robustness from various sites could be useful.

Clinical validation of a deep learning-based bone age software in healthy Korean children

W. W.-I. Lea, S.-J. Hong, H.-K. Nam, H. S. Yong, Z. Yang, J. Jeong, E. Noh;
Seoul/KR (lwooin17@gmail.com)

Purpose: To evaluate the clinical performance of a deep learning (DL)-based bone age software in healthy Korean children.
Methods and materials: This retrospective study included 371 healthy children (217 boys, 154 girls) aged between 4 and 17 years who visited the department of paediatrics for growth check-ups between January 2017 to December 2018. A total of 553 left-hand radiographs of 371 healthy Korean children were assessed using a commercial DL-based bone age software (BoneAge, Vuno, Seoul, Korea). Two sample t-test, Fisher's exact test (two side), Pearson's correlation coefficient, root mean squared error (RMSE), concordance rate, and Bland-Altman analysis were used to evaluate the clinical performance of DL software by comparing with their chronologic age.
Results: Two sample t-test (p<0.001) and Fisher's exact test (p=0.011) showed there is a significant difference between the normal chronological age and the bone age estimated by DL software. Between the two variables, there was a good correlation (r=0.96, p<0.001), however, the RMSE value was 15.2 months.

With a 12-months cut-off, the concordance rate was 58.8%. The Bland-Altman plot showed that the DL software had a tendency to estimate the bone age younger than the chronologic age, especially in children under the age of 10 years.
Conclusion: DL-based bone age software showed a low concordance rate and a tendency to estimate the bone age younger than the chronologic age in healthy Korean children.
Limitations: A retrospective study, single-centre trial, with a small number of patients.

RPS 1205-15 17:18
A cloud-based intelligent system for bone age determination in athletes: making AI available for sport imaging
M. Fatehi[1], R. Nateghi[1], P. Fatehi[1], F. Pourakpour[1], A. Sami[2]; *[1]Tehran/IR, [2]Shiraz/IR (mansoor.fatehi@gmail.com)*

Purpose: In order to implement fair play principles, FIFA has developed a bone age grading system consisting of I-VI levels which can be used in teenage athletes using MRI as a modality without ionising radiation. This grading system requires a particular imaging protocol and reporting guideline. The purpose of this paper is to describe an online cloud-based AI-enabled reporting system to provide the automated grading of wrist MR studies uploaded by football clubs or authorities.
Methods and materials: The football players of the national team were studied by Siemens Avanto 1.5 using a knee coil, following dedicated FIFA protocol, resulting in 9 coronal sections in T1W sequence. An AI model was developed in MATLAB. 72 cases with 648 slices were augmented to 11,034 images to train the model and then tested by 30 cases resulting in 420 images after augmentation. The system was adapted to a web-based application to get an MRI data set as an input and provide a grading report.
Results: The system was able to provide a grading report within 30 seconds after the upload of the study with an accuracy of 98-100% compared to trained experienced MSK radiologist familiar with the FIFA system.
Conclusion: The system provides fast reliable grading capacity to be available to any football federation or authority, as well as football clubs, to get the report from anywhere. The system is independent of the interpreting physician with immediate results available for decision making.
Limitations: The intelligence of the grading system needs to be adapted to different races and geographical background to be applicable for a wide international scale.

Survey of radiologists', radiology residents', and radiographers' knowledge regarding contrast materials and management of associated adverse reactions
F. Khan, M. Samad, G. Wahid; *Peshawar/PK (islamianfellow@hotmail.com)*

Purpose: To assess the knowledge of radiology personnel regarding the contrast media and management of associated adverse reactions.
Methods and materials: The survey conducted from 21st February to 31st March 2019 in five major hospitals of Peshawar, Pakistan. A 30-item questionnaire was adopted from the existing literature containing both open and closed-ended questions and a pilot study was conducted among 25 radiology personnel to assess the face validity of the tool. Universal sampling technique was adopted. Hospital ethical review committee approval was granted.
Results: 15.2%,46.7% and 28.6% correctly classified contrast media used in radiology, iodinated contrast media on the basis of ionicity and osmolality respectively. 63% chose severe contrast material induced allergic reaction as type I hypersensitivity reaction while 56.2% correctly identified the features of iodinated contrast media associated with lesser side effects. Only 6.7% of people had read the ACR 2018 manual on contrast media. Regarding the risk factors for acute adverse reactions and signs/symptoms of anaphylaxis 13.3% and 7.6% responded correctly. Twenty-eight percent of participants correctly identified epinephrine as the initial medication in an anaphylactic reaction. Regarding epinephrine, 43.8%,6.7%, and 8.6% of participants knew the preferred route of administration, concentration, and dose. More than sixty-five percent of participants could name a single intravenous corticosteroid and antihistamine.
Conclusion: Radiology personnel's knowledge regarding contrast material and management of severe contrast material-induced allergic reactions is unsatisfactory.
Limitations: The response rate was low and hence sample size.
Ethics committee approval: Ethical review committee approval was granted.
Funding: No funding was received for this work.

An experimental approach to the development of a 3D printed model of the hand and wrist for use in undergraduate radiography teaching
L. Kennedy; *Waterford/IE (laura.kennedy.3@ucdconnect.ie)*

Purpose: The impact of 3D printing in all industries is steadily increasing. The cost of 3D printing, which was once a deterrent, has declined, allowing for easier access to the technology and the benefits it has to offer the healthcare industry. As research highlights the shift away from conventional teaching at third-level, methods of achieving a hands-on learning approach are being explored. Radiography students have benefited greatly from the use of radiographic anthropomorphic while training. However, such phantoms are very costly for educational facilities. The importance of projection radiography in diagnosing wrist pathology cannot be disputed. Evidence shows problems that can arise from improper positioning of the wrist can cause morbidity in the patient. Thus the aim of the research project is to 3D print an anthropomorphic radiographic model of the hand and wrist for use in undergraduate radiography teaching.
Methods and materials: Materials were tested for their suitability to print various components of the model, the model was designed using CAD software and printed with specific parameters. Following the PDSA cycle the model was created. A beta test of success was carried out on undergraduate students.
Results: A 3D printed model of the hand and wrist was successfully developed with experimental materials. The model was well received in beta testing.
Conclusion: 3D printed models can provide an accurate and cost-effective alternative to radiographic anthropomorphic phantoms for undergraduate teaching, with opportunities for customisation knowing little boundaries.
Limitations: Funding was the primary limitation of the study which was carried out at the undergraduate level.
Ethics committee approval: The ethical exemption was granted by the School of Medicine Undergraduate Research Ethics Committee (UREC SM) on the 04th of February 2019, UREC number UREC-SM-2018-86.
Funding: No funding was received for this work.

MyT3 12-3 16:08
Estimation of pituitary gland volume and its correlation with age and gender: a magnetic resonance study
T. D. C. Cabrita[1], A. F. Abrantes[1], L. P. V. Ribeiro[2], S. Rodrigues[1], R. C. M. C. R. Gaspar[3], R. P. P. Almeida[1], K. B. Azevedo[1]; [1]Faro/PT, [2]Parchal/PT, [3]Coimbra/PT (tiagocabrita123@hotmail.com)

Purpose: To determine the dimensions of normal pituitary gland and correlate with age and gender, in order to obtain standard reference values.
Methods and materials: Head MRI scans of 410 patients with clinically normal pituitary function (173 males and 237 females) were retrospectively analysed and in the age range 10-90 years. T1-weighted images were reviewed in order to obtain volumetric measurements of the pituitary gland using RadiAnt DICOM Viewer software® (V.4.2.1). The height, width and depth of the pituitary were obtained from mid-sagittal and coronal planes, while the volume was calculated from these measured parameters. The data obtained were stratified based on age and gender for analysis.
Results: Females had greater pituitary height (5.59±1.29 mm), width (13.08±2.21 mm), and volume (398.98±123.80 mm^3) compared to males (5.53±1.23 mm, 12.59±2.09 mm and 378.58±106.46 mm^3, respectively). However, males had greater depth values (10.56±1.34 mm) compared to females (10.54±1.49 mm), having a positive correlation between depth and gender (r = 0.113, P= 0.022). Significant differences between pituitary height, width and volume with age were found and they correlated negatively with increasing age (r = −0.157, P= 0.001; r = −0.129, P = 0.009; and r = −0.140, P = 0.004, respectively). Also, it was possible to identify that these parameters have a peak at age range 41-50 for females, that may result due the intense hormonal activity at this age. Regarding the gender, no significant differences between pituitary height, width and volume were found.
Conclusion: We have provided reference values for the normal pituitary gland dimensions in the Portuguese population, in order to facilitate assessment and diagnosis in patients with abnormalities of the hypothalamic-pituitary axis.
Limitations: N/A
Ethics committee approval: Ethics committee approved the study.
Funding: No funding was received for this work.

Radiographer's communication skills in private imaging facilities
A. C. M. Gonçalves[1], S. Rodrigues[2], L. P. V. Ribeiro[3], A. F. Abrantes[2], R. P. P. Almeida[2], O. Lesyuk[4], B. Vicente[5]; [1]Tavira/PT, [2]Faro/PT, [3]Parchal/PT, [4]São Brás de Alportel/PT, [5]Olhão/PT (catarina.3@live.com)

Purpose: Effective communication is at the heart of quality health care. In radiography a considerable part of the working day is spent relating to others. Radiographers should base themselves on interpersonal competences throughout their daily work routine, to promote quality in diagnosis, patient safety and technical excellence. The aim of this study was the exploration of patient's perceptions regarding the performance of the Radiographer in terms of interpersonal communication skills in private imaging facilities.
Methods and materials: The instrument used was the questionnaire "Communication Assessment Tool" adapted to the professional reality of the radiographer. A final sample of 150 valid questionnaires including 15 questions with a five-point Likert scale ("poor" to "excelent") was used. The paper-based instrument was delivered and filled by the patients after the performance of imaging procedures from two private hospitals. The results were reported as a percentage of "excellent" ratings and mean scores.
Results: The average "excellent" response rate was 45% (= 4). The issues rated "excellent" relate to respect (55.3%, = 4.43) and to the use of accessible language (57.3%, = 4.41). The worst-rated "excellent" issues are related to the encouragement to ask questions (29.3%, = 3.75) and the understanding of the radiographer in face of patients' health problems (32%, = 3.99). Significant differences were found between age, gender, context and shift.
Conclusion: Radiographers' communication skills were evaluated with good levels of patient confidence with the radiological examinations. Despite the overall positive results, radiographers should have a marked impact on their communication with patients because they are often one of the first health professionals that patients see.
Limitations: n/a
Ethics committee approval: Ethics committee approved the study and written informed consent.

Ultrasound evaluation of abdominal muscles in asymptomatic and patients with chronic low back pain: the role of a radiographer
B. Vicente[1], A. F. Abrantes[2], L. P. V. Ribeiro[3], S. Rodrigues[2], J. Pinheiro[4], M. V. C. Reis[2], R. P. P. Almeida[2]; [1]Olhão/PT, [2]Faro/PT, [3]Parchal/PT, [4]São Brás De Alportel/PT (biancaicvicente@gmail.com)

Purpose: Abdominal muscles are one of the important elements to support the lumbar spine. Evaluation of muscle thickness using ultrasonography is considered to be a source of information from muscles characteristics. The aim of this study was to investigate whether there were differences between chronic low back pain (CLBP) and healthy subjects in abdominal muscles thickness using ultrasound.
Methods and materials: A sample of 23 CLBP patients and 20 controls was recruited. Four abdominal muscles (Rectus Abdominis (RA), External Oblique (EO), Internal Oblique (IO) and Transversus Abdominis (TA)), were bilaterally measured by a trained radiographer at rest and while contracted.
Results: The pattern of relative muscle thickness was IO > RA > EO > TA, bilaterally, both at rest and while contracted. The mean for RA, EO, IO and TA muscles thickness in asymptomatic subjects were (11.05, 3.735, 14.335, 4.015) at rest and (11.03, 3.295, 12.685, 3.63) while contracted, respectively. The mean for RA, EO, IO and TA muscles thickness in patients with CLBP were (11.11, 2.945, 15.565, 3.955) at rest and (10.99, 2.525, 13.645, 3.44) while contracted, respectively. Significant differences in the thicknesses of the abdominal muscles were measured during rest and while contracted, as well as between both genders. However, no significant differences were found between CLBP patients and control group.
Conclusion: Despite the results, ultrasound measurements of abdominal muscles are reliable, and radiographer can play a key role in this field. However, the validity of using thickness change as a measure of muscle function, their correlation with other clinical features and the effect of specific retraining all require further investigation.
Limitations: Sample size
Ethics committee approval: Ethics committee approved the study and written informed consent was delivered to the participants.

Sentinel lymphatic nodes scintigraphy in patients with vulvar cancer
E. Zykov, A. Ilyin, A. Meldo, G. Bozhukhin, G. Lungu, V. M. Moiseenko, S. Maksimov, K. Shelekhova; St. Petersburg/RU (zykov4@yandex.ru)

Purpose: Sentinel lymphatic nodes scintigraphy (SLN) allows for intraoperative choosing the optimal volume of surgery in patients with vulvar cancer without any clinical data on the presence of the metastasis in the inguinal lymph nodes. Purpose of the study was to evaluate the significance of SLN scintigraphy in patients with vulvar cancer in the stage of intraoperative planning.
Methods and materials: The study included 46 patients with vulvar cancer cT1N0M0 (average age 72 years old). To confirm the degree of cN0, MRI of the pelvis with contrast enhancement were performed. All patients underwent preoperational scintigraphy of SLN. The radioactive pharmacological preparation (RPP) Tc99m-Technephite 90-150 MBq in the volume of 0,7-1,0 to the patient was administered 3-16 hours before surgery. The scanning was conducted 30-60 minutes after the injection of RPP in the static mode in a prone position in two projections.
Results: The RPP accumulation in regional lymph nodes during SLN scintigraphy was detected in 100% of the patients. In the case of intraoperative histological examination, metastatic lesions of SLN were revealed in 9 patients (20%). With the expansion of surgery volume and subsequent histological evaluation, metastases in other excised lymph nodes were detected in three cases. In six cases, metastases were found in one lymph node only. In 37

patients (80%) there were no metastatic lesion of SLN. This allowed avoiding of lymphadenectomy.

Conclusion: SLN scintigraphy with biopsy as a clarifying diagnostic method allows individualising the volume of operative intervention.
Limitations: This study has no limitations.
Ethics committee approval: n/a
Funding: No funding was recieved for this work.

An investigation of post-registration PET/CT radiography training in Ireland

R. E. Whelan, K. Curran, L. A. Rainford*; Dublin/IE (rachel.whelan@ucdconnect.ie)*

Purpose: A well-trained workforce is essential in a PET/CT department. There is a lack of published literature regarding the training and education of PET/CT radiographers in Ireland. This study investigated the PET/CT training offered in Ireland and investigated in which areas further training might be beneficial for PET/CT radiographers in Ireland.
Methods and materials: An online questionnaire was distributed to PET/CT radiographers across Irish centres. Open and closed questions were asked about PET/CT training and further training areas. The questionnaire sought information regarding participants' individual training, important areas for training, and participant demographics.
Results: Questionnaire responses (n=26) were received from 7 of 9 sites nationally (estimated staff response rate of 74% within these sites). 'In-house' induction PET/CT training programmes varied in duration from 1-2 weeks long to more than 9 weeks long. Observation and shadowing were among the most commonly used approaches to training. The use of a competency checklist during training and the level of agreement that the training fully prepared the participant to work independently in PET/CT were significantly associated ($p<0.024$, $r=0.672$). Radiation protection, pathology, radiopharmaceutical administration, artefactual variants and critical situations associated with contrast media/radiopharmaceuticals were identified as important training topics.
Conclusion: Key training areas were identified. Changes in practice - for example the introduction of a new Gallium service - were identified as matters that may affect future training needs. Further research is warranted to identify how the training needs identified should be addressed.
Limitations: The participant responses are representative of Irish PET/CT radiographers therefore further research is recommended to collect data from other European countries for comparison.
Ethics committee approval: This study was performed following ethical permission from the School of Medicine, University College Dublin.
Funding: No funding was received for this work.
Author Disclosures:
R. E. Whelan: nothing to disclose
L. A. Rainford: nothing to disclose

Has the radiographer practice changed in the use of anti-scatter grid with the introduction of digital detectors: a scoping review

C. Campeanu*; Lausanne/CH (cosmin.campeanu@hesav.ch)*

Purpose: To scrutinise the changes in radiographer's practice regarding the use of the anti-scatter grid in flat-panel digital imaging.
Methods and materials: The scoping review method was applied to identify gaps in the existing literature and to formulate recommendations for practice and/or policy changings. The three major databases for healthcare literature have been consulted: Medline, CINAHL and EMBASE using a combination of key-words (anti-scatter grid, digital radiography, radiographers practice).
Results: 149 studies were identified. After title and abstract reading, 25 articles were selected and 12 were retained for analysis/discussion based on inclusion criteria. The studies were divided into four groups: paediatric imaging, musculoskeletal and chest imaging in adults and "virtual-grid-like" radiographies. Based on phantom-studies of paediatric abdomen, specific recommendations were provided for grid-use decision-making: the patient should be over 14cm thickness with small FOV (21x18cm) at 80kVp. For adults, the removal of the anti-scatter grid can promote a dose reduction (up to a maximum of 418%) on specific anatomical areas such as shoulder and "virtual-grid-like" bedside chest radiographies, while keeping diagnostic image quality. This study was already clinically assessed, being possible a direct introduction on practice. The non-grid lateral cervical spine and horizontal beam hip radiographies need a further clinical assessment before changing the practice.
Conclusion: The introduction of digital detectors has potential to change radiographers practice regarding the use of anti-scatter grid. However, this change can be clinically implemented in just 2 specific radiographic examinations: AP shoulder and bedside chest acquisitions. Further clinical research should be designed considering the irradiated volume (measured thickness multiplied by the displayed FOV), through multiple parameters variations and different anatomical areas.
Limitations: This was an extensive scoping review but no experimental research was conducted to complement the findings.
Ethics committee approval: Not applicable.
Funding: Not applicable.
Author Disclosures:
C. Campeanu: nothing to disclose

MyT3 12-9 16:32

An investigation into the necessary considerations when giving patients online access to their health records

N. Seymour[1], M. D. Davis[2]*; [1]Cork/IE, [2]Dublin/IE (niall.seymour@ucdconnect.ie)*

Purpose: The use of electronic health records is becoming widespread and with this comes the desire of many patients to have easy access to their stored imaging and healthcare records. This study aimed to investigate, on a global and national level, the necessary considerations for any stakeholder intending on giving patients online access to their health records.
Methods and materials: A rapid structured literature review was conducted to gain an international perspective on the primary concerns that arise when giving patients online access to their records. This review was supported by conducting interviews with people working in the Republic of Ireland who have experience relevant to this area. All data gathered was analysed quantitatively using NVivo, a qualitative data analysis programme.
Results: A total of 49 articles and seven interviews were subjected to thematic analysis, from which six key considerations have been identified. These are as follows: (1) accessibility and engagement barriers, (2) security, (3) results, (4) proxy access (5) patient-generated health data and (6) resources.
Conclusion: Giving patients online access to their health records has the potential to bring significant benefits to patients and healthcare providers. Addressing important considerations could help ensure that giving patients online access to their health records can be secure, beneficial and not cause unnecessary worry or concern for patients or unnecessary strain on healthcare providers.
Limitations: Given the time constraints for this research project, an in-depth analysis of each consideration identified was not possible. However, this study has provided an overview of the key considerations, which is a valuable starting point from which stakeholders could begin planning patient portal implementation.
Ethics committee approval: Exemption from a full ethical review was granted by the Undergraduate Research Ethics Committee in University College Dublin on November 5, 2018.
Funding: No funding received.

Nutritional support in cancer patients: radiographers' perceptions

A. Y. Dimitrova, P. Jones, G. van Dijk*; Msida/MT (angelina.y.dimitrova@gmail.com)*

Purpose: This study aimed to explore the perceptions of radiographers employed in an oncology centre regarding their ability to identify patients needing nutritional advice and to provide patients with the appropriate dietary support.
Methods and materials: A non-experimental, quantitative approach was employed. An existing questionnaire was modified, using published guidelines to suit the aim of this study, and distributed to all radiographers working in the radiotherapy department of the selected oncology centre. Data were analysed using descriptive statistics.
Results: With a response rate of 85% (n=22), 86% (n=19) of participants indicated that patients asked for nutritional advice. 36% (n=8) of the respondents did not have previous training on nutritional interventions. All participants expressed interest in receiving additional information or training regarding nutritional management of side effects and identification of cases needing a referral to a dietitian. 82% (n=18) of participants stated that a protocol for referrals to dietitians was available at their clinical site, however, only two respondents indicated that they referred patients to a dietitian. All radiographers

are self-rated as knowledgeable in identifying patients in need of dietary interventions and delivering the appropriate nutritional support. This was supported by the high level of agreement between literature recommendations and radiographers' responses.
Conclusion: Findings suggest that radiographers perceive themselves as knowledgeable and provide patients with the appropriate nutritional support. However, only two radiographers referred patients to dietitians and all radiographers indicated that they would like additional support. The researcher, therefore, proposed additional training, implementation of scripted nutritional advice and further studies into the lack of referrals to the dietetic team.
Limitations: Participants may have responded in their favour or sought assistance, leading to biased results. Use of close-ended questionnaires may have restricted data, limiting explanation of complex issues.
Ethics committee approval: N/A
Funding: No funding was received for this work.

SAFMEDS to improve medical students and trainees accuracy in interpreting chest radiographs: a pilot study
K. Dunne, D. Byrne, S. Lydon, P. McCarthy, C. Madden*; Galway/IE (kevindunne04@gmail.com)*

Purpose: To develop an efficient and effective educational tool that students can use in a self-directed manner to improve their chest x-ray (CXR) interpretation skills.
Methods and materials: Third-year medical students and medical interns took part in this study. Participants completed a pre-intervention assessment which required them to indicate a diagnosis for 25 CXR images. No clinical information accompanied the images. Participants then: 1) received a tutorial on CXR interpretation, and; 2) independently used a behavioural instructional methodology called SAFMEDS ("say-all-fast-minute-each-day-shuffled"), which involved 60-second practice trials with a set of flashcards depicting CXR images, for six weeks. Subsequently, participants completed a post-intervention. Dependent t-tests were used to compare the performance of each group at the pre-intervention and post-intervention assessments.
Results: A total of 13 third-year medical students, and 14 medical interns completed the pre-intervention assessment with a mean overall accuracy of 34.2% and 63.1% respectively. Post-intervention accuracy increased to 67.6% (n=11, p= <0.001) for the medical students and 77.3% (n=9, p= 0.02) for the medical interns.
Conclusion: SAFMEDS produced statistically significant improvements in accuracy for both groups in just six weeks when interpreting CXRs. This is in line with other research which has shown the efficacy of SAFMEDS in varied educational domains. As SAFMEDS constitutes a self-directed learning resource it is potentially a very valuable tool given the ever-increasing class sizes in medicine, and increasingly busy medical curricula, which impacts upon the time available to students in the class to master essential clinical skills.
Limitations: This study was limited by small sample size, single institution and only ten diagnoses included.
Ethics committee approval: Approval for the study was granted by the Research Ethics Committee at the National University of Ireland, Galway.
Funding: Received from National Doctors Training and Planning.

Evaluation of haemodynamic changes in the middle cerebral artery in smokers: an ultrasonography study
M. D. P. Brazuna[1], L. P. V. Ribeiro[2], S. Rodrigues[1], A. F. Abrantes[1], R. P. P. Almeida[1], M. V. C. Reis[1], K. B. Azevedo[1]; *[1]Faro/PT, [2]Parchal/PT (marciobrazuna@hotmail.com)*

Purpose: The effect of cigarette smoking on the brain is not clearly understood but is probably multidirectional and complex, predominantly affecting the circulatory system, both general and cerebral. Transcranial Doppler (TCD) ultrasonography is a noninvasive bedside monitoring technique that can evaluate cerebral blood flow haemodynamics in the intracranial arterial vasculature. This study aims to evaluate haemodynamic changes induced by smoking habits in the middle cerebral artery.
Methods and materials: Mean flow velocity (MFV), peak systolic velocity (PSV), end-diastolic velocity (EDV), resistive index (RI) and pulsatility index (PI) were determined in the middle cerebral artery by a trained radiographer. A sample of 34 volunteer participants (17 smokers and 17 non-smokers) were examined using a dedicated ultrasound equipment for the TCD and a comparative study of the haemodynamic parameters measured in both groups was performed.
Results: The mean values of the blood flow velocities measured in the smoking volunteer participants (MFV=53.74cm/s; PSV=89.02cm/s; EDV=38.10cm/s) were lower compared to non-smokers (MFV=59.85cm/s; PSV=99.94cm/s; EDV=39.82cm/s), worsening with the intensity of their smoking habits. Smoking subjects also had a higher blood pressure on average. All these phenomena presented a greater magnitude in male subjects.
Conclusion: The findings provide additional novel evidence of the adverse effects of cigarette smoking on the human brain since smoking has negative effects on middle cerebral artery and haemodynamics. Therefore, smoking is a risk factor for alterations in middle cerebral artery haemodynamics and male smokers are more likely to develop vascular changes. Radiographers can play a key role in the detection of pathophysiological changes from a preventive perspective.
Limitations: This study is limited by the sample size.
Ethics committee approval: Ethics committee approved the study and written informed consent was delivered to the participants.
Funding: No funding was received for this work.

Ultrasound measures of abdominal aortic caliber and quadriceps femoris muscle thickness: influence of physical activity and body mass index
H. S. Ponte[1], L. P. V. Ribeiro[2], S. Rodrigues[1], A. F. Abrantes[1], A. D. M. Ribeiro[3], R. P. P. Almeida[1], M. V. C. Reis[1], T. C. P. L. Guerreiro[4]; *[1]Faro/PT, [2]Parchal/PT, [3]Portimão/PT, [4]Santiago Do Cacém/PT (henrique_s_ponte@hotmail.com)*

Purpose: To evaluate the influence of physical activity level, body mass index (BMI) and gender on the ultrasound measurement of abdominal aortic caliber and quadriceps femoris muscle thickness.
Methods and materials: The International Physical Activity Questionnaire (IPAQ) was applied to 52 healthy volunteers to evaluate the health-related physical activity (PA) and BMI values were determined through a body composition analysis scale. Measurements of quadriceps femoris muscle thickness and abdominal aortic caliber were performed from B-mode ultrasound images, acquired twice by two independent radiographers. The thickness of the rectus femoris and vastus intermedius (RFVIMT), vastus medialis (VMMT) and vastus lateralis (VLMT) were measured. Standardised images of the aorta were recorded at three different levels: below the level of the origin of the splenic artery (AAC-SA), below the level of the origin of the renal arteries (AAC-RA) and 1-3 cm above the bifurcation (AAC-B).
Results: IPAQ showed that 21.2% of participants had a low PA level, 25.0% had a moderate PA level and 53.8% had a high PA level. Regarding BMI, 7.7% of the volunteers were classified as underweight, 63.5% as normal, 21.2% as overweight and 7.7% as obese. Significant positive correlations were observed between BMI and ACC-RA (r = 0.298, P= 0.032), BMI and RFVMIT (r = 0.638, P= 0.000), BMI and VLMT (r = 0.442, P= 0.001). Significant negative relationships were observed between gender and AAC-B (r = - 0.424, P= 0.002) and between gender and VMMT (r = - 0.536, P= 0.000).
Conclusion: A healthy lifestyle with proper physical activity levels is essential for the prevention of major cardiovascular diseases, obesity, muscular weakness, among others. However, further studies in this field are required.
Limitations: This study was limited by the sample size.
Ethics committee approval: Ethics committee approved the study.

Radiographers in cath-lab: new operating procedures to improve quality assurance and patient safety

F. Aragona[1], E. Stefani[2], M. Coccato[2], M. Centenaro[1], S. Cuman[3]; [1]*Treviso/IT,* [2]*Conegliano/IT,* [3]*Varese/IT*

Purpose: To analyse logistics arrangements in a modern cath-lab and to develop operating procedures for radiographers to improve teamwork and dose reduction during coronary angiography and angioplasty. To underline how multi-professional approach and competence enhancement affect quality during cardiac interventional procedures.
Methods and materials: Data produced are from international guidelines and from the literature review. Human and technological resources have been analysed. Cath-lab of the study has been compared to three major labs of regional heart disease-hub hospitals. Phantom based quality assurance measurements have been taken before the implementation of new operating producedures. A squared radiation field has been used to test dose amount with a normal and a low dose protocol.
Results: Operating procedures have been developed in order to define professional roles and responsibilities. Teamwork improved quality of services by sharing the procedures created. Dose reduction is expected to be significant with correct application of protocols and resultant time decrease. According to physical measurements, the use of low-dose protocol does not affect image quality.
Conclusion: Consciousness and cooperation between professionals are essential in a cath-lab. It allows a better interventional activities organisation, timing optimisation and risk management. The use of the low-dose protocol is recommended during angiography and angioplasty.

The environment preventing female radiological technologists from improving their career prospects: filling the duration of their pregnancy and child-rearing

T. Nakamura[1], S. Suzuki[2], K. Kato[3], S. Kamiya[4], S. Asegawa[1]; [1]*Shizuoka/JP,* [2]*Toyoake/JP,* [3]*Kanagawa/JP,* [4]*Nagoya/JP*

Purpose: There is a wide variety of diagnostic equipment for breast cancer and is becoming more technologically advance as years go by. A lot of female radiological technologists are worried about returning to work after taking maternity leave or childcare leave, some might be worried about being rusty with their skills and knowledge when returning to work, so we wanted to conduct this study to be able to help them with their reinstatement at work. The study aims to determine the necessary environment in order to balance work and child-rearing of female radiological technologists.
Methods and materials: Questionnaire surveys and interviews were conducted for technologists who can't participate in study sessions due to various problems including parenting, and examine the responses and what's the necessary environment in order to balance work and child-bearing.
Results: The results showed that regular study meetings should be done, where they can learn with children in the community, can freely participate, and can allow them to deepen the connection and share their concerns between technologists participating in the study group, and this kind of study will help support female radiological technologists who would like to continue working while reducing anxiety on return after childcare leave.
Conclusion: This type of study that can participate with children can hope to raise the level of child bearing generations of technicians and furthermore continue education during the childcare period that had previously hindered female career progress.
Limitations: This study conducted a survey of specific people and organisations.
Ethics committee approval: Obtained approval from our ethics committee (ECD2018-002).
Funding: No funding was received for this work.

Development of radiographer scheduling system considering skills and training: a case study

K. Hidaka, T. Miyamoto*; Suita/JP (hidaka@hp-rad.med.osaka-u.ac.jp)*

Purpose: Radiographers are limited human resources. From the long-term perspective of hospital administration, staff training is also an important issue. Allocating appropriate shifts is difficult for radiographers who manage the scheduling. Our objective is to construct an integer programming model of radiographer scheduling that considers the skills and training of radiographers to compare the results of computational experiments using real data.
Methods and materials: A mathematical optimisation model was constructed with the scheduling of radiographers as an integer programming problem. More than one staff member is allocated each day by modality, room, and time zone as a shift. Radiographer skills were set at three skills: self, trainer, and responsible skill. We included 32 restrictions, such as off-duty and the upper limit of the number of night shifts. Shifts were scheduled by minimising each radiographer's workload. We compared the workload of radiographers between shifts using actual data collected over two months in 2018 and the radiographer scheduling model to derive shifts. Analysis conditions were as follows: the number of staff 59, shifts 2379, trainee staff 2, modalities 15, rooms 57, days 38, the workload of daytime shift 1, swing shifts 3, and graveyard shifts 5.
Results: All staff were allocated shifts and off-duty without constraint violation. By optimising scheduling, the staff workload was equalised. The workload of each staff member could be reduced as compared to scheduling performed by the shift creator (average workload of optimisation model 36.8, real data 37.0), and the load of the shift creator could be reduced (calculation time was short, i.e. <30s).
Conclusion: It was useful for radiographer scheduling management to allocate shifts by optimising the workload.
Limitations: n/a
Ethics committee approval: n/a

A radiographers' preceptorship: educational needs in the United Arab Emirates

M. M. Abuzaid[1], W. Elshami[1], S. Hamid[2], M. A. Musallam[1]; [1]*Sharjah/AE,* [2]*Waterford/IE (mabdelfatah@sharjah.ac.ae)*

Purpose: Acting as preceptors, radiographers play an integral role in the preparation of the next generations. Therefore, hearing and responding to their stories is essential to the quality of the radiology education programme. The study investigates the educational needs of radiographer's preceptors and factors affecting their preceptorship role.
Methods and materials: A cross-sectional study among hospitals in the UAE who received students for radiography training. A survey covered demographics, education, practice, training, needs assessment scale, course content, and a teaching methods assessment scale.
Results: One-hundred twelve out of one hundred thirty invited radiographers from hospitals across the UAE responded. The preceptorship is un-paid services. 32.4% were nationals, 67.6% ex-pats, 48.6% males, 51.4% females, 63% baccalaureate (43%) diploma and (6%) master degree. 21% indicated that they did not receive dedicated preceptor training. The maximum training duration provided by local universities ranged from one to two days per academic years. The training concentrated on practice roles, regulation, and communications skills and students evaluation. 85% believed that a proper preceptor-training programme would improve preceptorship skills and students outcome. 62% were able to identify the barriers to preceptor training.
Conclusion: Standard and dedicated training programmes are required to enhance the quality of preceptorship and students practical experience. Precept knowledge and teaching skills can support education strategies for new radiographers generation.
Limitations: Surveying of department managers on their perceptions towards the preceptor-training programme.

The impact of talking to "experts by experience" on students' empathy scores

G. Harrison, A. Harris*; London/UK (gillhaha@gmail.com)*

Purpose: This study aims to assess medical ultrasound students' empathy scores in response to interaction with 'experts by experience'.
Methods and materials: Students completed the Toronto Empathy Questionnaire[5] before and after an interactive teaching and learning session with four 'patients'. Students completed a short questionnaire and were asked to reflect on what they had learnt and how it might impact their future practice. 23 students (48%) participated in the study at a single institution across two cohorts. A further cohort will be recruited.
Results: Twenty empathy scores were valid. Females had higher mean empathy scores initially and after the session, however males had a higher overall increase in mean empathy score after the interactions. Empathy scores increased or stayed the same for 75% of students. The event met or exceeded students' expectations.
Conclusion: Mean empathy levels were higher than published norms and increased or remained the same for three quarters of students after the session. Empathy can lead to improved trust between health care provider and patient, compliance with instructions and treatment, patient satisfaction and outcomes, so it is important to ensure ways to increase empathy and compassion are incorporated into the curriculum. Students highlighted various ways to change practice in light of this session, which would impact on patient care and communication.
Limitations: Students were self-selecting, which may impact on the results.
Ethics committee approval: Ethics approval was granted from the School of Health Sciences, City, University of London.
Funding: No funding was received for this work.

Using a standardised patient to authentically replicate the clinical experience during a trauma simulation for third-year radiological technology students in a Canadian undergraduate programme

S. Lea, R. Macleod*; Halifax, NS/CA (stephanie.lea@dal.ca)*

Purpose: Third-year radiological technology students at Dalhousie University must demonstrate the required knowledge, skills, and competence to safely, accurately, and efficiently perform complex radiographic examinations on a trauma patient. Student competency is assessed by a simulation; this simulation was not previously designed following established standards of best practice and lacked authenticity. Adding a standardised patient to simulation has been reported to improve authenticity in nursing and medical literature, but this has not been investigated in a radiography programme.
Methods and materials: Fourteen third-year radiological technology students completed a timed (30 minute) trauma simulation; this was the first time a standardised patient has been used as part of a simulation. Using open-ended interview questions students were individually interviewed and they described their experience participating in a trauma simulation that used a standardised patient. The transcripts were compiled and coded; phenomenological thematic analysis was used and resultant themes were verified with participants.
Results: Students enjoyed having a standardised patient as part of the simulation and stated that it made the experience realistic and authentic. Students found that they needed to employ their patient care and communication skills much more than in previous simulation experiences.
Conclusion: Standardised patients add authenticity to the radiological technology trauma simulation and students' patient care and communication skills can be more accurately assessed. This model of simulation will continue to be part of the Dalhousie radiological technology programme.
Limitations: The authors acknowledge they are both the designers of the simulation and educators of the students participating in the simulation; participation in the study was completely voluntary. As this is a qualitative study the results cannot be generalisable.
Ethics committee approval: The study went through REB and a written consent form was completed.
Funding: No funding was received for this work.

Shear-wave elastography-guided core-needle biopsy for the determination of breast cancer molecular subtypes

A. Peker, P. Balci, I. Başara Akin, H. A. Özgül, S. O. Aksoy, D. Gurel*; Izmir/TR (doktorpeker@gmail.com)*

Purpose: To investigate the role of shear-wave elastography-guided (SWE) core-needle biopsy for the accurate determination of breast cancer immunohistochemical subtypes.
Methods and materials: This study was conducted between May 2018 and April 2019 and included adult patients who had a lesion larger than 1 cm and were referred for a core-needle biopsy. Patients were divided into two groups by block randomisation. B-Mode ultrasonography-guided biopsy (control group, group 1) and SWE-guided biopsy (group 2) were performed in a total of 60 lesions. The biopsy in the control group was recorded as biopsy A, the SWE-guided biopsy from the relatively rigid area of the lesion was recorded as biopsy B, and the biopsy from the relatively less rigid area of the lesion was recorded as biopsy C. Diagnosis and immunohistochemical results were recorded and compared with the surgical results.
Results: The mean lesion sizes were 33.2 ± 22.6 mm in group 1 and 27.8 ± 11.9 mm in group 2. Sensitivity was 96.7% in biopsy A and 100% in biopsy B and C. Benign-malignant accuracy was 94.7%, 100%, and 90%, and diagnostic accuracy was 89.5%, 100%, and 90% in biopsy A, B, and C, respectively. When immunohistochemical markers were evaluated in one patient (14.3%) at biopsy A, Her2 receptor status was wrong. When the 10% difference in ER, PR, and Ki67 rates were considered significant, the accuracy of ER was highest in biopsy B as 77.8% (p = 0.04). Accuracy in immunohistochemical subtyping was 100% in biopsy B, and 71.4% in biopsy A and C (p = 0.08).
Conclusion: SWE-guided core-needle biopsy of breast lesions increased sensitivity, diagnostic accuracy, and accuracy in immunohistochemical subtyping to 100%.
Limitations: See attached file.
Ethics committee approval: Approved by the institutional ethics committee.

Ultrasound-guided tattooing of axillary lymph nodes in patients prior to neoadjuvant therapy and the identification of tattooed nodes at the time of surgery

N. Rotbart[1], T. Allweis[2], T. Menes[3], Y. Rapson[4], H. Cernik[2], I. Bokov[2], O. Golan[3], O. Givon Madhala[1], A. Grubstein[1]*; [1]Petah Tikva/IL, [2]Rehovot/IL, [3]Tel Aviv/IL (noarotbart@yahoo.com)*

Purpose: Breast cancer patients with lymph node metastases at diagnosis often undergo neoadjuvant therapy. Identification of a LN which regressed after NAC remains a challenge. A new concept of targeted axillary lymph node dissection has recently been proposed which involves the removal of a node with documented metastases in addition to the removal of the nodes most likely to harbour disease.
The aim of the study was to evaluate the possibility of tattooing biopsied nodes prior to NAT and identifying them at the time of surgery.
Methods and materials: Carbon suspension was injected into axillary LNs before starting NAC. During surgery, an attempt was made to identify the tattooed LN, which was removed and sent for pathological evaluation. All patients underwent a sentinel lymph node biopsy and/or axillary lymph node dissection as mandated by their clinical status.
Results: 63 patients underwent tattooing of involved axillary lymph nodes. At surgery, a tattooed node was identified in 60 patients (95.2%). Of 50 patients in whom both radioactivity and tattoo were identified in axillary LNs, 40 (80%) lymph nodes were radioactive and tattooed, however in 10 patients (20%) the tattooed LN was not radioactive.
Conclusion: Ultrasound-guided tattooing of involved axillary lymph nodes prior to neoadjuvant therapy is a safe, effective, and easily performed method of marking these nodes for future identification at the time of surgery. We found the tattooing was helpful in identifying the marked LN in the majority of cases. In our study, the identification rates of tatooed nodes was about 95.2%.
Limitations: The main limitation was the small number of patients.
Ethics committee approval: The study protocol was approved by our institutional review board and patients signed informed consent prior to injection.
Funding: No funding was received for this work.

Stereotactic 9-gauge vacuum-assisted breast biopsy: how many specimens do we need?

B. M. Den Dekker, P. J. van Diest, S. de Waard, H. Verkooijen, R. M. Pijnappel*; Utrecht/NL (bm.den.dekker@hotmail.com)*

Purpose: To determine the minimum number of stereotactic 9-gauge vacuum-assisted breast biopsy (VABB) specimens required to establish a final histopathological biopsy diagnosis of mammographically suspicious lesions.
Methods and materials: A total of 120 women referred for VABB of 129 mammographically suspicious lesions were included (December 2017-October 2018). Stereotactic 9-gauge VABB was performed, acquiring twelve specimens per lesion. Calcification retrieval was assessed with individual specimen radiography. Each specimen was histologically analysed in chronological order and findings were compared with the final histopathological result after assessment of all 12 specimens and with results of surgical excision. Cumulative diagnostic yield per specimen was calculated.
Results: In total, 131 VABB procedures were performed in 120 women (mean age 59y). In 95% (95%CI 90%-98%) of the procedures, a final histopathological biopsy diagnosis was reached after 6 specimens. After 9 specimens, the final diagnosis was established in all 131 cases. In the 41 patients with a DCIS or invasive diagnosis at biopsy, there were 8 procedures (20%) where calcifications were retrieved before the diagnostic specimen was obtained. Underestimation of subsequent resection diagnosis occurred in 6 out of 30 excised lesions classified as DCIS(20%) and in 1 out of 4 excised high-risk lesions.
Conclusion: With 6 stereotactic 9-gauge VABB specimens, a final histopathological biopsy diagnosis could be established in 95% (95%CI 90%-98%) of the procedures. Taking 9 specimens seems to be optimal. Ending the stereotactic VABB procedure as soon as calcifications are retrieved may cause false-negative results.
Limitations: Study-pathologist was not blinded to study design and clinical histopathological result. Fixed biopsy protocol was used, irrespective of lesion size and location relative to the needle.
Ethics committee approval: Approval from the IRB of the UMCU and written informed consent from study participants was obtained.
Funding: Funding was received from Hologic.

Failure of stereotactic core-needle biopsy in women recalled for suspicious microcalcifications at screening mammography: frequency, causes, and final outcome in an observational follow-up study

J. L. R. Lameijer[1], L. Duijm[2]*; [1]Eindhoven/NL, [2]Nijmegen/NL (joostlameijer@gmail.com)*

Purpose: To determine the failure rate of stereotactic core-needle biopsy (SCNB) and its causes and final outcome in women recalled for microcalcifications at screening mammography.
Methods and materials: We included a series of 466,647 screens obtained in a Dutch screening region between January 2009 and January 2017. Radiology

reports and pathology results were obtained of all recalls during two-year follow-up.
Results: A total of 2,815 women (19.9% of 14,142 recalls) were recalled for suspicious microcalcifications. SCNB was indicated in 2,220 women, of which 10 refused a biopsy. Breast cancer (DCIS or invasive cancer) was diagnosed in 671 of 2,210 women (30.4%). SCNB was technically not feasible in 36 women (1.6%, 36/2,210), of which ten underwent surgical biopsy (5/10 positive). Pathology showed no calcifications and no malignancy in the SCNB specimen in 30 women after SCNB (1.5%, 30/1,974), of which 5 proved to have breast cancer at subsequent surgery. The remaining 25 women, without a diagnosis of breast cancer two years after the recall, underwent follow-up imaging (n=14), surgical excision with the benign outcome (n=4), or were asked to re-attend the screening programme without follow-up (n=7). Breast cancer was diagnosed in 15% of women (10/66) who experienced either SCNB cancellation due to technical limitations, or whose SCNB yielded no malignancy in the absence of calcifications in the specimen.
Conclusion: Although the failure rate of SCNB is very low, a close surveillance with a low threshold for surgical biopsy is warranted as we found that breast cancer was present in 15% of these women.
Limitations: Due to differences in programmes, our data may not be extrapolated to other screening programmes.
Ethics committee approval: Ethical approval was waived.
Funding: No funding was received for this work.

RPS 1302-5 08:54
Conventional imaging occult DCIS diagnosed on MRI-guided biopsy: can we predict upgrade on surgical pathology?
Y. Amitai[1], T. Menes[2], A. M. Scaranelo[1], S. Kulkarni[1], S. Ghai[1], R. Fleming[1], V. Freitas[1]; [1]*Toronto, ON/CA,* [2]*Tel Aviv/IL (yoavslava@yahoo.com)*

Purpose: To identify clinical and imaging features of upgrade for invasive disease in patients with conventional imaging occult ductal carcinoma in situ (DCIS) diagnosed on MRI-guided biopsy.
Methods and materials: Results of consecutive patients with MRI-detected pure DCIS, occult on conventional imaging (CI) including mammography and ultrasound performed in a tertiary academic hospital in 2009-2018, were reviewed. Women were divided into 2 groups based on the gold standard final pathology: Pure DCIS or DCIS with an invasive component. Final surgical pathology was used to validate MRI results.
Results: 50 patients fulfilled the inclusion criteria and formed the study cohort. 46 patients (92%) had non-mass enhancement (NME) yielding pure DCIS diagnosis compared to 4 enhancing masses. The most common NME distribution was focal (22, 48%). The most common kinetic pattern was persistent (24, 48%). Overall, 12 patients (24%) were upgraded to invasive malignancy on final pathology. The only parameter showing statistically significant association with upgrade was kinetic characteristics; 10 (40%) of the women with plateau or washout kinetics, versus 2 (8%) of the women with progressive kinetics were upgraded to invasive cancer on surgery (P=0.034). On multivariate analysis, progressive kinetics remained inversely associated with upgrade when compared to washout kinetics (OR=0.012; P<0.021; 95% CI 0.02;0.73).
Conclusion: The washout kinetic pattern of enhancement proves to be the best predictor of invasion in conventional imaging occult DCIS diagnosed on MRI-guided biopsy. It may have implications for treatment planning as sentinel lymph node biopsy may be considered in the primary surgical procedure for this subset of patients. Larger studies should be encouraged to consolidate our findings.
Limitations: Retrospective design. High level of interobserver variability in DCIS. No diffusion calculations.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Tomosynthesis-guided vacuum-assisted biopsy for mammographic low-contrast, non-calcific lesions: technical and pathologic results
C. Faggioli[1], K. Jerman[2], A. Linda[2], R. Girometti[2], C. Zuiani[2]; [1]*Gorizia/IT,* [2]*Udine/IT*

Purpose: To evaluate technical and pathologic outcomes of tomosynthesis-guided vacuum-assisted biopsy (DBT-VAB) performed on low-contrast, non-calcific lesions (LC-NCL) found at mammography.
Methods and materials: Of women referred to DBT-VAB in our institution between January 2017 and March 2018, we retrospectively included 152 patients with 154 sonographically occult LC-NCL. Two radiologists with 15 and 2 years of experience in breast imaging worked in consensus to review mammographic examinations, radiology reports, and pathology reports to record patients' and lesions' features, the rate and reasons for technical failure, as well as pathologic and follow-up results (up to 12 months).
Results: DBT-VAB was unfeasible in 14/154 LC-NCL (9%) presenting as architectural distortions (11/14), asymmetry (2/14), and opacity (1/14). Reasons were lack of target visualisation and deep location in 13/14 and 1/14 cases, respectively. None of the patients developed malignancy at imaging follow-up. DBT-VAB was performed in the remaining 140/154 (91%) LC-NCL, including 66/140 (47%) architectural distortions, 46/140 (33%) opacities, 19/140 (14%) asymmetries, and 9/140 (6%) mixed lesions. Complications occurred in 11/138 (8%) patients, including 9 haematomas, 1 vasovagal reaction, and 1 subcutaneous emphysema. Biopsy found 25/140 (18%) malignant lesions (B5), 36/140 (26%) high-risk lesions (B3), 76/140 (54%) benign lesions (B2), and (2%) normal tissue in 3/140 cases (B1). After surgical excision, 7/36 high-risk lesions were upgraded to malignancy (2 invasive and 5 DCIS), corresponding to an underestimation rate of 19%. Additionally, surgical excision and/or follow-up demonstrated malignancy in 2/9 cases of imaging-pathology discordant B2 lesions. No malignancy was found at surgical excision of B1 lesions. Overall, the malignancy rate was 24%.
Conclusion: DBT-VAB was feasible in the majority of LC-NCL, with a few complications. About one-fourth of LC-NCL was malignant, supporting the need for biopsying those mammography findings.
Limitations: Monocentric and retrospective design.
Ethics committee approval: Informed consent waived because of the retrospective design.
Funding: No funding was received for this work.

Value of targeted fusion US with virtual mammographic navigation in B3 lesions
V. E. Gazhonova, M. Efremova, E. Bachurina, T. Kuleshova, H. Khlustina; *Moscow/RU (vx969@yandex.ru)*

Purpose: To evaluate the role of second-look targeted fusion MMG/US navigation in BI-RADS 3 lesions in comparance to standard HHUS.
Methods and materials: 45 women with 50 B3 lesions on mammography followed by ultrasound were studied by two experts for breast US (GV18y.exp; PI25 y.exp) blinded to each other results. The first radiologist performed standard HHUS and the second fusion ultrasound with virtual mammographic navigation. Fusion US and conventional HHUS were performed on My LAB Twice (ESAOTE) with a linear transducer BL433 (3-18MHz). 25 B3 lesions were biopsied under US and 10 with stereotactic MMG, 15 follow up for 2 years. The ROC-curves were compared for both methods.
Results: B3 lesions were upgraded to B5 by HHUS in 14 pts, and in 20 by fusion US, with cancer proven in 18 pts. B3 lesions were downgraded to B2 in 20 by HHUS, and in 25 by fusion US, none of them appearing to have cancer. ROC-curve analysis showed that fusion was superior to HHUS with AUC 0,889 (95%CI 0,768 to 0,960), and 0,794 (95%CI 0,656 to 0,895), respectively. Fusion US were superior to HHUS in the cases of grouped microcalcifications and subtle less than 4 mm B3 lesions. Agreement in BIRADS category between the examiners was 0,82.
Conclusion: Fusion US with virtual mammographic navigation may help in identify microcalcification and subtle less than 4 mm B3 lesions, thus increasing the diagnostic performance of targeted US.
Limitations: Limitations of the study were consecuted patients with B3 lesions and a small group of cancer patients.
Ethics committee approval: Written consent was received from all patients. The examination was approved by the Institutional Ethical Committee.
Funding: No funding was received for this work.

Calcified lesions with a low risk of malignancy on mammography and uncertain malignant potential (B3) detected at stereotactic vacuum-assisted breast biopsy

Z. C. Milosevich, V. Urban, K. Obradovic, N. Adzic, M. Nadrljanski; *Belgrade/RS*

Purpose: To analyse the management and outcome of calcified lesions with a low risk of malignancy on mammography (BI-RADS category 4a) and uncertain malignant potential (B3) detected at stereotactic vacuum-assisted breast biopsy (SVAB).
Methods and materials: Retrospective analysis of 91 consecutive SVAB procedures was performed. Inclusion criteria were BI-RADS category 4a calcified lesions on screening mammography and histologic diagnosis of B3 lesions. The three groups of patients were defined, based on the post-biopsy multidisciplinary team decisions, as 1) with a definite histology after surgical excision, 2) with breast dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) after SVAB, prior to surgical excision, and 3) the group that is followed by annual physical assessment and mammography. Malignancy rates were evaluated for each group.
Results: The first group consisted of 13 patients (14.3%), the second of 20 (22.0%), and the third of 58 (63.7%). Atypical ductal hyperplasia lesions (isolated or associated with other B3 lesions) were found in 45.0% patients, papillary lesions in 31.9%, lobular intraepithelial neoplasia in 15.4%, flat epithelial atypia in 6.6%, and radial scar in 1.1%, with no significant difference of B3 lesions histologic types between the three groups (p=0.09). An upgrade to malignancy in the first group was 38.5% (5 patients) and in the second, 20.0% (4 patients). Taking into account the absence or presence of angiogenesis on DCE-MRI, a negative predictive value of DCE-MRI was 92%. In the third group, 1-year to 6-year follow-up was negative for breast malignancy.
Conclusion: The rates of upgrade to malignancy in our study were high, up to 38.5%. The post-biopsy DCE-MRI may be an useful tool for further management of B3 lesions.
Limitations: Retrospective analysis study.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Comparison of calcification retrieval performance between upright tomosynthesis-guided and prone stereotactic vacuum-assisted breast biopsy

T. Uematsu; *Shizuoka/JP (t.uematsu@scchr.jp)*

Purpose: To compare the calcification retrieval performance of upright tomosynthesis-guided vacuum-assisted breast biopsy (Tomo VAB) with that of prone stereotactic vacuum-assisted breast biopsy (ST VAB).
Methods and materials: A retrospective review of records revealed 176 calcification lesions not detected by ultrasound in 176 women who underwent Tomo VAB or ST VAB. A mean of 6 specimens per lesion were obtained using 9-gauge or 11-gauge needle. Calcification retrieval success was defined as identification of calcifications on specimen radiographs. Procedure time, estimated exposure dose, and complications were also evaluated.
Results: During the study period, 88 ST VAB in 88 patients and 88 Tomo VAB in 88 patients were performed. Each calcification retrieval success rate was the same (99% vs 99%). No complications were observed in either group. Mean procedure time was shorter with Tomo VAB vs ST VAB (16 vs 26 min, respectively; p<.001), and fewer estimated exposure doses were acquired with Tomo VAB vs ST VAB (4.35mGy vs 9.6mGy, respectively; p<.001) as during Tomo VAB, only 3 reference tomosynthesis images were generally obtained, while 8 reference 2D images were generally obtained during ST VAB.
Conclusion: Tomo VAB has the same degree of clinical performance for diagnosing calcifications as ST VAB and can be performed in less than two thirds of the ST VAB procedure time and with about half of the exposures in ST VAB.
Limitations: This study had some limitations, mainly resulting from its retrospective single-institution nature and small patient numbers. Another limitation is that our comparison groups were not randomised but were rather divided by time.
Ethics committee approval: This retrospective study was approved by our institutional review board and the requirement to obtain informed consent was waived.
Funding: No funding was received for this work.

The value of contrast-enhanced ultrasound in breast cancer biopsy

Y. Zhu, Y. Chen, J. Jiang; *Shanghai/CN (tttmax2004@126.com)*

Purpose: To investigate the value of contrast-enhanced ultrasound (CEUS) in breast cancer biopsy.
Methods and materials: A total of 49 consecutive patients with biopsy-confirmed breast cancer were enrolled in this retrospective cohort study. All patients underwent CEUS to evaluate the homogeneity of perfusion of breast lesions. For lesions showed homogeneous enhancement on CEUS, the centre part and peripheral part were biopsied respectively. For heterogeneously enhanced lesions, the biopsies were thus performed targeting both the enhanced regions and non-enhanced regions. The sample adequacy rate and core cancer involvement of the biopsy cores taken from the enhanced regions were compared with those from the non-enhanced regions.
Results: A total of 53 breast cancer lesions were biopsy-confirmed in 49 patients. CEUS revealed homogeneous enhancement in 8 of 53 breast cancers (15.1%) and heterogeneous enhancement in 45 of 53 breast cancers (84.9%). The sampling adequacy rate was 98.5% for biopsy cores taken from the enhanced regions, significantly higher than those from the non-enhanced regions (72.9%, P<0.01). The core cancer involvement was higher in enhanced regions than non-enhanced regions (median: 55% vs 30%, P<0.01).
Conclusion: CEUS can differentiate the active area and necrotic fibrosis area of breast tumours by displaying the microvessels and might be the possible solution to the problem of biopsy site selection.
Limitations: This study might be limited by its retrospective study design and that all the patients were enrolled with biopsy-proven breast cancer.
Ethics committee approval: This retrospectively designed, single-institution study was approved by the local institutional review board (XHEC-D-2019-015).
Funding: No funding was received for this work.

Vacuum-assisted excision (VAE) as an alternative to open surgical excision for B3 lesions in a screening clinical unit

I. Allajbeu, K. Taylor, P. L. Moyle, C. Breast Unit, F. J. Gilbert; *Cambridge/UK (ia359@cam.ac.uk)*

Purpose: To investigate the usage of VAE techniques as an alternative approach to open excision diagnostic procedure for B3 lesions in clinical practice.
Methods and materials: Retrospective data collection was via K62, National Health Service Breast Screening Programme (NHSBSP) database, to identify all patients diagnosed with B3 lesions on biopsy between April 2015-March 2019. Audit standard was NHSBSP No.49 guidelines on B3 lesions. Mammographic findings, biopsy type, management, and final pathology results were recorded for each patient. Upgrade/downgrade rates were calculated for each subtype and compared with the previous years.
Results: 105 patients had B3 histopathology on core biopsy (CB), 14 G or vacuum-assisted biopsy (VAB) 9G. From these, 72 patients had VAE, either stereotactic or under ultrasound, and 20 surgical excision as second line, decided by MDT. 70 of the B3 lesions stayed the same/were downgraded to B2 in their final histopathology. 2 of the B3 lesions were upgraded to B5a (high grade DCIS) by VAE as second line. There was a progressive increase in second-line VAE from 58% in 2015 and to 80% in 2019. The unit was 94% concordant with the standard in terms of performed investigation for each lesion subtype.
Conclusion: The data shows our VAE policy saves patients having unnecessary operations for benign disease.Therefore, VAE should always be considered as an alternative pathway to the open surgical excision for the majority of B3 lesions in concordance with the official guidelines. This would potentially reduce the benign open biopsy rate whilst maintaining accuracy of cancer diagnosis. Management of all B3 lesions should be discussed in the MDT meetings.
Limitations: Single-centre study with a limited number of patients and data.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Ultrasound-guided core-needle biopsy of the axillary lymph nodes in different subtypes of newly diagnosed breast carcinoma
M. Jafari, M. Gity, A. Olfatbakhsh, K. Rezaei Kalantari; *Tehran/IR (maryjafarimd@gmail.com)*

Purpose: To assess the diagnostic accuracy of US-guided core needle biopsy (CNB) in the detection of axillary LN metastasis in different subtypes of breast cancer.
Methods and materials: From May 2018 through May 2019, in a prospective study of 1153, 153 cases with biopsy-proven breast cancer showed suspicious axillary LNs in ultrasound. They underwent axillary sampling and then pathologic correlation. 65 patients met the inclusion criteria.
Results: Axillary US-guided CNB correctly identified 55 (84.5%) of the 65 involved LNs. The sensitivity, specificity, positive/negative predictive values, and positive/negative likely hood ratio (LR) of CNB were 75.5 %, 93.7%, 92.5%, 78.9%, 12.2, and 0.25 respectively (p value< 0.001). Interestingly, we found that in hormone-positive tumours, the sensitivity and PPV of axillary CNB were higher, 80.9% and 94.4% respectively (p<0.001). In Her-2 negative cancers, the sensitivity of CNB was more, with no statistically significant difference.
Conclusion: CNB is a fast, simple and minimally invasive technique with a high LR (+) in ruling in and good LR (-) in ruling out the axillary metastasis. Because of the reliability of CNB in preoperative diagnosis of LN metastasis, we could suggest avoiding sentinel LN surgery in post-CNB negative cases similar to post-CNB positive cases. Biological markers seem to affect the CNB pathologic results; this emphasis should be investigated in the studies with larger sample size.
Limitations: The limitations of CNB are including mistargeting of the LN, the discordance of postoperative pathology and biopsy in micrometastasis, the failure of biopsy of deeply located/small-sized LN, trauma to the adjuscent tissue, and pain.
Ethics committee approval: This study achieved ethical approval from the Institutional Board of Motamed cancer institute (ACECR) with approval number of 9610101.
Funding: No funding was received for this research.

Breast biopsy performed the same day as diagnostic imaging: does it impact patient care?
K. Coffey, E. Cheang, V. Mango, E. A. Morris, D. D'alessio; *New York, NY/US (coffeyk@mskcc.org)*

Purpose: To determine the time to surgery for patients undergoing diagnostic breast imaging and breast biopsy on the same day compared to patients with imaging and biopsy on separate days.
Methods and materials: Retrospective case-control study reviewing 300 patients from 1/1/2009 to 1/1/2017 was performed. Review included 150 patients with diagnostic breast imaging and breast biopsy performed the same day compared to 150 patients with biopsy performed on days following imaging. Time interval from diagnostic imaging to biopsy, pathological diagnosis, surgical consultation, and surgery was determined.
Results: Same-day biopsies were more often performed in younger patients (55 vs 65 years) with a history of breast cancer (58.9% vs 30.0%), BRCA mutation (4.5% vs 0.8%), clinical symptoms (17.9% vs 10.0%), or a BI-RADS 5 lesion (2.7% vs 1.7%). No significant difference was observed in the time from biopsy to pathologic diagnosis (2.0 vs 1.7 days, p=.056) or from diagnosis to surgical consultation (11.5 vs 13.4 days, p=.43). The time between diagnostic imaging and surgical consultation was significantly shorter in the same-day group (13.3 vs 26.4 days, p<.001). The time from diagnostic imaging to surgery was shorter in the same-day group, however not statistically significant (37.8 vs 45.8 days, p=.16).
Conclusion: Same-day breast biopsies decreased the time from diagnostic imaging to surgical consultation (p<.001) in symptomatic and high-risk patients and may be valuable to patient care even without a statistically significant effect on time to surgery.
Limitations: Limitations include a small sample size.
Ethics committee approval: The United States Institutional Review Board approved this retrospective study with a waiver of informed consent.
Funding: No funding was received for this work.

Association of retrospective peer review and positive predictive value of magnetic resonance imaging-guided vacuum-assisted needle biopsies of breast
C. Yalniz[1], J. Rosenblat[2], D. Spak[1], W. Wei[1], M. Scoggins[1], H. C. Le-Petross[1], M. Dryden[1], B. E. Adrada[1], B. E. Dogan[3]; *[1]Houston, TX/US, [2]Los Angeles, CA/US, [3]Dallas, TX/US (mjdinok@yahoo.com)*

Purpose: To evaluate the association between retrospective peer review of breast magnetic resonance imaging-guided vacuum-assisted needle biopsies and positive predictive value of subsequent magnetic resonance imaging-guided biopsies.
Methods and materials: In January 2015, a weekly conference was initiated in our institution to evaluate all breast magnetic resonance imaging-guided vacuum-assisted needle biopsies performed over January 1, 2014-December 31, 2015. During these weekly conferences, 6 anonymised cases were discussed and the faculty voted on whether they agree with the biopsy indication, accurate sampling, and radiology-pathology correlation. We retrospectively compared the magnetic resonance imaging indication, benign or malignant pathology rates, lesion types, and the positive predictive value of magnetic resonance imaging-guided vacuum-assisted needle biopsy in the years before and after initiating this group peer review.
Results: The number of dynamic contrast-enhanced magnetic resonance imaging and magnetic resonance imaging-guided vacuum-assisted needle biopsies before and after initiating the review was 1447 vs 1596 (p=0.0002), and 253 (17.5%) vs 203 (12.7%) (p=0.04), respectively. The positive predictive value of magnetic resonance imaging-guided biopsy significantly increased after group review was implemented (positive predictive value in 2014=%39.1 and positive predictive value in 2015=%48.8) (p=0.03).
Conclusion: Our study showed an association between retrospective peer review of past biopsies and increased positive predictive value of magnetic resonance imaging-guided vacuum-assisted needle biopsies in our institution.
Limitations: A retrospective study performed in a single institution. The small number of patients included decreased the power of the statistical results. MRI-directed ultrasound and ultrasound guided biopsy rates are not included in this study.
Ethics committee approval: This was an institutional review board approved, HIPAA compliant, retrospective case review in which the requirement for patient informed consent was waived.
Funding: No funding was received for this work.

Blood oxygenation level-dependent MR imaging for the differentiation of prostate cancer with benign tissue: a preliminary experience
Y. Kim, C. Kim; *Seoul/KR (ytyson@naver.com)*

Purpose: To evaluate the feasibility of blood oxygenation level-dependent (BOLD) magnetic resonance imaging (MRI) in differentiating prostate cancer with benign tissue.
Methods and materials: 145 patients (mean age, 66.8 years) with biopsy-proven prostate cancer who underwent 3-T BOLD MRI at 3T were enrolled. BOLD MRI was performed using a multiple fast-field echo sequence to acquire 12 T2*-weighted images. The R2* value (rate of spin dephasing, 1/sec) was measured in the index tumour (n=145) and the benign peripheral (PZ, n=138) and transition zones (TZ, n=141), and the results were compared. The reproducibility of R2* measurements was evaluated.

Results: Tumour R2* values (26.1 ± 5.9) were significantly different from benign PZ (28.1 ± 9.8) and TZ (22.1 ± 4.0) (P < 0.001). For predicting the tumour, the area under the receiver operating characteristics curve of R2* was 0.606, with the optimal cutoff value of 22.8 (1/sec), resulting in a 73.8% sensitivity and 52% specificity. At the Altman-Bland test, the mean differences in R2* values were 4.9% for tumours, 9.5% for benign PZ, and 2.8% for benign TZ, respectively. There were no associations between tumour R2* and the Gleason score, age, prostate volume, PSA, or tumour size.
Conclusion: BOLD MRI at 3T appears to be a feasible technique for differentiating prostate cancer with benign tissue. However, a further study is required for direct clinical application.
Limitations: A retrospective study at a single institution. Potential errors of R2* measurements.
Ethics committee approval: Our institutional review board approved this retrospective study and the requirement for informed consent was waived.
Funding: No funding was received for this work.

Age-related and zonal anatomical changes in the microstructure of normal human prostatic tissues: a preliminary study with VERDICT MRI
X. Wang, F. Lin, Y. Lei, Y. Wang*; Shenzhen/CN (1263165281@qq.com)*

Purpose: To identify differences in the histological features of the prostate by age- and region-related changes in normal prostatic tissues by using VERDICT (vascular, extracellular, and restricted diffusion for cytometry in tumours) MRI.
Methods and materials: In total, 31 male volunteers were included in the study. The derived VERDICT parameters (the fIC, fEES, and vascular fraction fVASC) were analysed with a histogram. Based on the whole prostate volume and the PZ, CG, and AS ROIs, histogram parameters were computed. Two-way ANOVA and Pearson correlation coefficients were performed.
Results: There were significant differences between the histogram parameters and regions of the prostate (P < 0.05). In the PZ, there was a correlation between age and the mean, median, skewness, and entropy of the fIC (all P < 0.05). Age was significantly correlated with the statistics of the fEES (all P < 0.001). In the CG, age was found to have a significant positive correlation with the entropy of the fIC (P < 0.001). There was a significant positive correlation between age and the mean, median, and entropy of the fEES (all P < 0.001). Similar to the PZ (P < 0.001), age also showed a significant positive correlation with the entropy of the fVASC (P < 0.001), but no correlation with other parameters of the fVASC.
Conclusion: VERDICT MRI successfully reveals microstructural changes across anatomical zones and age groups in normal prostate glands.
Limitations: A relatively small sample size.
Ethics committee approval: This study was approved by the institutional human ethics board and all participants provided signed consent prior to entry into the study.
Funding: No funding was received for this work.

Utility of a quantitative ADC/DCE model in dynamic contrast enhancement (DCE)-positive, upgraded PI-RADS-3-to-4 lesions
A. A. Tavakoli[1], P. Badura[1], T. Tubtawee[1], V. Schütz[1], D. Tichy[1], A. Stenzinger[1], M. Hohenfellner[1], H.-P. Schlemmer[1], D. Bonekamp[2]; *[1]Heidelberg/DE, [2]Hirschberg/DE (S.tavakoli@gmx.de)*

Purpose: To study the value of a quantitative ADC/DCE regression model in predicting clinically significant prostate cancer (csPCa) in an analysis of DCE-positive upgraded PI-RADS-3-to-4 lesions.
Methods and materials: Clinical lesions reported in 3T MR exams with suspicion for csPCa were segmented on ADC maps and a visually identified early DCE time point. DCE was normalised to minimally enhancing parenchyma (DCEnorm). Logistic regression models included mean ADC and mean ADC/DCEnorm. The binary outcome was a Gleason grade group (GGG) >=2 and the maximum targeted GGG was used for patient-based analysis. In a subset of PI-RADS-3-to-4 upgrades, the model performance of the mean ADC was compared to the model performance of combined ADC/DCEnorm.
Results: Of 308 successful exams, 274 patients had 454 MR lesions that served as biopsy targets. 211 patients had a total of 275 MR lesions in the PZ. 34 patients received a PI-RADS-3-to-4 upgrade due to the radiologist's DCE assessment. Of these 34 patients, 9 had GGG ≥2 after biopsy, 2 had GGG=1, and 23 had no malignancy. Sensitivity/specificity of the mean ADC model was 56%/80%, whereas sensitivity/specificity of the model mean ADC model/DCEnorm was 100%/76%. 25 lesions were overcalled by the clinical assessment, whereas n=6 were false-positive for the combined ADC/DCEnorm model and n=5 for the ADC only model.
Conclusion: A quantitative regression model of a mean ADC/normalised DCE yielded reduced false-positive calls in comparison to clinical PI-RADS-3-to-4 calls without a loss of sensitivity. The ADC only model also reduced false-positive calls but missed 4 out of 9 csPCa.
Limitations: Our results quantify DCE utility for PI-RADS-3-to-4 upgraded lesions, however, do not provide guidance on increasing the detection rate of PI-RADS-3 calls.
Ethics committee approval: Ethics committee approval with written informed consent waived (S-156/2018).

Quantifying age-related differences in diffusion tensor imaging biomarkers for the male urethral sphincter complex of prospective prostate cancer patients
A. S. C. Verde, J. Santinha, A. Gaivao, N. Loucao, J. Fonseca, C. Matos, N. Papanikolaou*; Lisbon/PT (nickolas.papanikolaou@research.fchampalimaud.org)*

Purpose: Urinary incontinence is a major post-surgical complication that diminishes prostate cancer patients' quality of life. This study's purpose was to explore the feasibility of diffusion tensor imaging to access age and disease-related differences in the male urethral complex.
Methods and materials: 95 consecutive patients with a clinical suspicion of prostate cancer underwent a multi-parametric MRI examination including a diffusion tensor imaging (DTI) sequence with 16 directions and a b-value=600 s/mm^2. The proximal and distal sphincters and the membranous urethra were reconstructed using a deterministic tractography algorithm. DTI metrics, including tract length and density, fractional anisotropy (FA), axial diffusivity (AD), mean diffusivity (MD), radial diffusivity (RD), and 14 additional histogram metrics, were analysed. Pearson or Spearman correlations and linear regressions were performed between age and each DTI metric. Differences in DTI metrics between age and disease groups (healthy controls, benign prostatic hyperplasia, and prostate cancer patients) were accessed by analysis of variance (ANOVA) or the non-parametric Kruskal-Wallis test. Post-hoc t-tests were used to identify statistically significant differences between groups.
Results: Statistically significant changes with age were found in MD and RD distributions. Particularly, older subjects evidenced lower RD kurtosis in the proximal sphincter, lower MD maximum in the distal sphincter, and higher MD median absolute deviation in the membranous urethra. No statistically significant differences were found in DTI metrics between disease groups.
Conclusion: Age should be included as a covariate in the model that uses sphincters' DTI biomarkers to predict the post-surgical urinary continence recovery time.
Limitations: The minimum patients' age under study and the patients' heterogeneity within each disease group.
Ethics committee approval: The Champalimaud Foundation EC approved the DTI acquisitions, additional to the mpMRI.
Funding: No funding was received for this work.

Risk stratification of patients with prostate cancer: promising results with high b-value DWI radiomic features

M. Mottola[1], F. Ferroni[2], D. Barone[2], G. Gavelli[2], A. Bevilacqua[1]; [1]*Bologna/IT,* [2]*Meldola/IT (margherita.mottola@unibo.it)*

Purpose: To investigate the potential role of radiomic features computed on high b-value diffusion-weighted imaging (DWI) to perform risk stratification of patients with a clinical suspicion of prostate cancer (PCa).
Methods and materials: 42 patients of our institution, representing 7 risk levels, were retrospectively enrolled in the study and grouped into 4 classes of risk: (a) clinically significant (CS) PCa split over 4 levels (ISUP=2÷5), (b) non-clinically significant (NCS) PCa (ISUP=1) patients with a negative biopsy, and (c) positive mpMRI (NP) or (d) negative mpMRI (NN). After computing radiomic features on DWI b=2000s/mm^2, the correlation between radiomic features and risk level was investigated through two steps, (i) Spearman index (ρ) and (ii) Kruskal-Wallis and Wilcoxon tests ($p<0.05$), for multi- and pairwise- comparison of the 4 classes, respectively.
Results: The mean of the local coefficient of variation (CV_L-m), a measure of local dispersion of DWI values, resulted in the most discriminant radiomic features among the four classes ($p\sim10^{-6}$), able to rank the four increasing risk classes with ρ=0.81, with a high pairwise separability ($p\leq0.026$). ρ=0.81 was also achieved when correlating the CV_L-m with all 7 increasing risk level groups.
Conclusion: This study allows performing an early stratification of all 7 PCa risk levels. Increasing values of CV_L-m in DWI images describe a higher degree of local heterogeneity in accordance with tissue over-proliferation and, consequently, an increasing level of tumour aggressiveness.
Limitations: The number of patients could be low for a proper stratification of the cohort in 7 classes. However, the excellent results achieved when using CV_L-m values to correctly rank all risk levels give CV_L-m the most promising role in depicting PCa risk progression.
Ethics committee approval: IRB approval and written informed consent was waived.
Funding: No funding was received for this work.

Why a b-value of 1,400 s/mm2 or higher is optimal for evaluating prostatic index lesions on synthetic diffusion-weighted imaging

S. Y. Cha, S. Y. Park*; Seoul/KR*

Purpose: PI-RADS recommends the use of high-b-values of 1,400 s/mm2 or greater for diffusion-weighted imaging (DWI) interpretation. However, lesion signal intensity on DWI decreases as b-values increase. Thus, the fundamental reasons regarding optimal b-value range are still unclear. We qualitatively and quantitatively analysed the optimal b-value range for calculated DWI (cDWI) in the prostate.
Methods and materials: 92 patients who underwent DWI and targeted biopsy for index lesions were retrospectively included. We generated cDWI for a range of b-values, 1,000-3,000 s/mm2, using dedicated software and true DWI data of b-values of 0, 100, and 1,000 s/mm2. We assumed lesion conspicuity would be best when background (benign prostatic areas [bP] and periprostatic areas [pP]) signal intensities (SI) become homogeneous. We firstly analysed the b-value showing the best visual conspicuity (qualitative analysis) and then assessed the b-value showing same SI between bP and pP (quantitative analysis). The 95% confidence interval of a qualitative or quantitative b-value was considered as the optimal b-value range.
Results: Optimal b-value ranges for qualitative and quantitative analyses were 1,761-1,805 s/mm2 and 1,640-1,771 s/mm2 (med, 1,790 vs 1,705 s/mm2; p= 0.003) for reader 1, and 1,835-1,895 s/mm2 and 1,705-1,841 s/mm2 (med, 1,872 vs 1,763 s/mm2; p= 0.022) for reader 2, respectively. Bland-Altman plots consistently demonstrated the mean difference of less than 100 s/mm2 between qualitatively and quantitatively determined b-values for the two readers.
Conclusion: Calculated b-values showing homogeneous SI between bP and pP seem to be optimal for evaluating prostatic index lesions on cDWI. Our qualitative and quantitative findings consistently suggest the use of a b-value of 1,600-1,900 s/mm2.
Limitations: The data analyses were performed retrospectively. We evaluated patients of a single institution. Further prospective and external validation studies are required.

RPS 1307-7 09:06

Accelerated, high-resolution quantitative T2 mapping at 3T for the detection of prostate cancer

A. M. Bucher[1], A. Polk[1], R. Strecker[2], B. Kaltenbach[1], D. T. Hilbert[2], E. Weiland[2], T. J. Vogl[1], B. Bodelle[1]; [1]*Frankfurt am Main/DE,* [2]*Erlangen/DE*

Purpose: To test the reliability of the latest-generation, fast, high-resolution T2-mapping prototype sequence supporting parallel imaging and model-based reconstruction ($T2_M$) in the detection of malignant prostate lesions of the peripheral zone.
Methods and materials: We included 350 image series (T2-weighted-imaging, diffusion-weighted-imaging, T1-weighted pre-contrast-imaging, dynamic contrast-enhancement, and $T2_M$) from 50 multiparametric MRI datasets at 3 Tesla (MAGNETOM Prisma^{fit}, Siemens Healthcare, Erlangen, Germany), clinically indicated for suspected prostate cancer (pCA). The standard multiparametric prostate protocol was rated for the occurrence of prostate lesions. In 22 cases, there was biopsy-confirmed pCA in the peripheral zone. Regions of interest (ROI) were drawn on axial $T2_M$ (0.7x0.7x3.0mm^3, 16 echoes with delta TE 10.8ms, TR 5000msec) for each examination: on 3 slices (apex, mid-base, and base) to measure healthy prostate tissue of the peripheral and transitional zone and for confirmed malignant lesions on the most representative slice. The average and minimum values of transverse relaxation time (T2) in each ROI were recorded.
Results: The average acquisition time for $T2_M$ was 4:36 min. Healthy prostate tissue had a mean T2 of 151.3±42.6ms in the peripheral zone and 95.1±22.5ms in the transitional zone. The mean T2 in the peripheral zone was significantly reduced for confirmed pCA (71.6±13.3ms, p=0.001). T2 measurements could differentiate infiltration of the transitional zone from peripheral pCA (p=0.001). When comparing minimal values of $T2_M$, we found a good distinction between healthy tissue and pCA (healthy: 99.4±19.9ms, malignant: 52.0±10.6ms; p=0.001).
Conclusion: The detection of malignant prostate tissue is feasible using quantitative measurements from high-resolution T2-mapping sequences with a good distinction of pCA. $T2_M$ could be added with an acceptable acquisition time.
Limitations: Results should be confirmed in a larger cohort.
Ethics committee approval: Ethics committee review granted approval and informed consent was waived.
Funding: No funding was received for this work.

Advanced postprocessing in diffusion-weighted imaging of the prostate: impact on image quality and lesion detectability

D. Zinsser[1], J. Weiß[1], M. Esser[1], M. Nickel[2], A. E. E. Othman[1]; [1]*Tübingen/DE,* [2]*Erlangen/DE (dominik.zinsser@med.uni-tuebingen.de)*

Purpose: To investigate the effect of advanced postprocessing consisting of adaptive combination and motion correction of multiple acquisitions in diffusion-weighted magnetic resonance prostate imaging and its potential to improve image quality and prostate cancer detection.
Methods and materials: We retrospectively evaluated clinically indicated multiparametric 3T-MRI-examinations of 53 patients (mean age 68.8±10 years) including diffusion-weighted imaging of the prostate with and without prototypical advanced postprocessing for the extraction of trace-weighted images from the original diffusion-weighted acquisitions. Two readers rated image quality, artefacts, distortion, and detectability of lesions in high b-value images (b=1000/calculated 2000 s/mm²) of both datasets using a 4-point Likert scale (1=poor, 4=excellent). Measurements of signal intensity of the peripheral zone and lesions were carried out. This enabled us to calculate the ratio of signal intensity of lesions to the peripheral zone and therefore produce a quantitative comparison of lesion detectability. Lesions were assessed according to PI-RADS V2.
Results: With advanced postprocessing, image quality was rated significantly better for b1000 (4 vs 3, p=0.0001) and b2000 (3 vs 2, p=0.0006) while artefacts were rated significantly better for b2000 (3(IQR 3-3) vs 3(IQR 2-3), p=0.0005). No significant differences for distortion were found. Due to improved lesion/tissue contrast with advanced postprocessing, detectability of lesions was qualitatively and quantitatively better for b1000 (4 vs 3, p=0.0084; 1.36 vs 1.31, p<0.0001) and b2000 (4(IQR 4-4) vs 4(IQR 3-4), p=0.0003; 3.24 vs 2.92, p<0.0001). With advanced postprocessing, two additional lesions (overall 38 instead of 36) were found.

Conclusion: Advanced postprocessing significantly improves image quality and reduces artefacts in diffusion-weighted prostate imaging. Furthermore, it significantly enhances the detection of potentially malignant lesions and enables the recognition of more suspect lesions compared to standard diffusion-weighted imaging.

Updated PI-RADS 2.1: does it affect the diagnostic outcome of multiparametric prostate MRI?
J. Knapp, M. Sinn, C. Berliner, L. Well, G. Adam, D. Beyersdorff, M. Sauer; *Hamburg/DE (m.sauer@uke.de)*

Purpose: To evaluate whether the recent update on PI-RADS (2.1) has significant impact on the assessment of multiparametric prostate MRI (mpMRI) in comparison to PI-RADS 2.0.
Methods and materials: 125 consecutive patients (median age 65 years) underwent standardised, in-house mpMRI at 3T in the first quarter of 2019. All examinations were re-assessed retrospectively according to PI-RADS 2.1, acknowledging the updates on DWI scoring in the transitional zone (TZ), volumetry (e.g. used for PSA density calculation), and lesion localisation. Relevant clinical parameters, as well as subsequent diagnostics and therapies, were co-registered. P-values were determined by paired Student's t-tests.
Results: In 125 MRIs, 23 lesions were upgraded (PI-RADS "2" to "3") due to PI-RADS 2.1 DWI criteria, but only 2 of these 23 lesions replaced the previous index lesion. Therefore, the overall PI-RADS score was only two times increased (PI-RADS "2" to "3", ~ "equivocal biopsy target"), one time decreased (PI-RADS "2" to "1"), and remained unchanged in 122 cases. Analysis of the overall PI-RADS scores of all patients demonstrated no significant differences (p=0.57). 8 index lesions were topographically relocated within the new sector map to the additionally defined sectors. The updated recommendations on prostate volumetry demonstrated a mean deviation of 6.4 ml compared to previous PI-RADS 2.0 without significant differences (p=0.38). Correlation in linear regression was good (r^2=0.83; CI:0.85-1.0).
Conclusion: PI-RADS 2.1 updates had no significant impact on the overall MRI scores, especially with respect to biopsy guidance. Revised volumetry does not cause significant changes compared to PI-RADS 2.0.
Limitations: A retrospective, single-reader, and single-centre analysis.
Ethics committee approval: Informed consent was waived by the ethics committee.

Comparison of abbreviated MRI protocols for the detection of prostate cancer in a cohort of radical prostatectomy patients: a multi-reader study
F. Bonato, G. Giannarini, L. Di Mico, L. Cereser, G. Como, C. Zuiani, R. Girometti; *Udine/IT*
Purpose: To compare multiparametric magnetic resonance imaging (mpMRI)-derived abbreviated protocols in detecting prostate cancer (PCa).
Methods and materials: We retrospectively included 108 patients (mean age 64.8 years) who performed mpMRI to stage biopsy-proven clinically-localised PCa before radical prostatectomy between January 2016-May 2019. Examinations were performed on a 3.0T magnet with a prostate imaging reporting and data system version 2 (PI-RADSv2)-compliant protocol. Two readers (R1 and R2, with an experience of <600 and <250 examinations) blinded to definitive pathology, independently analysed mpMRI examinations, attributing a PI-RADSv2 score to each observation on a per-sequence basis. A study coordinator assessed the final PI-RADSv2 category of each observation by combining readers' categorisations according to the following combinations: fast-MRI (diffusion-weighted imaging+T2-weighted imaging), fast-MRI+dynamic contrast-enhanced imaging (DCE), biparametric MRI (bpMRI), and mpMRI. Based on pathology results, we calculated the cancer detection rate (CDR) and false-discovery rate (FDR) (false-positives/true-positives + false-positives) of each protocol. The analysis was performed on the index lesion, using category ≥3 as the cut-off.
Results: 108 index lesions predominated in the peripheral zone, showing a median Gleason score 3+4 and pT stage ≤2c in 74% of cases. Fast-MRI, fast-MRI+DCE, and bpMRI equalled mpMRI, showing 78.7% (95%CI 69.6-85.8) and 77.8% (95%CI 68-6-85.0) CDR, and 10.5% (95%CI 5.0-19.3) and 9.6% (95%CI 4.4-18.3) FDR for R1 and R2, respectively. Fast-MRI+DCE upgraded 53.8% and 90% of category 3 assignments achieved with fast-MRI by R1 and R2, respectively. Upgraded cases were true-positives in 95% of cases.
Conclusion: In a medium-to-low experience setting, fast-MRI+DCE was the abbreviated protocol better balancing CDR and minimising PI-RADS 3 assignments.
Limitations: A monocentric and retrospective study.
Ethics committee approval: Informed consent acquisition was waived due to the retrospective design.
Funding: No funding was received for this work.

Accuracy of a double-reading strategy using abbreviated prostate MRI in patients with prostate cancer candidate to active surveillance
S. Maresca, C. Zuiani, L. Cereser, G. Como, M. Lorenzon, R. Girometti; *Udine/IT (silviomaresca@gmail.com)*

Purpose: To investigate the diagnostic performance for index prostate cancer (iPCa) of a double-reading strategy with an abbreviated magnetic resonance imaging (aMRI) protocol in patients candidate to active surveillance.
Methods and materials: Between February 2015 and November 2018, we retrospectively included 54 men with biopsy-proven low-risk prostate cancer candidate to active surveillance who underwent 3.0T multiparametric magnetic resonance imaging (mpMRI) before a confirmatory biopsy. Three radiologists (R1, R2, and R3) with average-to-low experience in mpMRI, blinded to clinical history and biopsy results, reviewed examinations under the form of aMRI (transverse T2-weighted imaging and diffusion-weighted imaging). Prostate imaging reporting and data system version 2.1 (PI-RADSv2.1) was used for categorising aMRI observations. Using category ≥4 as the cut-off and a confirmatory biopsy as a reference standard, we assessed the sensitivity and specificity for iPCa of single readings (R1, R2, and R3), as well as the readings resulting from the combination of R1+R2, R2+R3, and R1+R3. In double-reading, a case was assessed positive if suspicious for at least one reader.
Results: Saturation targeted confirmatory biopsy was performed with the transperineal approach. At biopsy, iPCas included 42/54 (78%) low-risk lesions. The remaining 12/54 (22%) patients were reclassified to the intermediate-to-high-risk category. Sensitivity/specificity for R1, R2, and R3 were 67% (95%CI 35-90)/57% (95%CI 41-72), 83% (95%CI 52-98)/60% (95%CI 43-74), and 42% (95%CI 15-72)/79% (95%CI 63-90), respectively. Double-reading provided a sensitivity/specificity of 83% (95%CI 52-98)/50% (95%CI 34-66) for R1+R2, 83% (95%CI 52-98)/57% (95%CI 41-72) for R2+R3, and 75% (95%CI 43-95)/55% (95%CI 39-70) for R1+R3, respectively.
Conclusion: A double-reading approach using an abbreviated magnetic resonance imaging (aMRI) protocol improved the sensitivity for iPCa in patients candidate to active surveillance.
Limitations: A retrospective design.
Ethics committee approval: IRB-approved.
Funding: No funding was received for this work.

In-vivo tissue characterisation of prostate cancer: an extreme gradient boosting algorithm to predict Gleason scores in multiparametric MRIs of the prostate
S. Ellmann, M. Schlicht, M. Dietzel, M. Hammon, R. Janka, M. Saake, B. Wullich, M. Uder, T. Bäuerle; *Erlangen/DE (stephan.ellmann@uk-erlangen.de)*

Purpose: Radiomic features extracted from routine MRI sequences are increasingly used for in-vivo tissue characterisation. The aim of this study was

to develop a computer-aided diagnosis (CADx) algorithm to predict the Gleason score (GS) of prostate cancers (PCa) in multiparametric MRIs of the prostate (mpMRI).
Methods and materials: 83 PCa reported in mpMRI were included in this retrospective study. Histopathology of TRUS-guided biopsy cores with reported GS served as a standard of reference (SOR). mpMRIs were performed following international guidelines and current practice. Imaging parameters included lesion size, T2w-signal intensity, diffusion restriction, prostate volume, and dynamic parameters (wash-in, wash-out, peak enhancement intensity, the initial area under the curve, and time-to-peak) along with zonal anatomy (peripheral zone vs central gland), patient age, and serum PSA level. Predicting the GS was defined as a regression problem. Using the above-mentioned parameters, an extreme gradient boosting algorithm was trained to predict the lesions' GS. A leave-one-out cross-validation was applied to ensure generalisability. Performance optimisation was focused on minimising the root-mean-square-error (RMSE). Inter-reader agreement of the imaging parameters was assessed using intraclass correlation coefficients (ICC).
Results: Histopathological assessment revealed n=17 Gleason-6 PCa, n=45 Gleason-7 PCa, n=8 Gleason-8 PCa, and n=13 Gleason-9 PCa. The CADx reached an RMSE of 0.653. Predicted and observed GS correlated significantly (P<0.0001, r=0.503). All imaging parameters featured excellent inter-reader agreement (all ICC≥0.87).
Conclusion: This study describes a CADx for GS prediction of PCa in mpMRI with high accuracy and excellent inter-reader agreement.
Limitations: Limitations include the retrospective and monocentric study design.
Ethics committee approval: The ethics committee approved this study, with a waiver of informed consent.
Funding: This work was supported by the German Research Foundation (DFG, CRC 1181-Z02).

Follow-up of patients within PI-RADS category 3: analysis of an advisable control interval

S. Dörfler, L. Schimmöller, M. Quentin, T. Ullrich, C. Arsov, P. Albers, G. Antoch*; Düsseldorf/DE*
(Stephan.Doerfler@med.uni-duesseldorf.de)

Purpose: To analyse follow-up (FU) mpMRI in patients within a PIRADS category of 3.
Methods and materials: This retrospective single-centre study includes consecutive patients with a PIRADS category 3, ≥1 follow up mp-MRI (T2WI, DWI, DCE), and target plus systematic TRUS-guided biopsy or transurethral resection (TUR-P) as histological reference standard between 2012-2018. Study endpoints were analyses of PIRADS, PSAD, PSA, and prostate volume during FU MRIs with subgroup analyses of patients with a positive histology.
Results: Of 89 included patients (median PSA 6.6ng/ml; PSAD 0.13ng/ml/ml) with a FU period of 31±18 month, PCa was detected in 19 cases (median PSA 6.0ng/ml; PSAD 0.13ng/ml/ml) and csPCA in 5 cases (median PSA 5.5ng/ml; PSAD 0.13ng/ml/ml). Only the PI-RADS score, but not PSA, PSAD, or prostate volume, showed a significant difference in FU MRIs. Prostate volume rose in biopsy-negative cases (median initial 53 ml to 68 ml in FU; p=0.07). There was a significant PIRADS downgrade in cases with a negative biopsy during FU after 36 to 48 month (p=0.001) and a significant PI-RADS upgrade after 13 to 24 month in cases with verified PCa (p=0.02).
Conclusion: There was a very low rate of csPCA in PIRADS 3 patients. Patients with PCA and an initial PI-RADS 3 showed an upgrade to PIRADS 4 in FU MRI within 13-24 months. In cases with a negative biopsy, there seems no benefit to follow-up MRIs earlier than 36-48 months in cases of stable PSAD.

Fractal analysis of perfusion MRI for predicting prostate cancer grading: validation of previously established cutoffs

F. Michallek[1], H. Huisman[2], B. Hamm[1], M. Dewey[1]; *[1]Berlin/DE, [2]Nijmegen/NL (florian.michallek@charite.de)*

Purpose: MRI is used for detecting prostate cancer (CaP), however, non-invasive grade prediction remains challenging. The perfusion pattern might allow non-invasive prediction of CaP-grading by quantifying chaos of perfusion. This study validates the fractal analysis of perfusion-MRI for CaP grade prediction.
Methods and materials: The openly available PROSTATEx2-dataset (testing cohort) was analysed with the Gleason grade group (GGG) from MRI-guided biopsies as a reference. Fractal analysis was applied to dynamic contrast-enhanced MRI-sequences (3Tesla, 3D-turbo-flash gradient-echo, resolution around 1.5x1.5x4 mm, each 3.5 seconds). Fractal dimension (FD) cutoffs were established in a previous study to predict low, intermediate, and high GGG1-4 CaP, and were validated in this study. GGG agreement with FD was assessed by quadratic-weighted kappa-statistics. Performance of fractal analysis was compared to an apparent diffusion coefficient (ADC) analysis.
Results: A cohort of 72 CaP in 64 patients was studied. Significant FD differences were found in pairwise GGG predictions (p<0.005), except for the highest groups (GGG4, n=8, vs GGG5, n=6). Using previously established FD thresholds, very good agreement of fractal analysis with GGG was achieved with quadratic-weighted kappa κ_{FD}=0.88 [CI: 0.79-0.98] for multi-class prediction. In comparison, ADC differences were significant for predicting GGG1 vs GGG2-5 CaP (p≤0.02) with moderate performance (κ_{ADC}=0.36 [CI: 0.12-0.59]). The differentiation of GGG4 from GGG5 CaP was neither reliable by fractal analysis nor ADC analysis.
Conclusion: Using previously determined FD thresholds for predicting CaP grading, fractal analysis achieved a high agreement with GGG and outperformed ADC analysis in an independent cohort.
Limitations: The differentiation of GGG4 from GGG5 CaP was neither reliable by fractal analysis nor ADC analysis.

mpMRI detection of suspected prostate cancer with a negative biopsy: can radiomic features help radiologists?

A. Bevilacqua[1], M. Mottola[1], F. Ferroni[2], G. Gavelli[2], D. Barone[2]; *[1]Bologna/IT, [2]Meldola/IT (margherita.mottola@unibo.it)*

Purpose: To investigate whether DWI-based radiomics features could differentiate patients with a clinical suspicion of PCa and negative TRUS-biopsy that have a positive mpMRI from patients where mpMRIs do not show any evidence.
Methods and materials: The records of 17 patients undergoing 3T-mpMRI for suspected PCa subsequently not confirmed at TRUS-biopsy were extracted from our institutional database. The ground truth was available for only a few. 7 patients did not report evidence at mpMRI, while 10 patients showed suspected PCa lesions, contoured in consensus by two radiologists. 84 image-based radiomic features were computed on high b-value DW-MRI sequences of all patients of the two groups. The ROC curve was computed for each feature and the one yielding the highest AUC was selected. Its discrimination power was also assessed via a Wilcoxon rank-sum test (p<0.001).
Results: The mean of local skewness (S_L-m), related to local inhomogeneities of DWI values, confirms radiologist reports in 94% of cases, with AUC=0.93 (95% CI, 0.56-1.00), specificity=100%, and sensitivity=86% (one false-positive only). Median S_L-m values in patients with suspected PCa were greater than 30% ($p \sim 10^{-4}$) with respect to patients showing no evidence at mpMRI.

Conclusion: DWI-based radiomic features strongly support mpMRI evidence in cases of suspected, and for some patients clear, PCa although TRUS-biopsy is negative. These outcomes suggest further investigation on the role that these extremely promising features could have in PCa patient's stratification.
Limitations: Although it confirmed the mpMRI evidence to be PCa for the few patients where the ground-truth was available, for most of them it was not at our disposal because patients did not belong to a dedicated study.
Ethics committee approval: IRB approval, written informed consent was waived.
Funding: No funding was received for this work.

Comparison of CT findings in successful and unsuccessful non-operative management of acute appendicitis

C. Civan Kuş, D. Tüney, C. Yegen, T. Demirbas, C. Ilgın*; Istanbul/TR (drceydacivan@hotmail.com)*

Purpose: Although acute appendicitis standard treatment has been performed surgically, it has been seen that treatment is possible with antibiotic and non-operative observation in recent years. In this study, we aimed to determine whether CT findings in patients diagnosed with acute appendicitis should be used for directing treatment.
Methods and materials: A total of 60 patients, who underwent abdominal CT and antibiotic treatment for acute appendicitis were retrospectively evaluated. Patients who were treated with antibiotics were followed up for at least six months to determine the recurrent disease rate and CT findings of successful and unsuccessful medical treatment cases were compared. Appendiceal wall thickness, diameter, wall contrast enhancement, intraabdominal free fluid, periappendiceal fat stranding severity, perirectal lymph node, appendicolith and adjacent organ findings in CT of groups were compared with chi-square and Mann-Whitney-U tests.
Results: A total of 60 patients were evaluated. Because of 6 of the 60 patients who received medical treatment didn't complete the 6-month follow-up period, and 17 of them couldn't be followed-up, 23 patients have not been included in the research. As a result, at the end of the 6-month follow-up, 23 of the 37 medical treatment patients were successful and 14 of them were unsuccessful. Comparing the CT findings of the successful and unsuccessful medical treatment groups, just the severity of appendix wall enhancement was found statistically significant (p=0.005). After at least 6 months follow-up, the recurrent disease rate of patients who received medical treatment was 38%.
Conclusion: The likelihood of unsuccessful treatment increases when the severity of appendix wall contrast enhancement is evident in patients treated with medical therapy. The recurrent disease rate of medical treatment after at least 6 months follow-up was 38%.
Limitations: Retrospective study.
Ethics committee approval: Ethics committee approval obtained.

Dynamic contrast-enhanced MR imaging of rectal cancer using a golden-angle radial stack-of stars VIBE sequence: pharmacokinetic analysis and associations with different histopathological findings

Y. Li, Z. Li, C. Xia*; Chengdu/CN (18108087220@163.com)*

Purpose: To explore the role of pharmacokinetic analysis of perfusion parameters derived from golden-angle radial stack-of stars VIBE sequence in discriminating tumour characteristics and the associations with histopathological findings.
Methods and materials: 56 pathologically confirmed rectal cancer patients who received radial VIBE DCE-MRI examination were enrolled in our study. Pharmacokinetic parameters were correlated with tumour histopathological findings including staging, perineural lymphatic invasion and Ki67. The comparison of K^{trans}, Kep, V_e and iAUC between tumour and normal tissue was performed. Correlation between different pharmacokinetic parameters and pathological findings were calculated. Logistic regression analyses were used to determine the association between PNI, lymphatic metastasis and pharmacokinetic parameters.
Results: The values of K^{trans}, V_e and iAUC were significantly higher in tumour than in normal tissue; all $P<0.05$, the same as K_{ep}, $p<0.05$. Those parameters did not demonstrate statistical signifcance in correlating with N staging and Ki67 except for T staging and K^{trans}; the correlation coefficient r_s was 0.374, p=0.038. Combined K^{trans}, K_{ep}, V_e and iAUC can predict PNI as high as 78.1%. Combined K_{ep}, V_e and iAUC reached 79.4% in predicting lymphatic metastasis.
Conclusion: Pharmacokinetic parameters derived from golden-angle radial stack-of stars VIBE sequence can distinguish tumour from normal tissue. The combination of K^{trans}, K_{ep}, V_e and iAUC can act as a potential predictor of PNI and in combination with K_{ep}, V_e and iAUC as a promising predictor of lymphatic metastasis in rectal cancer patients.
Limitations: Limitations are the small sample size, participants belonging to different staging and the classification and differentiation groups, which may affect the objective evaluation.
Ethics committee approval: The study was approved by our institutional review board and written informed consent was obtained from all participants.
Funding: 1.3.5 project for disciplines of excellence, West China Hospital, Sichuan University

Computed tomography volumetric analysis of rate and factors affecting liver regeneration in liver transplant recipients

A. Jayant[1], T. B. S. Buxi[2], K. S. Rawat[1], P. Singh[1]*; [1]New Delhi/IN, [2]Gurgaon/IN, (abhishekjayant@gmail.com)*

Purpose: The purpose of this study was to assess liver regeneration with CT volumetry in patients who have undergone liver transplantation and to evaluate factors impacting liver regeneration in these patients.
Methods and materials: The study was done in the Department of Radiodiagnosis at Sir Ganga Ram Hospital. 34 patients were included in this study. Inclusion criteria: all adult patients who underwent living donor liver transplantation at our centre and gave consent for participation in our study. Exclusion criteria: paediatric liver transplant patients and acute liver failure patients. After taking valid consent, demographic, clinical and laboratory parameters, as well as pre-operative graft weight of these patients, were noted. CT was done on the 7th and 30th post-transplant day and The volume was calculated using CT volumetry software. Percentage and absolute growth of graft on these days were calculated. Correlation of various pre-transplant variables (age, sex, height, weight, BMI, BSA, MELD score, graft lobe, pre-transplant graft volume, graft to recipient weight ratio and indication for liver transplant) with graft regeneration was assessed.
Results: Rapid regeneration of graft was noted with a mean absolute and percentage regeneration on the 30th day being 685.4 ± 200.3cc and 119.2 ± 44%. Significant (p value <0.05) and positive correlation was found between weight, BMI, BSA, graft volume, graft to recipient weight ratio (GRWR) and 30th-day graft volume.
Conclusion: We concluded that graft regeneration in liver transplant recipients is a rapid and continuous process in the first thirty days. There is a positive and significant correlation between graft regeneration and pre-transplant variables as well as recipient's weight, BMI, BSA, graft volume and GRWR.
Limitations: The study is limited by the relatively small sample size of 34 patients and the fact that is was a time bound study.
Ethics committee approval: The study was approved by the institute's ethics committee.
Funding: No funding was received for this work.

Can CT findings predict the surgical outcome in patients of adhesive small bowel obstruction: a retrospective cum prospective study

P. Singh[1], S. S. Ghuman[2], T. B. S. Buxi[3], A. Jayant[1]; [1]New Delhi/IN, [2]Noida/IN, [3]Gurgaon/IN (priyanka.dolly21@gmail.com)

Purpose: The purpose of this study is to assess the accuracy of MDCT findings as predictors for impending surgical intervention in patients with adhesive small bowel obstruction.
Methods and materials: The study was done in the Department of Radiodiagnosis (CT) at Sir Ganga Ram Hospital. The study was done in two phases. In the first phase, 75 retrospective cases meeting the inclusion criteria were included in this study. 8 MDCT features: small bowel dilatation, bowel wall thickening, degree of obstruction, small bowel air-fluid level, small bowel faeces sign, mesenteric fatty stranding, the presence of transition point and the presence of intraperitoneal free fluid were assessed in these patients. Sensitivity, specificity, positive predictive value, negative predictive value and the accuracy of these features for the prediction of surgical outcome were evaluated. Correlations of these features individually and in combination were assessed with surgical management. In the second phase of our study, the validity of the results obtained in the retrospective group was tested by applying them to 25 prospective cases.
Results: In the retrospective group, small bowel dilatation (>4cm) and high-grade obstruction were found to be statistically significant and a positive predictor of surgical outcome in patients of adhesive small bowel obstruction both individually and in combination. The model generated on the basis of the retrospective data showed an outstanding discrimination between surgical and conservative management when applied on prospective cases, thus validating our results.
Conclusion: MDCT features of small bowel dilatation >4cm and high-grade obstruction can both independently and in combination predict surgical outcome in patients with adhesive small bowel obstruction.
Limitations: There is no widely accepted definition for the grade of obstruction. The clinical status of the patient was not taken into consideration.
Ethics committee approval: Approved by the ethical committee of our institutuion.
Funding: No funding was received for this work.

Contrast-enhanced CT-based textural parameters as potential prognostic factors of survival for colorectal cancer patients receiving targeted therapy

H. Xu, H. Liang; Chengdu/CN (xhydoris@gmail.com)

Purpose: This study was designed to estimate the clinical significance of the contrast-enhanced computed tomography textural features for the prediction of survival in colorectal cancer patients receiving targeted therapy (bevacizumab and cetuximab).
Methods and materials: The LifeX software was used to extract the textural parameters of the tumour lesions in the contrast-enhanced computed tomography. Progression-free survival and overall survival were estimated using the Kaplan–Meier method. Univariate and multivariate analyses using the Cox proportional hazards model were performed to assess the prognostic value of textural parameters.
Results: Eighty colorectal cancer patients receiving targeted therapy (bevacizumab 42; cetuximab 38) were included. In the multivariate analysis, 8 textural parameters were revealed to be independent predictors of progression-free survival and overall survival, including skewness, kurtosis, homogeneity, energy and entropy of gray-level co-occurrence matrix, LRE, LRHGE, and contrast. Further, sphericity, compacity, LRLGE, LZGE and SZLGE were shown to be significantly associated with progression-free survival, while entropy and energy form a histogram-based matrix. Dissimilarty, SRE, SRLGE, RP, LZE, LZLGE and LZHGE were significantly associated with the overall survival.
Conclusion: In conclusion, our study provides preliminary evidences that several radiomic parameters derived from CT images were prognostic factors and predictive markers for CRC patients who are candidates for targeted therapy (bevacizumab and cetuximab).
Limitations: First of all, patients in this study were from a single centre. Secondly, the population was relatively small although we reviewed a relatively large database. Finally, there is subjectivity in the process of manually drawing VOIs. Thus, further studies are needed to validate the results of our study.
Ethics committee approval: This study was approved by the Ethics Administration Office of our hospital.
Funding: No funding was received for this work.

Diagnostic accuracy of ultrasound in the detection of amoebic liver abscess

S. Khan, W. A. Mirza; Karachi/PK (shahmeer.khan@aku.edu)

Purpose: The purpose of this study was to determine the diagnostic accuracy of ultrasound in the detection of amoebic liver abscess in patients undergoing liver abscess aspiration at the Department of Radiology (Aga Khan University Hospital).
Methods and materials: Setting: Department of Radiology, Aga Khan University Hospital, Karachi. Duration of the study with dates: The study was carried out over a period of six months from 22-01-2019 to 21-07-2019. Subjects and Methods: A total of 105 cases undergoing liver abscess aspiration were included in the study. Ultrasound was performed by a sonologist / radiologist with a minimum of 5 years experience of abdominal sonography. The same interpreted the images. Patient demographics and sonographic features were recorded on a proforma.
Results: The mean age of the patients was 49.3±17.5; 74 (70.5%) male and 31 (29.5%) female patients. A single lesion was found in 98 patients (93.3%) and multiples lesions in 7 patients (6.7%). Out of 105 patients, the location of the lesion was right in 93 (88.6%) and left in 12 patients (11.4%). Ultrasound showed a sensitivity of 97.5%, specificity 82.6%, PPV 95.2%, NPV 90.4% and diagnostic accuracy 94.2%, in the detection of amoebic liver abscess. Stratification for age, gender, number of lesions and location of lesions was also carried out.
Conclusion: In conclusion, ultrasonography is highly sensitive in diagnosing amoebic liver abscess. Ultrasound is an ideal, safe, sensitive, non-invasive and easily available imaging modality for the diagnosis. Ultrasound is an excellent imaging modality for the identification and location of the ALA, for the estimation of size and volume, and for the evaluation of complications.
Limitations: The study does not enumerate how these features would help to differentiate from a pyogenic abscess.
Ethics committee approval: Ethical review committee exemption was obtained.
Funding: No funding was received for this study.

Contrast-enhanced ultrasonography (CEUS) vs dynamic contrast-enhanced MRI (DCE-MRI) for the characterisation of focal liver lesions: where do we stand?

K. Sood, Y. Agarwal, S. Gupta, R. Prasad; New Delhi/IN (komalsood16@gmail.com)

Purpose: To compare and determine the role of CEUS and DCE-MRI in the diagnostic evaluation of focal liver lesion and to qualitatively classify lesions using contrast washout patterns on CEUS (LI-RADS).
Methods and materials: An observational cross-sectional study was performed on 102 patients. All patients with focal liver lesions on grayscale ultrasound were included in the study except for those with simple cysts, patients with COPD, CKD (GFR<30 ml/min/1.73 m²), IHD and patients with contraindications to MRI. First CEUS was done on our subject and a provisional classification of the lesion using LI-RADS was done using the washout pattern of the contrast followed by DCE-MRI on which the lesion was classified again using LI-RADS. The final diagnosis was confirmed by histopathology. Results of these non-invasive modalities were then compared to histopathology (gold standard).
Results: For the contrast-enhanced ultrasound studies, sensitivity is 90% (95% CI 88-90), specificity is 82% (95% CI 80–84), and 41 for diagnostic odds ratio (DOR); for the CEMRI studies, sensitivity is 88% (95% CI 86-90), specificity is 83% (95% CI 81–85), and 35.80 for DOR.
Conclusion: CEUS can be a promising and cost-effective modality for focal liver lesions as compared to DCE-MRI for an initial evaluation. It not only shows comparable results in identifying the final diagnosis but also makes use of a contrast agent which gets excreted through lungs (SF6) and hence can easily be used in patients with liver/renal disease.
Limitations: The only limitation to our study is that CEUS is operator-dependent, so specificity of CEUS can further be increased when performed by the same and experienced sonologist.
Ethics committee approval: Approval taken.
Funding: No funding for this study was received.

Reproducibility of intravoxel incoherent motion of liver on a 3.0T scanner: free-breathing and respiratory-triggered sequences acquired with different numbers of excitations

A. Cieszanowski, K. Pasicz, M. Naduk-Ostrowska, J. Podgorska, E. Fabiszewska, W. Skrzyński, J. Jasieniak, I. Grabska, P. Kukołowicz; *Warsaw/PL (naduk.martyna@gmail.com)*

Purpose: To optimise the IVIM imaging of the liver on a 3T scanner by assessing parameter reproducibility on free-breathing (FB) and respiratory-triggered (RT) sequences acquired with different numbers of signal averages (NSA).
Methods and materials: 20 subjects underwent IVIM MRI on a 3T scanner using four different echo-planar sequences, each with 10 b values: 0-900 s/mm2. Images were acquired with FB and RT with NSA = 1-4 (FBNSA1-4, RTNSA1-4) and with NSA = 3-6 (FBNSA3-6, RTNSA3-6). For the assessment of the reproducibility of IVIM-derived parameters (f, D, D*), each subject was scanned again with an identical protocol during the same session. IVIM parameters were calculated. The distribution of IVIM-parameters for each DWI sequence was given as the median value with first and third quartile. Inter-scan reproducibility for each IVIM parameter was evaluated using the coefficient of variance and Bland-Altman difference. Differences between FB sequence and RT sequence were tested using the non-parametric Wilcoxon signed-rank test.
Results: The mean coefficient of variance (%) for f, D, and D* ranged from 60 to 64, from 58 to 84, and 99 for FBNSA1-4 sequence; from 50 to 69, from 41 to 97, and from 82 to 88 for RTNSA1-4 sequence; from 22 to 27, 15, and from 70 to 80 for FBNSA3-6 sequence; and from 21 to 32, from 12 to 17, and from 50 to 80 for RTNSA3-6 sequence, respectively.
Conclusion: Increasing the NSA for IVIM acquisitions allows us to improve the reproducibility of IVIM-derived parameters. The sequence FBNSA= 3-6 was optimal in terms of reproducibility and acquisition time.
Limitations: The number of studied subjects was limited to 20.
Ethics committee approval: The study was approved by the Institutional Review Board, and all volunteers signed an informed consent form.
Funding: No funding was received for this work.

A model based on liver stiffness measured by shear-wave elastography and future liver remnant ratio to predict post-hepatectomy liver failure in patients with hepatocellular carcinoma

H. Long; *Guangzhou/CN (longhaiy@hotmail.com)*

Purpose: This study aimed to develop a clinical model based on liver stiffness for predicting post-hepatectomy liver failure (PHLF) among patients with hepatocellular carcinoma (HCC).
Methods and materials: Patients undergoing upper abdominal CT or MRI and liver stiffness (LS) measured by shear wave elastography (SWE) prior to hepatectomy for HCC between August 2018 and September 2019 were enrolled prospectively. 80 consecutive patients in our center were enrolled as a derivation set and another 40 patients served as an independent internal validation set. Future liver remnant ratio was estimated based on a three-dimensional reconstruction of the liver and virtual surgery simulation. PHLF was defined per the International Study Group of Liver Surgery (ISGLS) criteria. Multivariate logistic analysis was used to establish the predictive model. The discriminative ability of the model was determined by area under curve (AUC) and compared with commonly predictive systems. A nomogram based on the model was established to display the risk of PHLF.
Results: PHLF occurred in 29 patients (36.3%) in the derivation set. A model based on the basis of future liver remnant ratio, liver stiffness and clinical signs of portal hypertension (CSPH), had a good discrimination ability with AUC of 0.903 (95% confidence interval[CI]: 0.826-0.981, p<0.001) and calibration ability (P=0.116). The model showed satisfactory discrimination ability in the validation set with AUC of 0.815. The AUC of our model was significantly bigger than those of conventional predictive systems in the derivation patients (corresponding AUC, 0.649–0.703).
Conclusion: This model provides good preoperative prediction of PHLF in patients with HCC.
Limitations: Limitations were the small sample size and the fact that the external validation cohort was not available at the time.
Ethics committee approval: This research was approved by the Ethics Committee for the First Affiliated Hospital of Sun Yat-sen University.
Funding: No funding was received for this work.

A game-changer for non-transfusion-dependent thalassemia patients: T2* MRI in liver and myocardium iron quantification

G. Nagenthran, P. R. Radhakrishnan, R. J. D. Santosham, B. Jeevanandham; *Chennai/IN (g3nagikrish@gmail.com)*

Purpose: To study the correlation of liver (LIC) and myocardial (MIC) iron concentration using T2* MRI with serum ferritin in non-transfusion-dependent thalassemia patients.
Methods and materials: In this prospective study done between September 2016 and 2018, thirty patients of non-transfusion-dependent thalassemia (17 males and 13 females) were studied. Serum ferritin was determined using the chemiluminescent method. T2* MRI was done using 1.5T Seimens Magentom Avanto. Post-processing: T2* analysis spreadsheet. Inclusion criteria: patients who were diagnosed with non-transfusion-dependent thalassemia (NTDT) - age: 5-50 years. Exclusion criteria: patients on chelation therapy, patients with fever or active infections and patients with contraindications to MR imaging.
Results: Out of 30 patients, 24 had a liver iron overload and only 1 patient had a myocardial iron overload. There was a non-linear correlation between LIC and serum ferritin (P-value <0.01). The rate of change of serum ferritin was not proportional to LIC. No correlation was found between MIC and serum ferritin. A negative correlation was found between LIC and haemoglobin. Liver iron concentration increases as age increases, indicating the accumulation of iron over time. A significant positive correlation was found between LIC and liver size and spleen size (P-value <0.01).
Conclusion: Since the serum ferritin level does not reflect the level of liver iron overload in non-transfusion-dependent thalassemia patients, the assessment of liver iron concentration using the T2* relaxometry method helps in the early detection of iron overload, the early initiation of chelation therapy and the prevention of complications.
Limitations: Respiratory artifact can cause false interpretation.
Ethics committee approval: The Ethics committee approval was obtained.

Calculating the cut-off value of the damping index using the ROC curve to identify Child-Pugh C patients

N. K. Agrawal[1], A. N. Kamble[2]; [1]*Mohali/IN,* [2]*New Delhi/IN*

Purpose: The Child-Pugh score is based on clinical indices and lab results and gives the idea about patient's severity about liver disease. The Child-Pugh C score carries the grave prognosis. In emergency settings, all the values might not be known. Thus it becomes important to have a proxy for laboratory indices which can be promptly and non-invasively done. Thus, we looked at Doppler ultrasound as an alternative. Previous studies have shown that Colour Doppler is useful in prognosticating patients with liver disease. However, very few studies have used objective parameters like the damping index to assess the severity of liver failure objectively, to be used as a prognostication marker.
Methods and materials: 30 patients with portal hypertension underwent Doppler ultrasound. The damping index was calculated by a reader who was blinded to the patient's Child-Pugh score. SPSS was used to calculate the ROC curve. Middle hepatic artery waveform was taken, then the damping index was calculated, dividing the minimum velocity by maximum velocity.
Results: The damping index of 0.56 has good sensitivity (94%) and specificity (84%) to identify the Child-Pugh C patients (p-value <0.001).
Conclusion: The damping index can be used as an alternative to identify Child-Pugh score C patients who have severe liver disease and carry a bad prognosis. Kim et al have shown a 0.6 cut off of DI for a severe portal hypertension (hepatic venous pressure gradient >12 mm Hg) sensitivity of 75.9% and a specificity of 81.8%. Thus the findings of our study support the hypothesis that the damping index can be a useful parameter in evaluating patients with liver disease, especially for their prognostication.

Limitations: The study sample size is small and it was done in one centre.
Ethics committee approval: Institutional ethic committee approval was obtained.
Funding: No funding was received for this study.

Is visual estimation of liver lobe proportion sufficient to decide on the adequate distribution of the chemotherapeutic agent in uveal melanoma patients undergoing hepatic artery infusion?

T. Goeser, J. Grueneisen, J. M. Ludwig, Y. Li, L. Umutlu, M. Forsting, J. Theysohn, B. M. Schaarschmidt*; Essen/DE*

Purpose: In uveal melanoma patients, hepatic metastases can be treated by intraarterial hepatic chemo infusion (IHC). If both liver lobes have to be treated separately due to anatomical variants, the volume proportion of both lobes are visually estimated on angiographic images in order to adapt the correct distribution of the chemotherapeutic agent. The aim of this study was to compare the visually estimated volume proportions on angiographic images with measured volume proportions between both lobes on CT to determine a potential aberrance.
Methods and materials: In this retrospective study, patients with uveal melanoma that underwent separate IHC of the right and the left liver lobe and received pre- and post-treatment CT were included. Volume measurements were performed for both liver lobes pre-and post-treatment and the volume proportions prior to the intervention were compared with the volume proportions described in the angiographic report by the interventional radiologist.
Results: A total of 31 patients (mean age: 64.9, 16 female, 15 male) were eligible for the analysis. The mean aberrance between volume proportions measured in CT and the estimated values described in the angiographic report was 6,8%. In 9 cases, an aberrance of more than 10%, in one patient an aberrance of more than 20% was observed.
Conclusion: In uveal melanoma patients with liver metastases, the visual pre-estimated volume proportion between the right and the left liver lobe is normally matching the measured values. In singular cases with atypical liver anatomy, it might be necessary to perform a volume measurement in order to decide on an appropriate distribution of the chemotherapeutic agent.
Limitations: Small cohort, retrospective study design.
Ethics committee approval: Informed consent was waived by the institutional review board.
Funding: No funding was received for this work.

MyT3 13-13 09:18

The effect of glycemic-control on renal triglyceride content assessed by proton MR spectroscopy in patients with type 2 diabetes mellitus

I. Dekkers[1], M. B. Bizino[1], E. H. M. Paiman[1], J. W. A. Smit[2], I. M. Jazet[1], A. de Vries[1], H. J. Lamb[1]*; [1]Leiden/NL, [2]Nijmegen/NL (i.a.dekkers@lumc.nl)*

Purpose: Since renal steatosis is a potential driver of diabetic kidney disease, and tight glycemic control can reduce the risk of diabetic nephropathy, we assessed whether glycemic control influences renal triglyceride content (RTGC). Furthermore, we compared GLP-1 receptor agonist liraglutide vs standard glucose-lowering therapy.
Methods and materials: In this single-centre parallel-group trial, T2DM patients were randomised to liraglutide or placebo added to standard care (metformin/sulfonylurea-derivative/insulin). Participants were included if RTGC measurement using proton-spectroscopy (^{1}H-MRS) met the quality criteria. The change in RTGC after 26 weeks of glycemic control and the difference of RTGC change between treatment groups was analysed using ANCOVA while adjusting for baseline differences. Between-group differences in RTGC were tested using non-parametric tests.
Results: Fifty out of 85 T2DM patients (59%) of the MAGNA VICTORIA studies who underwent ^{1}H-MRS had renal spectra that met the quality criteria and were included in the present study. The baseline study population consisted of 50 T2DM patients with a mean age of 56.5±9.1 years (range 33–73 years; 46% males). The baseline median RTGC was 0.23% [25th, 75th percentile; 0.12, 0.36], compared to 0.14% [0.09, 0.23] at the follow-up (p=0.06). The mean HbA1c was 61.6±8.4 mmol/mol at the baseline, which changed to 56.3±9.5 mmol/mol at the follow-up (p=0.046). An analysis of covariance did not show a significant association between liraglutide and difference in RTGC after adjustment for baseline RTGC (p=0.33).
Conclusion: Twenty-six weeks of glycemic control resulted in lower RTGC with a trend towards significance. These findings warrant the need for larger clinical studies on glycemic control and renal steatosis.
Limitations: Although renal outcomes were pre-specified, the MAGNA VICTORIA studies were powered for other primary endpoints than RTGC.
Ethics committee approval: The study was approved by the institutional review board.
Funding: The study was funded by the Dutch Kidney Foundation and Novo Nordisk.

Improvement of ultrasonographical differential diagnosis of gastric lesions: the value of contrast-enhanced sonography with gastric distention

T. Li, M. Lu*; Chengdu/CN*

Purpose: The purpose of this retrospective study is to evaluate the diagnostic value of contrast-enhanced sonography plus gastric distention sonography and the Double Contrast-enhanced Ultrasound (DCUS) in gastric lesions.
Methods and materials: 107 cases with pathology confirmed gastric lesions were retrospectively reviewed, DCUS and oral contrast agent ultrasound (US) were performed in all cases prior to the operation. Perfusion parameters including arrival time (AT), peak intensity (PI), time to peak (TTP), area under the curve (AUC) of the lesion and surrounding normal tissue were analysed. A reader blinded to pathology results was asked to rate and compare each case with surgical or resection biopsy pathology results.
Results: From the 107 gastric lesions, 75 were malignant gastric lesions (33 gastric cancers, 42 gastrointestinal stromal tumours (GISTs)) and 32 were benign gastric lesions (11 inflammatory masses and 21 polypoid adenomas). Compared with US, DCUS achieved a higher value in sensitivity (90.6% vs 70.6%), specificity (75% vs 62.5%), and overall accuracy (85.9% vs 68.2%). When US was tested against DCUS, the increase in the correct diagnoses value was significant (P = .01). Gastric cancer had faster AT, higher PI and AUC than normal tissue (P<0.05); gastric cancer and GIST had faster AT than polypoid adenoma (P<0.05).
Conclusion: The combination of different CEUS enhancement characteristics with quantitative perfusion parameters may provide a promising tool helping to differentiate gastric cancer and GIST from benign lesions.
Limitations: Due to an insufficient number of partial cases, we did not evaluate the diagnostic accuracy by each pathological type.
Ethics committee approval: This study was approved by the Institutional Review Board and Ethics Committee of the Sichuan Cancer Hospital.
Funding: No funding was received for this work.

Shear-wave elastography method in the diagnosis of acute appendicitis

C. Yıldırım[1], Ö. Tunçyürek[2]*; [1]Aydin/TR, [2]Nicosia/CY (cihatyil50@gmail.com)*

Purpose: Acute appendicitis (AA) is the most seen disease with acute abdominal pain. Our purpose is to assess shear-wave elastography (SWE) in the diagnosis of acute appendicitis and to compare SWE findings and postoperatively histopathologic results of appendicitis.
Methods and materials: Patients with right lower quadrant pain underwent ultrasonography (US) between 01.01.2018 and 01.05.2019. If appendices visualized with US, the tissue elasticity of the appendices was measured by SWE. Besides, the presence of free fluid in the peritoneal cavity, lymph node and peri-appendicular inflammation were recorded for AA diagnosis in US. The demographics of the patients were also recorded. US-SWE results were compared with histopathologic scores of inflammation statistically with the Mann-Whitney U test.
Results: 84 patients were evaluated with US. 36 patients had findings for AA diagnosis. All patients diagnosed with AA were operated. There was a significant difference between the inflammation score and SWE results (p<0.001). According to the ROC curve analysis, the sensitivity and specificity of shear-wave elastography US in the diagnosis of acute appendicitis were calculated as 77% and 65%, respectively.

Conclusion: The SWE method is currently under development. Several types of SWE methods are used for the diagnosis of several diseases as a helper, routinely. In AA, the perforation risk is related to the inflammation score. The SWE method may be useful in the diagnosis of early AA when US findings are insufficient and to predict the risk of perforation due to its correlation with inflammation intensity.
Limitations: Limitations in this study are that the shear-wave elastography measurements can be affected by tissue depth and respiratory movements and that the size of the sampling window can not be changed.
Ethics committee approval: Ethical committee approval and written consent forms were obtained.
Funding: No funding was received for this work.

MyT3 13-16 09:30
Comparison of spin-echo echo-planar imaging (SE-EPI), MR elastography with gradient-recalled echo (GRE), MR elastography and correlation with transient elastography (TE)
J. Yoon, E. S. Lee, H. J. Park, B. I. Choi, S. B. Park*; Seoul/KR (yoonjw1203@caumc.or.kr)*

Purpose: To compare the liver stiffness (LS) values obtained by newly developed spin-echo echo-planar imaging (SE-EPI) MR elastography (MRE) with conventional gradient-recalled echo (GRE) MRE in the same condition. In addition, to assess the statistical correlation of the obtained LS values with those of transient elastography (TE).
Methods and materials: From April 2018 to September 2019, we retrospectively included a study population who underwent liver MRE with both SE-EPI and GRE sequences in the same session. Among them, we excluded patients without TE within one year and finally enrolled 43 patients. LS measurements for MRE were performed using free-drawing region-of-interest and reliable TE measurements were defined as the median value of 10 measurements with interquartile range/median (IQR/M) ≤30%. We compared technical success rates, median LS values and areas of confidence for MRE measurements between SE-EPI and GRE sequences using paired t-test. We also evaluated the correlation co-efficient between LS values obtained by each MRE sequence and TE, respectively.
Results: The technical success rate of MRE in SE-EPI was significantly higher than that of GRE (100% vs. 86.0%, p=0.03). LS values from SE-EPI and GRE MRE were not significantly different (SE-EPI; 3.78kPa vs. GRE; 3.54kPa, p=0.08). The areas of confidence for MRE measurements were significantly larger in SE-EPI than those of GRE MRE (8215.1981 vs. 2691.4759 mm2, p<0.001). The LS values from two MRE sequences were significantly correlated with those from TE (SE-EPI; r=0.64, p<0.001 vs. GRE; r=0.61, p<0.001).
Conclusion: SE-EPI MRE is technically stable, and LS values obtained by this sequence would be reliable. LS values obtained by GRE and SE-EPI MREs are significantly correlated with those by TE.
Limitations: The MRE examinations were performed using a single MR unit.

CT signs evaluation in predicting the site of gastrointestinal tract perforation: a review of 100 operated patients
S. Ferraro, M. Giannotta, G. Zanirato Rambaldi, F. Dardi, P. E. Orlandi, M. Imbriani*; Bologna/IT (sissina9@libero.it)*

Purpose: The aim of this study was to retrospectively evaluate the accuracy of CT for preoperative determination of the site of surgically proven gastrointestinal (GI) perforation and to determinate the most predictive findings in this diagnosis.
Methods and materials: We retrospectively reviewed the abdominal CT of 100 patients who had a surgically proven GI perforation (64 males; aged between 32-92 years) performed in our centre, from March 2017 to March 2019. IV contrast agent was used in 83 patients. Two observers, respectively with 25 and 4 years of radiological experience, blinded to the surgical diagnosis, reached a consensus prediction of the site of perforation using the presence of the following CT findings: extra-luminal air (grade and distribution), defect in the wall, wall thickening, abnormal wall enhancement, peritoneal fluid, fat-stranding and inflammatory masses. We also evaluated these signs in predicting perforation due to peptic ulcer disease vs diverticulitis, respectively the most common cause of upper and lower GI perforation. A Chi-Square test was used to analyse the results.
Results: 37 patients presented an upper GI perforation and 63 a lower GI perforation. Severe free air (p=0.04), free air in the supra-mesocolic compartment (p=0.00) and peritoneal fluid (p=0.00) resulted in strong predictors of upper GI perforation, while mild and moderate free air (p=0.04) and fat-stranding (p=0.00) indicated a lower GI perforation. 35 patients had a peptic ulcer disease and 28 patients had diverticulitis. Free air in the supra-mesocolic compartment (p=0.00) and peritoneal fluid (p=0.00) suggested a perforation due to peptic ulcers, while free air in pelvis and retroperitoneum (p=0.03), fat-stranding (p=0.00), abnormal wall enhancement (p=0.05) and inflammatory masses (p=0.05) indicated a perforation due to diverticulitis.
Conclusion: CT is highly accurate for distinguishing upper from lower GI perforation.
Limitations: 17 patients performed unenhanced CT.

Value of CT enterography for predicting the incidence and short-term surgery in patients with Crohn's fistulising disease in the era of biologics
G. Minyi*; Guangzhou/CN (wfbbq@163.com)*

Purpose: To analyse the value of CT enterography (CTE) in predicting the incidence in patients of perianal fistulising disease and the risk of surgical treatment within one year, to provide the evidence for guiding clinical evaluation and rational selection of treatment options.
Methods and materials: 279 cases of newly diagnosed Crohn's disease patients were analysed retrospectively. All patients were followed-up for one year. CTE imaging parameters were recorded and pelvic MR images were evaluated with regard to the presence of anal fistulas.
Results: 204 patients were eligible for the analysis. The presence of colonic involvement was seen in 47/88 (53.41%) cases in the anal fistula group (Group 1) and in 38/116 (32.76%) cases in the non-anal fistula group (Group 2) (P=0.006). The bowel wall enhancement in Group 1 mainly manifested as type 1 and type 2 as 69/88 (78.41%) compared with type 3 and type 4 in Group 2 as 78/116 (67.25%)(P＜0.001). Rectal involvement was present in 12/18 (69.62%) cases of the surgical group (Group 3) vs 22/53 (41.51%) of the non-surgical group (Group 4), luminal stenosis in 15/18 cases (83.33%) of Group 3 vs 4/18 cases (22.22) in Group 4, intra-abdominal fistula in 33/53 (62.27%) of Group 3 vs 2/53 (3.77%) of Group 4. In the multivariate analysis, rectal involvement (OR 1.911 (1.102 to 4.185), P＜0.001), luminal stenosis (OR 2.627 (1.760 to 6.024), P=0.028) and intra-abdominal (OR 1.337 (1.093 to 3.585), P=0.006) increased the risk of surgery.
Conclusion: Colonic involvement and bowel wall enhancement can predict the onset of perianal fistulising disease. Rectal involvement, luminal stenosis, and intra-abdominal fistula increase the risk of short-term surgery for perianal fistulising disease.
Limitations: Limitations were: 1. Single-centre, selection bias; 2. Very few patients did not use enema; 3. Few patients' drug treatment was not standardised.
Ethics committee approval: n/a
Funding: No funding was received for this study.

The role of CT gastric volumetry in sleeve gastrectomy
M. S. T. M. Elfeshawy, A. E. Mohamed, E. Sokker*; Cairo/EG (mst1200@yahoo.com)*

Purpose: The study is aimed at the correlation between the operative gastric volume reduction and body weight reduction after surgery.
Methods and materials: Our study included 30 cases; all were overweight/obese individuals. There were 20 females and 10 males. All patients underwent MSCT abdomen with oral contrast. Post-processing in form of multi-planner reformatting and 3D reconstruction was performed in all cases before and 3 months after sleeve gastrectomy.
Results: The collection and correlation of preoperative and postoperative data revealed that the percentage of operative gastric volume reduction ranged between 76% and 98% with a mean value of about 84%, while the percentage of body weight reduction ranged between 7% and 24% with a mean value of

about 15%. The correlation between body weight and gastric volume measured preoperatively in the studied patients was found to be insignificant, which means that the stomach volume does not have a direct impact on body weight.
Conclusion: MSCT volumetric study of the stomach is the gold standard imaging technique for the evaluation of the gastric size in the preoperative and postoperative stages in the context of bariatric sleeve gastric surgery. Gastric volume does not have a direct impact on body weight in obese individuals. Further evaluation of gastric volume and bodyweight of the studied patients one year after surgery is recommended for a continuous observation as well as monitoring the rate of weight loss and incidence of gastric pouch dilatation.
Limitations: Patients who are candidates for gastric reduction surgery other than sleeve gastrectomy. Patients with recurrent weight gain after a previous gastric reduction procedure.
Ethics committee approval: An approval of the study was obtained from Al-Azhar University Academic and Ethical Committee. Every patient signed an informed written consent for the acceptance of the operation.
Funding: No funding was received for this study.

CT gastroscopy: a convenient tool to evaluate gastric mass lesions
S. Siddharth, P. Narang, D. S. Srivastava, P. Gupta*; New Delhi/IN (siddharthsharma100@gmail.com)*

Purpose: The purpose of this study was to assess the role of computed tomography gastroscopy (CTG) in the evaluation and treatment planning of gastric mass lesions (GML) and to compare the diagnostic accuracy of the same with conventional endoscopy (CE).
Methods and materials: 26 patients with GML detected by CE and confirmed by histopathology prospectively underwent a 256 slice CT scan at a tertiary care centre between August 2017 and September 2018. CTG was done after distending the stomach by oral effervescent agents and insufflation of air through foley's catheter inserted via nasopharyngeal route. CTG images were developed by a dedicated software. GML morphology on CTG was compared to CE using appropriate statistical tools and Kappa value was calculated to find the agreement.
Results: All lesions (100%) diagnosed by CE were successfully detected on CTG. Sensitivity and specificity for evaluating lesion size were 92.9% and 50% respectively, while PPV and NPV were 68.4% and 85.7% respectively. The sensitivity for evaluating the length of the stricture was 100% with 73.1% accuracy. Sensitivity and PPV for the detection of the surface of lesions were 65.4% and 100% respectively, with 65.4% accuracy. Kappa value of 0.79 suggested a good intermodality agreement.
Conclusion: CTG helps in identifying lesions and has bright prospects in cases with obstructive pathology where CE provides limited information. A combined interpretation of axial and 3D images is necessary to make an accurate diagnosis. Being a non-invasive technique with fewer complications it can be carried out in a safe, compliant and effective manner for complete evaluation of GML.
Limitations: Limitations were the small sample size and the single-centre experience. Patient preparation is stringent and cumbersome. Radiation dose is an issue in the paediatric population.
Ethics committee approval: n/a

Radiologic findings of ampullary cancer on contrast-enhanced MRI (CEMRI) with a liver-specific contrast agent: pay attention to the 30-min delayed scan
I. Son, S. Hong, N. Lee, S. Kim*; Busan/KR*

Purpose: To determine the radiologic findings of ampullary cancer on contrast-enhanced MRI (CE-MRI) with a liver-specific contrast agent.
Methods and materials: This retrospective study included 120 patients (65 male and 55 female; mean age: 70.62 years) who were suspected to have ampullary cancer and who performed CE-MRI with a liver-specific contrast agent from January 2015 to January 2019. We collected data including the presence of the bulging ampulla, size, T1/T2-signal intensity, enhancement patterns, diffusion restriction of the ampulla, the extent of common bile duct (CBD) and pancreatic duct dilatation, the change of shape in distal CBD, CBD wall thickening and asymmetry, the contrast secretion to duodenum on a 20-min and a 30-min delayed scan. We also reviewed the pathologic and clinical diagnostic information. In addition, we performed a subgroup analysis according to the presence of the bulging ampulla. Univariate and multivariate analysis was performed to determine the malignancy-associated factor.
Results: 54 patients had ampullary cancer and 66 patients had a benign condition. On the multivariate analysis, diffusion restriction (p=0.028) and heterogeneous enhancement (p=0.045) of the ampulla, no change of shape in distal CBD (p=0.010), and no contrast secretion to duodenum 30-min delayed scan (p=0.001) were significantly associated with ampullary cancer. On the subgroup analysis, the presence of diffusion restriction and the extent of CBD dilatation, no contrast secretion to duodenum 30-min delayed scan was significantly associated with ampullary cancer in the group with the bulging ampulla. In the group without the bulging ampulla, no contrast secretion to duodenum 30-min delayed scan is the only significant factor for ampullary cancer.
Conclusion: Diffusion restriction and heterogeneous enhancement of the ampulla, no change of shape in distal CBD, and no contrast secretion to duodenum 30-min delayed scan were significantly associated with ampullary cancer. Among them, no contrast secretion to duodenum 30-min delayed scan is the only significant factor regardless of the presence of the bulging ampulla.
Limitations: Single centre, retrospective study with a small number of subjects.

MRI-guided microwave ablation of hepatic malignancies: feasibility, efficacy, safety and follow-up
N. Yang*; Shanghai/CN (eoslulu@foxmail.com)*

Purpose: To investigate the feasibility, technical success, safety and follow-up of hepatic malignancies microwave ablation under MRI-guidance.
Methods and materials: From August 2015 to February 2019, 26 patients (38 lesions) were enrolled. T1WI, T2WI, DWI and enhanced MRI were performed as pre-treatment and follow-up (range on 3-36 months). The feasibility evaluation included the successful detection of target tumour and the tumour delineation under MRI during targeting. The technical success was defined as a successful performance of the ablation procedure as initially intended and the achievement of a coagulation zone covering the target tumour with ＞5mm margin. The technique efficacy was evaluated on a contrast-enhanced MR follow-up imaging 4 weeks later. The safety evaluation was based on procedure-related complications according to the clinical practice guidelines of the society of interventional radiology.
Results: 100% primary efficacy rate was achieved and no major complication were observed. The 3D visualisation image has given more and precise information for evaluation and follow-up. 60W/5 MIN ablation power was given in lesions under 1 cm in which the ratio of the ablation zone volume to applied energy and sphericity was calculated. 6 lesions with incomplete circle on reconstructed DWI immediately postprocedural, and persistent hyperintense signal (rang on 3 days to 1 week) was developed into new lesions in the next 6-12 months.
Conclusion: MRI-guidance is feasible and effective in the planning and evaluation of microwave ablation in hepatic malignancies. The available clinical data strongly supports the advantages of 3D-reconstructed image tumour assessment over the one based on routine axial image.
Limitations: Our study has many pitfalls: 1. The relatively small sample size of patients, 2. A lack of imaging-pathologic data, 3. Further studies are required to reveal the inner linking between microstructural changes with a signal on multi-b-value DWI and on the early stage after ablation.

The current state of knowledge of imaging informatics amongst Spanish radiologists

D. D. Eiroa Gutiérrez[1], M. Fdez. Del Castillo Ascanio[2], N. Roson Gradaille[1], R. Mast Vilaseca[1], K. Ramirez Tucas[1], V. Pantoja Ortiz[2]; [1]*Barcelona/ES,* [2]*Santa Cruz de Tenerife/ES (contrasteyodado@gmail.com)*

Purpose: To evaluate general knowledge and concerns about trends on imaging informatics among radiologists currently working in Spain (both residents and attending physicians).
Methods and materials: Type of study: a cross-sectional survey. Inclusion criteria: a radiologist currently working in Spain (public and private). Survey preparation: a survey comprising a total of 20 questions was confectioned, inquiring about technical issues and ethical and professional perspectives. Outcome measures: observational statistical analysis, mainly of frequencies, was carried out.
Results: Most of the 223 surveyed radiologists [52 (23.32%) residents and 171 (76.68%) attending radiologists (AR)] work in National Health Services, at least partly. The most heard-of technologies were machine learning (72.55%) and artificial intelligence (67.26%), with the latter (22.59%) and algorithms (18.39%) being the most used technologies among the surveyees.100% of respondents considered they should pursue academic training in IT and new technologies and around 98% of them reckon it should be included in the speciality's academic program. However, 76.23% of the interviewees think there is not enough time in four years of academic training to include said skills and competencies. Moreover, the main issue expressed by the respondents was patient safety.
Conclusion: Although most of the main commercial technologies are recognised by Spanish radiologists, there is a lack of knowledge of the underlying methods used. There is a will to learn about these topics, although there is no time during residency years. The main concern is patient safety, which highlights the ethical implications of the implementation of such technologies.
Limitations: The main limitation is the selection bias due to convenience sample. A larger sample would allow to draw better conclusions. A higher participation, particularly among residents, was desired.
Ethics committee approval: n/a

Should we perform all the radiological tests that are requested?

P. Fraga Rivas[1], C. Benito Vicente[1], L. Garcia Del Salto Lorente[1], M. I. Diez Perez de las Vacas[1], J. de Miguel Criado[2], F. Aguilera Del Hoyo[1], A. Marco Sanz[2]; [1]*Madrid/ES,* [2]*Coslada/ES (fragarivas@gmail.com)*

Purpose: To present a computer system to assess the justification in radiology that allows us to evaluate the requested examinations, the justification of exposures being applied and determining whether patients fit the recommended criteria for the procedure, and to evaluate its use in a radiology service in the last 6 months
Methods and materials: We have a tool in the electronic history that allows the evaluation of radiological requests before they are cited. When the radiologist considers the test is indicated, they proceed to its validation, and then it can be cited. Otherwise, they deny the indication and the test is cancelled or changed to another imaging test more appropriate to clinical suspicion. Any change in the request is communicated to the petitioning physician.
Results: Of the 84,342 requests made in the last semester of 2018, we included in this validation system all the CT, MR, Doppler, biopsy, and puncture tests, which represent 10,342 requests (12.2%). 10,044 requests were considered indicated but were not indicated 249 (0.29%). We analyse the results by radiological modality, service, petitioning physician, and diagnostic suspicion. We evaluated those tests that, not being indicated, have been modified to other tests more adjusted to the clinical suspicion.
Conclusion: Justification of radiographic examinations is the practice of evaluating requested radiological examinations to assess for clinical merit and appropriateness based on clinical notes and patient information. We believe that our validation process has been useful in the radiological management of the patient, in reducing the radiation received, and in avoiding unexpected findings that divert the main diagnosis in unjustified tests. Radiologist who actively participate in the decision-making process of justification of an examination will ultimately contribute towards improved patient care and management.

National diagnostic imaging trends in Spain: 2010-2017

A. Perez Girbes, M. P. Barreda Solana, V. Navarro Aguilar, A. Torregrosa Andres; *Valencia/ES (aperezgirbes@gmail.com)*

Purpose: To describe the national trends in diagnostic imaging used in Spain from 2010 to 2017 in public and private healthcare.
Methods and materials: Data was obtained from National Hospitals Statistics, an annual report published on the Spanish Health Ministry webpage (https://www.mscbs.gob.es/estadEstudios/estadisticas/estHospiInternado/inforAnual/homeESCRI.htm). Included variables were annual examinations rate per 1,000 inhabitants, annual scanners/rooms per million inhabitants, and a ratio between the number of examinations per scanner/room. Included modalities were CT, MR, PET-CT, SPECT, digital angiography, mammography, conventional radiography, and scintigraphy.
Results: For cross-sectional imaging, annual national examinations rates per 1,000 inhabitants increased 114.8% for PET-CT (1.62 to 3.48), 51.4% for MR (47.58 to 72.04), 42.5% for SPECT (2.40 to 3.42), and 33.4% for CT (83.13 to 110.92). In 2017, public healthcare accounted for 81% of PET/CT examinations, 61% of MR studies, 87% of SPECT examinations, and 83% of CT.
Conventional radiography and mammography also increased their examination rates by 9.9% and 38.1%, respectively. Conversely, digital angiography and scintigraphy decreased by 1.8% and 12.5%. All modalities except conventional radiography and scintigraphy increased the number of scanners/rooms per million inhabitants.
Conclusion: All diagnostic imaging modalities significantly increased the number of examinations per 1,000 inhabitants in Spain between 2010 and 2017, except digital angiography and scintigraphy.
Limitations: This is an observational study for a period of 8 years. Data should be used carefully due to amount of aggregation.

The effect of changing the method of teaching radiology to interactive clinically-based learning on the achievements of medical students in imaging

U. Wachsman, I. Shelef, Y. Lior, G. Ben- Arie; *Beer-Sheva/IL (gal_b_a@yahoo.com)*

Purpose: To evaluate the efficacy of changing teaching methods in the 4th year medical school radiology course from lecture-based teaching to interactive clinical case-based teaching.
Methods and materials: We compared the assessments in the radiology course taken from 4th year medical students during 2018-2019. In the first year, teaching was primarily done via conventional lectures. In the following year, case-based teaching with interactive web application named “NEARPOD” was employed to motivate student participation. The student knowledge assessments were comprised of identical post-test questions, encompassing 5 images of common diagnoses such as pneumothorax, pneumonia, normal chest x-ray (CXR), subdural haematoma, and ischaemic stroke. We also compared

pre- and post-tests taken in the later year, similarly, composed of 5 different images of common radiographic diagnoses.
Results: 72 students answered the post-test in the first year and 50 students answered in the following year. 55 students answered the pre-test in that year. Post-test student achievements following the methodological changes were significantly higher when compared with the control group (p <0.001). Students provided positive feedback to the methodological teaching changes.
Conclusion: Our study shows that teaching radiology in a clinical case-based manner, combined with web-based interactive applications, results in significant improvements, specifically in identifying key imaging pathologies, as compared to conventional lecture-based teaching.

RPS 1305-5 08:54
Professional social media use is associated with having received advanced scientific training: results from an international survey in 1,041 radiologists and residents
M. Huisman[1], E. R. Ranschaert[2], W. Parker[3], D. Mastrodicasa[4], M. Kočí[5], D. Pinto Dos Santos[6], T. Leiner[1], M. J. Willemink[7]; [1]*Utrecht/NL,* [2]*Turnhout/BE,* [3]*Vancouver/CA,* [4]*Stanford, CA/US,* [5]*Palo Alto, CA/US,* [6]*Cologne/DE,* [7]*Menlo Park, CA/NL (merel.huisman1@gmail.com)*

Purpose: Social media use has increased substantially over the last decade, particularly in medical professional fields. We intended to characterise current social media use for professional purposes in the international radiology community.
Methods and materials: A web-based survey was accessible from April to July 2019 and included questions on demographics, professional background, and social media use. Multivariable logistic regression was used to assess independent predictors for professional social media use.
Results: Participants (n=1,041) were working in 54 different countries, mostly Europe (n=867, 83%). Slightly more than half (n=553, 53%) indicated the use of social media for professional purposes. Among participants who used social media, LinkedIn was most frequently mentioned (n=360, 65%), followed by Facebook (n=199, 36%), Twitter (n=115, 21%), and Instagram (n=99, 18%). Professional social media use was inversely associated with age (OR 0.98 (0.97-0.99), p<0.001), and positively associated with advanced scientific training (PhD/research fellowship; OR 1.65 (1.24-2.18), p<0.001) after adjusting for gender and region. There were no significant differences in professional social media usage between residents, fellows, and radiologists; academic and non-academic participants or gender. Male gender was a predictor for Twitter use (p<0.05), female gender for Instagram use (p<0.05). Working in Europe was a predictor for Twitter and Instagram usage (p<0.001). Advanced scientific training was a predictor for LinkedIn and Twitter (p<0.001). There were no predictors for Facebook.
Conclusion: Our international survey indicates radiologists and residents with advanced scientific training more frequently use social media for professional purposes, especially LinkedIn and Twitter. European radiology professionals more frequently use Instagram or Twitter for professional purposes.
Limitations: "Social media use for professional purposes" is subjective as indicated by the participants.

First peer review experience among a French teleradiology community
M. Schertz[1], E. Morau[2], G. Sozeau[2], M. Cavet[1]; [1]*Paris/FR,* [2]*Montpellier/FR (schertzmathieu@hotmail.fr)*

Purpose: Peer review is seldom reported in France and double reading has been recommended in teleradiology. We therefore report our peer review experience among a community of teleradiologists.
Methods and materials: Peer review was performed anonymously and on a voluntary basis. Over one year, randomised CT and MRI cases were reviewed within our RIS-embedded system. The rate of review, discrepancies, doctor's participation, and satisfaction were reported. The discrepancy scoring system derived from the RADPEER program.
Results: Over a period of one year, 1,691 (1.1%) of 155,879 cases were reviewed: 89.7% (1,517) were qualified as concordant, 6.0% (102) as a minor discrepancy, 4.3% (72) as a major discrepancy, and 3.4% (54) as major discrepancies likely to be clinically significant.
52 of 65 radiologists (80%) participated in the review. 85% of them were overall satisfied with the peer review system, 88% felt that being reviewed was beneficial for them, 48% felt that reviewing others was beneficial for them.
All discrepancies likely to be clinically significant were consensually revised and the updated conclusions shared with the referring clinicians.
Conclusion: We highlight the feasibility of peer review on a voluntary basis within our network of teleradiologists. The recorded rate of discrepancies likely to be clinically significant was below the rates previously published (4). Participation and satisfaction among radiologists were high.
We therefore recommend the continuation of peer review in our community and encourage other teams to do so.

Innovation in radiology using a needs-based approach: clinical radiologists' experience
R. A. Rippel, A. El-Zein; *Oxford/UK (radoslaw.rippel@gmail.com)*

Purpose: To present our experience and promote the learning and utilisation of a needs-based innovation approach in clinical radiology.
Methods and materials: Need-based innovation is a methodology enabling a structured approach to screening for problems worth pursuing followed by a thorough system for idea generation and product development.
Oxford Biodesign offers two programmes which focus on a systematic approach to clinical-needs finding. Fellowship is a 9 month full immersion course taking participants from observations, through clinical needs finding, needs assessment, generation of solutions, stakeholders assessment, and market research, all the way to prototyping and start-up with seed funding. The short programme follows a similar curriculum, however, it is run as a series of two-hour interactive sessions once a week during the academic year.
Results: Needs-based innovation is a systematic approach to problem-finding and solution generation which is well-tailored to the complex and high-barrier entry field of medical device and digital health industries. Clinician participation in the programme not only enables the team to benefit from the clinical insight but also enables the clinician to experience a broader view of healthcare and different cognitive approach to the clinical environment. In this presentation, we will demonstrate our project outcomes and their potential impact on clinical practice. In addition, we showcase our experience of participation in both of the programmes as well as the road to innovation in radiology.
Conclusion: Radiology is a rapidly developing, technology-based clinical speciality. Use of the systematic need led innovation is an effective way to guide radiologists and develop collaborations focused on medical innovation, including digital health and medical device development.
Limitations: n/a
Ethics committee approval: n/a
Funding: The Oxford Biodesign Programme is supported by institutions such as the European Institute of Innovation and Technology (EIT).

Challenges, opportunities, and strategies of global health radiology in low-middle income countries (LMIC): an excerpt review
S. L. Shem[1], H. Umdagas[2], F. B. Nkubli[3], D. Z. Joseph[4], M. Z. Ibrahim[2]; [1]*Gombe/NG,* [2]*Zaria/NG,* [3]*Maiduguri/NG,* [4]*Kano/NG (samuelshemm@gmail.com)*

Purpose: More than half of the world's population lacks adequate medical imaging services according to the World Health Organisation (WHO). However, radiology plays an important role in public health initiative programs such as tuberculosis, trauma, breast cancer screening, and maternal-infant health. The purpose of this study was to identify challenges, opportunities, and strategies of

radiology in global health initiatives in low-middle income country where resources may be scarce.
Methods and materials: White paper reports of RAD-AID conferences on international radiology for developing countries since inception in 2009 were reviewed. Additionally, resources from national and international organisations that published data such as the World Bank and the World Health Organisation (WHO) were reviewed, as well as the medical literature databases from the Cochrane Library and PubMed. Search terms such as global health radiology, challenges, and strategies were used.
Results: Establishment and sustainability of medical imaging services was a major long-standing challenge of radiology global health initiative programs in many low-income countries. To overcome this barrier, certain components of sustainability were identified as strategies to the implementation and optimisation of radiology services including economic development, technological innovation, clinical imaging models' implementation, educational approaches, and the integration of public health to radiology.
Conclusion: Components of radiology global health initiative programs should consider economic sustainability, information technology innovation, tested clinical models, education, and public health policies as keys to optimising radiological services in low middle-income countries.
Limitations: No known bias.

First national teleradiology pilot project in the Saudi Ministry of Health
S. Alshaikh[1], A. Aldosari[1], H. Alasmari[1], M. Almuaiqel[1], M. Mutabi[1], Q. Alalwan[2], A. F. T. Gashgari[3]; *[1]Riyadh/SA, [2]Al-Hassa/SA, [3]Dammam/SA (salshaikh@moh.gov.sa)*

Purpose: The need for high-quality radiology reports is necessary for accurate and better diagnosis. However, due to the lack of subspecialised consultant radiologists in the Ministry of Health remote hospitals, this is a real challenge. The need for qualified medical physicists is another major concern for image quality assessment. Moreover, the impact of technologists and imaging protocols was investigated. The goal of this project is to establish a National TeleRadiology Platform (NTRP) to provide high-quality radiology reports for remote hospitals.
Methods and materials: The NTRP has been established to provide a centralised national radiology reporting system for remote hospitals. All remote hospitals send their radiology CT and MRI cases to one pool at the NTRP. The radiologists from all referral hospitals can access the pool remotely via NTRP for reporting. The final report is sent back to the remote hospitals within a pre-defined turn-around time (TAT). The reimbursement for radiologists' workloads has been estimated using the relative value unit (RVU). The NTRP serve routine cases and urgent cases were covered as a second opinion.
Results: The number of reported cases per month increased from 130 reports in July 2018 to 1,360 reports in September 2019. The percentage of reported cases performed with CT and MRI modalities were 65% and 35%, respectively.
Conclusion: The quality of reports was improved for remote hospitals. The clinicians started to request advanced exams with advanced protocols for subspecialised cases. The referrals from these hospitals to do subspecialided exam is no longer needed, in addition to the direct cost saving on hiring subspecialised radiologists. Based on the promising outcomes, the service was expanded from 10 to 20 remote hospitals.

RPS 1305-10 09:24
Relative value unit system: a new approach for quantifying radiologists' workloads
S. Gelmez; *Istanbul/TR (sgelmez@yahoo.com)*

Purpose: Proper understanding and accurate quantification of the workload of radiologists is needed to effectively plan the workflow. Relative value unit (RVU) systems are used to assign values to radiologists' activities. Different methods, mainly based on reporting times, are used in various countries to create RVU tables. In this study, a more comprehensive method, taking in more input variables in accordance with the complexity level of local case-mix data, was used to assign RVUs.
Methods and materials: A total of 20 radiologists from 3 linked hospitals analysed the radiologic examinations from the reporting perspective and stated the subjective mean exam RVU and exam subgroup RVUs of 34 different types of CT, MRI, and ultrasonography examinations. Time and experience needed, extra time and effort that should be spent completing a report, and potential medicolegal issues associated with the reporting were considered in the assessment. In order to address the inherent variability of the workload, radiologic examinations were subgrouped according to the complexity level of the examination. Final exam RVU's were determined using the median as the central tendency because the data was skewed. RVU tables were generated according to the results.
Results: The workload of radiologists is difficult to measure. Reporting time based measurements have got many procedural bias. Variability and the complexity levels of the radiologic studies should be addressed to correctly assess the RVUs.
Conclusion: Working further on different local units is advised and the local units should be classified in order to create more accurate global RVU tables.
Limitations: The main concern in this study is the local case-mix data, so the final RVUs may not be representative of global or other local units.
Ethics committee approval: Ethics committee approval obtained.
Funding: No funding was received for this work.

RPS 1305-11 09:30
Data mining of metrics from a report comparison tool can reveal daytime and shift dependent trends in the quality of residents' reports
J. Vosshenrich, I. Nesic, J. Cyriac, D. Boll, E. M. Merkle, T. Heye; *Basel/CH (jan.vosshenrich@usb.ch)*

Purpose: To investigate the feasibility of detecting daytime and shift dependent trends in residents' reporting with the help of a report comparison tool.
Methods and materials: In 2017, we developed a report comparison tool tracking changes between residents' preliminary and final reports signed by staff radiologists on a word level. Additional quantitative metrics (e.g. similarity index (0 to 1) and the ratio of added words) are automatically calculated for each report and stored in a local database.
Data for all CT reports from 2018 was retrieved along with metadata of the reported exams (e.g. date and time). Following data aggregation per weekday and shift (day-, late-, and night-shift), analysis was performed using trending line graphs.
Results: While trending line graphs of the mean report similarity, the mean number of added, and the mean number of deleted words from preliminary reports remained relatively stable over the week during day-shifts, a gradual decrease in the mean report similarity from 0.87 to 0.35 could be observed for reports created by residents over the course of their week of night-shifts (residents in our department perform 7 night-shifts in a row). The accompanying continuous rise in the mean number of added words suggests an increase in overlooked/misinterpreted findings.
When looking at the acquisition time of reported exams, a slight decrease in report similarity was observed during day-shifts in the afternoon on several weekdays. The similarity was also frequently lower in late-shifts compared to day-shifts.
Conclusion: Our results show that data mining from report comparison tools can reveal shift dependent trends in the completeness of preliminary reports and may be used as a quality measure or even indicator of a necessary rescheduling of radiologists' shifts to maintain high report quality.

RPS 1305-12 09:36
MR site assessment using a Power BI-based reporting platform
P. Szatmari, R. Illing, L. Refi*; Budapest/HU*

Purpose: To monitor and report the performance of MR installations using a Power BI-based reporting platform.
Methods and materials: A vendor-neutral analytics tool (the 'agent') has been developed for use on selected magnetic resonance imaging (MRI) systems to monitor protocols used, image quality, and operational metrics. Data from these systems are collated centrally and displayed on a PowerBI interface (Microsoft, Redmond, USA). Reports generated from the interface are generated and distributed to a network of 210 personnel every month; the system also allows data access for the users on a web-based and a mobile-based platform for those requiring real-time access. The processed data is used by the operational and clinical management to evaluate and optimise the performance on both the country and centre level. Operational teams have used one of these metrics ('time between scans') to target centres in which efficiency gains could be made.
Results: The agent has been installed on a network of 112 MR systems in 11 countries. By using this data, the team in Lithuania, operating 9 MR systems, have been able to make proactive operational improvements, increasing the number of patients from 27.64 per day to 28.32 per day, and the machine utilisation rate from 75.75% to 79.91%, on average. On a price per scan basis of Eur119, this works out to be a gain of Eur19 420 overall for the country network per year.
Conclusion: By combining Power BI-based reporting and operational improvement methods, efficiency gains can be made, increasing utilisation by 4.16% or Eur19 420 per year.

Value-based workflow in radiology: what to expect from the PACS orchestrator
C. C. C. Quattrocchi, P. D'alessio, G. Carosi, I. Galdino, A. Ricciardi, C. A. Mallio*; Rome/IT (c.quattrocchi@unicampus.it)*

Purpose: To assess the impact of the PACS orchestrator management platform on the workflow of an imaging centre in terms of efficiency, workload, and turn-around times.
Methods and materials: This study was not subject to review by the institutional ethical committee as data was collected from those archived by the RIS-PACS of the hospital within a quality improvement initiative. Data was extracted by means of a tailored statistics output from RIS-PACS of our imaging centre after the implementation of the PACS orchestrator (Philips Healthcare, IT), a management platform embedded in the PACS. The following key performance indicators (KPI) of workflow were used: number of patients per full-time equivalent radiologist (FTE), number of procedures per FTE, relative value units (RVU)/FTE/year), difficulty index, and turn-around-time. The data was compared with earlier data (Jan 2017-Aug 2019) extracted from RIS at our institution.
Results: We showed the changes measured on the key performance indicators after the implementation of the PACS orchestrator, with statistical analysis of data compared with a period of two years of data collected in our institution as part of the institutional quality improvement program.
Conclusion: Management platforms show promise in increasing process capability in terms of individual workloads and turn-around times in radiology, and to expand the frame of performance of radiologists to non-clinical domains.
Limitations: A single-institution study where interventions are routinely made to correct for undesired trends of quality, safety and workflow efficiency. The quality of reports was not measured, as we only relied on the number of complaints from patients to the hospital. The average time-based RVUs have their limitations as the study ascribable time may be biased by specific clinical assets.
Ethics committee approval: n/a

RPS 1305-14 09:48
Assessment of the user acceptance of a radiology information system (RIS) and picture archiving and communication system (PACS) at a hospital in Qatar
P. S. Mahajan, A. Sanousi, N. Al Maslamani*; Doha/QA (medmantra.com@gmail.com)*

Purpose: To evaluate user acceptance related to the RIS-PACS implementation in a clinical imaging department. To evaluate the degree to which the 3 constructs (deduced value, appreciated operational simplicity, and change) influence user acceptance and to assess whether socio-demographic variables explain user acceptance.
Methods and materials: User acceptance levels among employees of the clinical imaging department at Al-Khor Hospital were assessed using a modified "model for adoption of technology (MAT)". 54 RIS-PACS questionnaire surveys were put in place to obtain user characteristics data, 6 items for deduced value (DV), 4 items for appreciated operational simplicity (AOS), 4 items for change construct, and 9 items for behaviour (acceptance) construct. Each item on the list used a five-point Likert scale for grading.
Results: DV scored highly (4.31 out of 5), AOS 4.14 points, change scored 4.27, and acceptance level scored 3.88 points. Three constructs explained 42% of RIS-PACS variation in user acceptance, the most significant predictor being change construct explained by 32% of user variation. Users stated that the new RIS-PACS had a great impact on their work as it significantly improved overall service quality. Gender, age, profession, and frequency of RIS-PACS use did not alter the acceptance level. The influence of culture on the level of acceptance of RIS-PACS did not appear to have any influence.
Conclusion: Prior to RIS-PACS implementation, user acceptance should be assessed, as better user acceptance boosts chances of a successful adoption. Training programs are advised prior to its implementation. Healthcare organisations should measure all given factors influencing RIS-PACS acceptance. This will optimise system productivity and help in the realisation of its vast benefits.
Limitations: Reasons for low acceptance levels among particular professional groups and other promising predictors of user acceptance need to be explored.
Ethics committee approval: Ethics committee approval obtained.
Funding: No funding was received for this work.

Problem-specific detailed structured reporting: moving towards intelligent reporting based on musculoskeletal referral guidelines
M. Fatehi[1], A. Sami[2]*; [1]Tehran/IR, [2]Shiraz/IR (mansoor.fatehi@gmail.com)*

Purpose: The current practice of radiology is mostly based on template-driven reporting methods, so structured reporting can produce lengthy reports due to the necessity of completeness of the subparts. But the referring physicians prefer short reports pointing to the most relevant information in a concise manner. The purpose of this paper is to describe the experience of using an automated system to modify the subparts of the reporting template.
Methods and materials: We analysed all MSK guidelines in the ACR appropriateness criteria to achieve a wide range of real clinical problems expected to be solved by the radiologist. We used all MSK reporting templates in the RSNA-ESR library and disintegrated them into sub-templates, each focusing on a particular subset of information. We then mapped each sub-segment of the templates to the list of the clinical conditions and their variants. A system was developed to put the sub-segments together according to the selected clinical condition.
Results: We found 259 clinical condition variants sorted into 29 musculoskeletal referral guidelines. On the other hand, we subdivided 30 RSNA-ESR templates for MSK imaging into distinct modules, summing up to 87 segments. The system could compose flexible templates according to the selected clinical situation, helping the user to adapt the length and content of the template to the needed extent.
Conclusion: The system provides a flexible template builder, intelligently tailored to the clinical condition of the patient, drawn from the request form or entered by the interpreting radiologist, thereby enabling the radiologist to be more efficient in terms of timing and relevance of the report content.
Limitations: For those templates with less extensive details and itemised components, we prepared similar templates following the same concepts.

The added value of molecular genetic group as a prognostic indicator of overall survival and progression-free survival in glioma patients: machine learning based analysis
S. Zhang; *Guangzhou/CN (shui7515@126.com)*

Purpose: Glioma could be categorised as five molecular groups based on three biomarkers: IDH mutation, 1p/19q codeletion, and TERT promoter mutation. We aimed to explore the added value of the molecular group in predicting survival outcome of glioma.
Methods and materials: A total of 573 patients with confirmed glioma between January 1, 2011, and December 31, 2016, were included. The clinical and imaging findings and molecular biomarkers were retrospectively collected for analysis. An improved causal assumption inferring algorithm from the additive noise model was employed to discover the risk factors combination for progression-free survival (PFS) and overall survival (OS). Cox regression and seven machine learning models with 10-fold cross-validation were developed to predict PFS and OS based on the discovered risk factors. AUC was used to compare the prognostic performance of models.
Results: WHO grade, tumour location, and the molecular group were the three risk factors for PFS and OS. The support vector machine model achieved the highest AUC of 0.835 (95% confidence interval [CI]: 0.802-0.864) in predicting PFS and 0.871 (95% CI: 0.840-0.897) in predicting OS. The addition of the molecular group to the models could improve the predictive performance and the naive Bayes model obtained the highest AUCs of 0.854 (95% CI: 0.822-0.882) and 0.894 (95% CI: 0.866-0.918) in predicting PFS and OS, respectively.
Conclusion: The results showed good performance of machine learning-based clinical models for survival outcome prediction in glioma. The accuracy of clinical models could be increased by combining molecular group.
Limitations: We did not perform external validation with independent datasets for generalisation.
Ethics committee approval: This retrospective study was approved by the local Institutional Review Board before data collection and analysis.
Funding: No funding was received for this work.

RPS 1405a-2 11:31
Machine learning-based MRI texture analysis for predicting 1p/19q codeletion status of lower-grade gliomas
B. Kocak, E. Ş. Durmaz, E. Ateş, I. Sel, S. T. Turgut Güneş, O. Korkmaz Kaya, A. Zeynalova, O. Kılıckesmez; *Istanbul/TR (drburakkocak@gmail.com)*

Purpose: To evaluate the value of the machine learning (ML)-based MRI texture analysis for predicting 1p/19q codeletion status in lower-grade gliomas (LGG), using various ML algorithms.
Methods and materials: For this retrospective study, 107 patients with LGG were included from a public database. 10 different training and unseen test data splits were created using stratified random sampling. Radiomic features were extracted from conventional T2-weighted and contrast-enhanced T1-weighted MRI images. Dimension reduction was done using collinearity analysis and feature selection. Classifications were done using adaptive boosting, k-nearest neighbours, naive Bayes, neural network, random forest, stochastic gradient descent, and support vector machine. Friedman test and pairwise posthoc analyses were used for comparison of classification performances based on the area under the curve (AUC) metric.
Results: Overall, the performance of the ML algorithms was statistically significantly different, $\chi2(6) = 40.46$, $p<0.001$. In the pairwise analysis, 5 algorithms outperformed others, adjusted $p<0.05$. Mean AUC and accuracy values for the top 5 algorithms ranged from 0.813 to 0.871 and from 79.4% to 81.9%, respectively, with no statistically significant difference, adjusted $p>0.05$. The ML algorithm with the highest mean rank and stability was naive Bayes with a mean AUC and accuracy of 0.869 and 80.6%, respectively.
Conclusion: The ML-based MRI texture analysis might be a promising non-invasive technique for predicting the 1p/19q codeletion status in LGGs. Using this technique along with various ML algorithms, more than four-fifths of the LGGs can be correctly classified.
Limitations: Potential and most important limitations of the study are retrospective study design, dependency on the limited data on the public database, and a lack of other MRI sequences.
Ethics committee approval: No ethics committee approval was obtained because this work is based on a publicly available database.
Funding: No funding was received for this work.

Prediction for the grading of stereotactic biopsy glioma targets based on preoperative MRI textural analysis
W. Rui, H. Pang, Q. Xie, Y. Ren, S. Duan, Y. Zhang, Z. Yao; *Shanghai/CN*

Purpose: To explore the value of textural analysis based on T1-weighted brain volume with gadolinium contrast enhancement (T1 BRAVO+C) images for the grading of glioma targets by stereotactic biopsy.
Methods and materials: A total of 36 diffuse glioma cases and 64 puncture targets were included in the study. All patients underwent a preoperative MR scan and intraoperative MR-guided stereotactic puncture biopsy. All cases had a histopathological diagnosis of WHO grade II or III diffuse gliomas. ROIs consistent with puncture targets were delineated on T1 BRAVO+C images and texture features were automatically calculated using Omni Kinetics software. Mann-Whitney rank-sum test was used to analyse texture differences between grade II and III ROIs. ROC curves evaluated the diagnostic value of textural analysis for grading glioma targets. The cutoff value was set according to the Youden index.
Results: Texture features, including max intensity ($P=0.001$), 95th quantile (0.002), range (< 0.001), variance (< 0.001), standard deviation (< 0.001), sum variance (0.022), and cluster prominence (< 0.001) were higher in grade III gliomas than grade II. Whereas, grade II gliomas showed increased uniformity ($P=0.001$) and short-run low grey-level emphasis values (0.018). Diagnostic efficiency of high-order grey-level run-length matrix features was slightly lower than first- and second-order features. AUC was 0.887 (95% confidence interval: 0.805-0.969, $P<0.001$) with combined texture features.
Conclusion: Textural analysis of T1 BRAVO+C images is valuable for grading glioma (WHO II and III) and may help in guiding artificial intelligence selection of preoperative puncture targets.
Limitations: Biopsy samples couldn't achieve 100% “point to point”.
Ethics committee approval: Institutional Review Board approval was obtained. All included patients signed written informed consent.

Glioma segmentation in sparse label applications: a federated learning solution
S. Niehaus[1], L. Lampe[1], A. Merola[2], G. Mihai[2], J. Reinelt[2], N. Scherf[3]; [1]*Berlin/DE,* [2]*Leipzig/DE,* [3]*Dresden/DE (sebastian.niehaus@aicura-medical.com)*

Purpose: Accurate tissue segmentations are essential for clinical applicability. We propose an improved approach to segmentation using federated learning for the decentralised training of a convolutional neural network (CNN) on heterogeneous MRI datasets of glioma patients.
Methods and materials: We split the BRATS-dataset (braintumorsegmentation.org) into three virtual hospitals (VHs) and added a fourth VH with data from a subsample of 121 patients of a publicly available

dataset (figshare.com/articles/brain_tumor_dataset/1512427). Two VHs (54 and 69 patients respectively) have contrast-enhanced T1-weighted MRIs with five classes [necrosis (N), oedema (E), enhancing tumour tissue (ETT), non-enhancing tumour tissue (N-ETT), and background]. One VH has only a binary segmentation map (61 images). The last VH has only unlabelled data (120 images). We trained the CNN with a federated learning setup without central data aggregation. In each VH where segmentations were available, a segmentation model was trained. An autoencoder was trained in each VH to learn volume reconstruction. Noise and rotation were used for data augmentation. In the federated learning merging process of the different models, only the decoder path of the CNN was combined into a global model.
Results: For the evaluation, we used the Dice similarity score and evaluated the performance classwise. The CNN trained with federated learning [evaluation score: 0.43 (N), 0.56 (E), 0.34 (ETT), and 0.74 (N-ETT)] outperformed results obtained with a baseline model [0.28 (N), 0.38 (E), 0.29 (ETT), and 0.54 (N-ETT)] trained in a single VH.
Conclusion: The proposed federated learning setup is superior for training CNNs on radiological data with sparse labelling, improving performance, and allowing for the use of larger datasets without compromising patient confidentiality.
Limitations: The experiments are limited to a single modality.

Deep learning radiomics algorithm for glioma (DRAG) for predicting survival in gliomas
A. Mahajan, S. Rane, U. Baid, M. Akolkar, S. Talbar, A. Moiyadi, S. Gupta*; Mumbai/IN (drabhishek.mahajan@yahoo.in)*

Purpose: Segmentation of brain tumours from multi-modal MR imaging remains a challenge and deep learning has a potential role in diagnosis, prognosis, and survival prediction. The project aimed at tumour segmentation and finding potential radiomic features for predicting overall survival.
Methods and materials: The proposed method was trained and validated on BRATS 2018 dataset. We developed a patch-based 3D-Unet model for tumour segmentation and evaluated the efficiency of radiomic features for overall survival prediction. Radiomic features were extracted from all four MR modalities for OS prediction. The training dataset included 210 high-grade-gliomas (HGG) and 75 low-grade-gliomas (LGG), while the validation set consisted of 66 cases. The trained model was validated on 191 sets of patient data from our hospital.
Results: All 285 training datasets were used in the model training process. The results were based on all 46 validations dataset. The final mean Dice indexes of the enhanced tumour (ET), whole tumour (WT), and tumour core (TC) were 0.75, 0.89, and 0.81, which shows our approach outperforms other submissions of the BRATS18 challenge. The method achieved good performance with Dice scores of 0.88, 0.83, and 0.75 for whole tumour, tumour core, and enhancing tumour, respectively. For the prediction of survival categories (<300 & >=300 days), the neural network demonstrated an accuracy of 70.2% in the training subset and 62.5 and 63.6% in the validation and testing subsets, respectively. The accuracy was 73% for the entire training dataset. The AUC was 0.799.
Conclusion: Our study demonstrates that transfer learning-based deep features are able to generate prognostic imaging signatures for OS prediction and patient stratification for GBM, indicating the potential of deep imaging feature-based biomarkers in the preoperative care of GBM patients.

Smart protocol: real-time brain MRI pathology detection by deep learning for online protocol control
A. Pai[1], B. Low[1], L. Sørensen[1], M. Lillholm[1], M. D. E. B. Dam[1], R. Lauritzen[1], R. Kashyape[2], M. Nielsen[1]; [1]*Copenhagen/DK,* [2]*Nashik/IN (rskashyape@gmail.com)*

Purpose: Brain MRI protocols are determined prior to the patient entering the scanner and information collected during scanning rarely influences the scanning protocol. Real-time detection of pathologies may guide the choice of MRI sequences most informative for diagnosis while the patient is still in the scanner. Hereby, the scanner may be used optimally, patient discomfort minimised, and downstream reading and reporting prioritised.
Methods and materials: 2 million radiology reports were automatically scanned using natural language processing for pathologies, selecting 5,000 brain MRI studies obtained in collaboration with Medall Diagnostics, India, reflecting the most predominant pathologies; infarcts (hyperacute and acute) and tumours. Infarcts and tumour pathologies were annotated pixel-wise by trained annotators under a radiologist's supervision and quality control. Two sets of MRI brain protocols for clinically normal patients, patients with tumours, and patients with infarcts (and both) were established: A) standard clinical protocol and B) smart protocol (consisting of 4 base sequences and up to 2 additional specialised pathology specific sequences).
Results: On an independent dataset of 88 scans, the turn around time from scanning a sequence to reporting results back to the hospital system was less than 60 seconds. The specificity and sensitivity for detection was for tumour 95% (88-99%) and 78% (52-94%), and for infarcts 75% (63-85%) and 100% (83-100%). In a study with simulated protocols, on an average, 1.25 fewer sequences were acquired per patient and an overall 0.23 specialised sequences were missed for patients with pathology.
Conclusion: Turn around time is sufficiently low to influence protocol selection in clinical practice. Accuracy and fewer sequences acquired allow for the informing of the MRI operator, potentially saving scanner time, contrast administration, and patient recall. This has led to a trial installation in several hospitals.

RPS 1405a-7 12:01
Classifying brain metastatic disease by an unknown cancer primary organ site using whole-brain clinical MRI data: a 3D convolutional neural network approach
S. Namjoshi, E. McTyre, M. Chan, C. Cramer, G. Lesser, R. Strowd, S. Tatter[1], W. Zhang, C. T. Whitlow*; Winston-Salem, NC/US (cwhitlow@wakehealth.edu)*

Purpose: Treatment decisions for brain metastatic disease are driven by knowledge of primary organ site cancer histology, which can require invasive biopsy. We propose an automated deep learning algorithm and image-preprocessing pipeline for rapid non-invasive imaging-based identification of brain metastatic tumour histology based on conventional whole-brain T1-weighted MRI data. Using whole-brain data obviates the need for brain tumour segmentation, which can be time intensive. We hypothesise that whole-brain imaging features will be sufficiently discriminative, allowing for accurate diagnosis of the primary organ site of malignancy.
Methods and materials: This single-site retrospective diagnostic study was comprised of patients (n=1,302) referred for gamma knife radiosurgery from July 2000 to May 2019. Contrast-enhanced T1-weighted brain MRI exams (n=2,104 MRIs) acquired from these patients were minimally preprocessed (voxel resampling and signal intensity rescaling/normalisation), requiring only seconds per MRI dataset, and used to train a 3D convolutional neural network (CNN) for determining the primary organ site associated with brain metastatic disease in one of three classes (breast, lung, and melanoma).
Results: After nested 10-fold cross-validation, our algorithm achieved best AUCs of 0.987 [95%CI: 0.983,0.991] (breast vs lung) and 0.988 [95%CI: 0.984,0.991] (lung vs melanoma). Although breast versus melanoma demonstrated low AUC with images alone (0.550), the algorithm performed better after the incorporation of demographic data (AUC = 0.704).

Conclusion: Our results demonstrate a robust CNN algorithm for effectively classifying metastatic tumour histology types for breast and lung based on conventional whole-brain MRI, without need for tumour segmentation. Further refinement may offer an invaluable tool to expedite primary organ site cancer identification for brain metastatic disease and perhaps improve patient outcomes and survival.
Limitations: Limitations include relatively small sample size and our retrospective approach from a single institution.
Ethics committee approval: IRB-approved.

Can we predict a brain metastases primary site by using deep learning algorithms, even in small datasets?

Y. Çuşkun[1], B. Alparslan[1], K. Kaplan[1], F. Çalışkan[1], O. Tavas[1], E. Dervişoğlu[1], H. M. Ertunç[1], A. K. Sivrioglu[2]; [1]*Kocaeli/TR,* [2]*Istanbul/TR (burcu.alparslan@gmail.com)*

Purpose: To investigate the feasibility of deep learning algorithms in the classification of brain metastases according to their origin.
Methods and materials: 177 patients with brain metastases from lung cancer (n=99), breast cancer (n=44), and other cancer types (n=37) were evaluated in our single-centre retrospective study. The dataset was derived by radiologists from pretreatment brain MR images of patients including 4 sequences: pre- and postcontrast T1-weighted spin-echo (T1W SE), fluid-attenuated inversion recovery (FLAIR), and apparent diffusion coefficient (ADC) maps. Since the sequence plans were different from each other, a 4-path convolutional neural network (CNN) had been developed in which the sequences images were given separately to the algorithm. We used 124 patients' data for training and 53 patients' data for testing in our 3-class (lung, breast, and others) and 2-class (lung and breast) CNN models.
Results: The accuracy of classification in the 3-class model was 74.07%, the area under the ROC curve (AUC) for lung cancer class was 0.87, for breast cancer 0.89, and for the others group 0.75. The two-class model had a higher accuracy of 81.48% and AUC of 0.76.
Conclusion: Deep learning algorithms using multisequence MRI can give satisfactory results in classifying brain metastases even in small datasets. What about with 'big data?'
Limitations: A small dataset.
Ethics committee approval: The study was approved by Kocaeli University institutional review board.
Funding: No funding was received for this work.

Deep convolutional neural network for automated segmentation of brain metastasis trained on clinical data acquired during six years of stereotactic radiosurgery

K. Bousabarah, P. D. M. Kocher, P. D. M. Ruge, J.-S. Brand, P. D. V. Visser-Vandewalle, D. H. Treuer; *Cologne/DE*

Purpose: Deep convolutional neural networks (DCNN) have demonstrated enormous performance in many segmentation tasks in medical imaging. Brain metastasis, with their large variability in imaging appearance, remain a challenge. To properly evaluate the clinical performance of a state-of-the algorithm in this task, we collected a clinically representative set of imaging data acquired for stereotactic radiosurgeries between 2013 and 2019.
Methods and materials: Registered MR images (contrast-enhanced T1, T2, and FLAIR) and the contour data containing the delineated lesions were restored from our treatment planning system. The data (509 patients with 1,223 metastasis) was split into a training (469 patients) and a test (40 patients) set. Ground truth segmentations on the test data were individually checked by a senior oncologist with 25 years of experience (MK). In addition to a conventional U-Net, a U-Net with multiple outputs (moU-Net) and a U-Net (sU-Net) only trained on small lesions (< 0.4ml) were employed.
Results: The U-Net, moU-Net, and the sU-Net detected brain metastasis with a sensitivity of 69%, 69%, and 51%, respectively. The sU-Net performed better at detecting small lesions (64% sensitivity) compared to the conventional U-Net (48%) and the moU-Net (48%). An ensemble of those networks had a sensitivity of 79%/74%, with a mean false-positive rate of 0.8/0.175 and a mean Dice score of 0.7/0.71, depending on if the segmentations were merged through summation or averaging.
Conclusion: We demonstrated that DCNNs trained on data collected during clinical practice produce state-of-the-art results and that in-house development of such algorithms is a feasible option. It was furthermore shown that a single network fails to generalise and that an ensemble of differently trained networks is superior.
Limitations: A single-centre study.

RPS 1405a-10 12:19

CNN based deep learning enhances 3D FLAIR brain perceived quality, SNR, and resolution at ~30% less scan time

L. N. Tanenbaum[1], S. Bash[2], W. Gibbs[3], L. Wang[4], H. Gandhi[4], P. Gulaka[5], A. Shankaranarayanan[6], T. Zhang[7]; [1]*Riverside, CT/US,* [2]*Los Angeles/US,* [3]*Pasadena/US,* [4]*Palo Alto/US,* [5]*Menlo Park/US,* [6]*Waukesha, WI/US,* [7]*Menlo Park, CA/US (nuromri@gmail.com)*

Purpose: To evaluate the capability of deep learning (DL)-based image processing of brain MRI to improve quality while reducing acquisition times.
Methods and materials: With IRB approval and patient consent, 11 patients (age: 48+/-15 years; 7 female) undergoing clinical brain 1.5T MRI exams underwent an accelerated sagittal 3DFLAIR scan (average scan time reduction 27.1%+/-3.5%) in addition to the institution's routine protocol, which included a submillimeter isotropic 3DFLAIR. A third image set was created by processing the faster series with an FDA-cleared CNN-based DL algorithm (SubtleMR™). The 3 sets (standard series (SS), accelerated series (AS), and DL processed accelerated series (DL)) were randomised and presented side-by-side for pair-wise comparisons (33) and evaluated for relative (1) image sharpness, (2) perceived SNR, and (3) lesion/anatomy conspicuity. Each series was also independently scored on overall quality. A two-sided paired t-test was performed for overall image quality, with $P<0.05$ considered statistically significant. Average image preference and 95% confidence interval were calculated for each paired series and reader.
Results: Overall quality scores (SS/AS/DL) were 4.0/3.1/5.0, 4.0/3.2/5.0, and 4.8/4.5/5.0 for reader 1-3. Paired t-test results suggested that DL is significantly better than SS ($P<0.05$) for reader 1 and 2, but not for reader 3 ($P=0.10$). When presented side-by-side, DL is superior (significantly superior for reader 1 and 2, mildly superior for reader 3) for image sharpness, perceived SNR, and lesion/pathology conspicuity when compared with SS or AS.
Conclusion: CNN-based DL image processing of 3DFLAIR brain MRI produces a boost in perceived image quality, SNR, and resolution despite a ~30% reduction in scan time.
Limitations: A limited number of subjects and imaging methods tested.
Ethics committee approval: Approved by IRB.

Brain metastases in malignant melanoma: fully automated detection and segmentation on MRI using a deep learning model

L. Pennig[1], S. Lennartz[1], L. Goertz[1], F. Thiele[2], M. Perkuhn[1], J. Borggrefe[1], L. Caldeira[1], K. R. Laukamp[1]; [1]Cologne/DE, [2]Aachen/DE
(lenhard.pennig@uk-koeln.de)

Purpose: Given the growing demand for magnetic resonance imaging (MRI) of the head in patients with malignant melanoma and consecutively associated workload, physician fatigue with the inherent risk of missed diagnosis poses a relevant concern. The automatisation of detection and segmentation of brain metastases could serve as a tool for lesion preselection and assessment of therapeutic success in an oncological follow-up. The purpose of this study was the development and evaluation of a deep learning model (DLM) for fully automated detection and segmentation of brain metastases in melanoma patients on multiparametric MRI, including heterogenous data from different institutions and scanners.
Methods and materials: In this retrospective study, we included MRI scans (05/2013-10/2018; T1-/T2-weighted, T1-weighted contrast-enhanced (T1CE), T2-weighted fluid-attenuated inversion recovery) from 54 melanoma patients (mean age 63.54±13.83 years, 24 females) with 102 metastases at initial diagnosis. Independent manual segmentations of the metastases (based on T1CE) in a voxel-wise manner by two radiologists provided the ground truth of metastases count and segmentation. A 3D convolutional neural network (DeepMedic, BioMedIA) initially trained on glioblastomas was used receiving additional dedicated training applying five-fold cross-validation (5-FCV). For comparison of segmentation accuracies, Dice coefficients were calculated.
Results: The mean size of metastases was 2.35±7.81 cm^3 [range: 0.003–66.6 cm^3]. The glioblastoma DLM achieved a detection rate of 0.47 and a reasonable segmentation accuracy (median Dice: 0.64). After 5-FCV training, detection rate 0.87 ($p<0.001$) and segmentation accuracy (median Dice: 0.74, $p<0.05$) increased.
Conclusion: After dedicated training, our DLM detects brain metastases of malignant melanoma on multiparametric MRI with high accuracy. Despite small lesion size and heterogenous scanner data, automated segmentation achieved good volumetric accuracy compared to manual segmentations.
Limitations: A retrospective study.
Ethics committee approval: Ethics committee approval obtained and consent waived.
Funding: No funding was received for this work.

The application of model-adaptive artificial intelligence algorithms in breast ultrasound imaging

A. Abate[1], R. Giovanazzi[2], C. Di Bella[2], S. de Beni[3], S. D'onofrio[3], M. Cereseto[3], G. Querques[2], V. Besostri[4], R. Corso[2]; [1]Lesmo/IT, [2]Monza/IT, [3]Esaote/IT, [4]Pavia/IT (abate.anna75@gmail.com)

Purpose: Application of model-adaptive artificial intelligence (AI) algorithms in breast ultrasound (US) to improve diagnostic confidence and optimise daily clinical workflow.
Methods and materials: In 6 months, 50 female patients (mean age:45 ys) underwent breast US, using MyLab9 system (Esaote, Italy) with electromagnetic-tracking options (BreastNav), linear transducer (L4-15) with dedicated tracking sensor. On 11 patients, with a benign nodule detected for the first time, US follow-up examination was performed after 3 months with BreastNav that reproduces on a virtual-model the actual morphology of the patient's breast. Furthermore, BreastNav allows re-evaluation on follow-up US or US-guided biopsy procedures, the area previously highlighted by a target.
Results: Before US examination, a registration phase between the virtual-model and US was performed and 6 anatomical markers were selected. The model automatically adapts the shape of the breast to provide 1:1 correlation in "real-time" with US. BreastNav records 3D-US datasets and reproduces their positions on a virtual-model, reshaping it according to the pressure applied by the probe and providing immediate visual feedback on where US has been performed. Moreover, it is possible to put a target on the lesion and save it with the patient's study. During follow-up US, BreastNav technology shows the previously saved target, US reference image, and probe position in order to quickly identify the interested lesion. Furthermore, traffic-light feedback helps to identify the exact transducer spatial position to reach the archived target. In all patients, BreastNav correctly traced through AI-modelling technique the lesion indicated by the target, even with different breast morphologies and patient's position.
Conclusion: The AI algorithm of BreastNav technology supports follow-up examination of breast lesions, providing a visual feedback (target, probe position, and inclination) and simplifying clinical workflow.

Classification of benign and malignant breast lesions using ultrasound shear wave elastography features: a non-black-box machine learning approach

A. Angelakis[1], H. Sportouche[2]; [1]Athens/GR, [2]Aix-en-Provence/FR
(ath.angelakis@gmail.com)

Purpose: To tune a non-black-box robust machine learning model on a relatively big, heterogeneous and multicentric data-set including shear wave elastography (SWE) features in order to classify benign and malignant breast lesions achieving high specificity and sensitivity.
Methods and materials: The data-set consisted of 1,989 breast lesions (995-994, benign-malignant determined by cytopathology or follow-up) coming from 16 European/American and 22 Asian centres with BI-RADS 2-5 scores. Features of the initial data-set were age, palpability, mobility, SWE lesion shape, and homogeneity of the mass. From measures on 3 SWE images we also included the SWE lesion dimension, the maximal and mean SWE values in Q-Box areas on lesion and fatty tissue, and the ratio of mean SWE values on lesion versus fatty tissue. We used feature engineering and tuned a CatBoost classifier of 97 iterators of depth 11.
Results: The performance of a 10-fold Cross-Validation was: sensitivity: 0.8732, specificity: 0.8983, and ROC-AUC: 0.8858 with 95% CI [0.849 - 0.930]. On an unseen validation dataset, the model's performance was: sensitivity: 0.8918, specificity: 0.8963, and ROC-AUC: 0.8941. The BI-RADS performance was: sensitivity: 0.9758, specificity: 0.5175, and ROC-AUC: 0.7466, and on the validation data-set was: sensitivity: 0.9837, specificity: 0.5233, and ROC-AUC: 0.7535. The SWE Emax performance was: sensitivity: 0.8490, specificity: 0.8182, and ROC-AUC: 0.8336, and on the validation data-set: sensitivity: 0.8864, specificity: 0.8031, and ROC-AUC: 0.8447.
Conclusion: In this study, we used a heterogeneous data-set of breast lesions and we tuned a gradient boosted tree classifier trained on SWE features. It achieved high classification scores outperforming conventional approaches (BI-RADS and SWE cut-off value). The model's result may be considered from radiologists during an examination's medical report.

Quantitative analysis of contrast-enhanced ultrasound imaging omics in evaluating the efficacy of adriamycin combined with cetuximab in the treatment of triple-negative breast cancer in nude mice

L. Tang, Q. Liu, M. Chen*; Shanghai/CN (13661657380@163.com)*

Purpose: To evaluate the effect of two-dimensional contrast-enhanced ultrasound (CEUS) on the chemotherapy of triple-negative breast cancer in nude mice and to find out the changes of haemodynamics in the tumours during the treatment.
Methods and materials: A female BALB/c nude mouse model of triple-negative breast cancer was established by human breast cancer MDA-MB-231 cells. Esaote Mylab90 ultrasound instrument and SonoVue contrast agent were used. Contrast-enhanced ultrasound (CEUS) was performed before administration of adriamycin combined with cetuximab on the 1st, 3rd, and 5th day, and before execution on the 7th day. The images were quantitatively analysed by contrast-enhanced imaging omics. On the basis of delineating the tumour boundary, different ROI regions were extracted respectively (more details are shown in the attached picture).
Results: 16 nude mice in the experimental group completed the 7-day experiment, while 5 in the control group failed to reach the 7-day survival period. All parameters basically reflected the characteristics of increasing with the number of days of treatment, which indicated the normalisation of blood vessels in lesions (more details are shown in the attached picture).
Conclusion: MTT, TTP, and BI values in the quantitative analysis of two-dimensional contrast-enhanced ultrasound imaging omics showed an upward trend during the treatment of adriamycin combined with cetuximab, which is expected to be helpful in predicting the efficacy of combined therapy for triple-negative breast cancer and will be more suggestive in the prediction of curative effect.
Limitations: The number of mice used in our experiment is not large enough and there may be selection bias from ultrasound instrument and quantitative analysis software.
Ethics committee approval: Our animal experimental research has been approved by the Animal Ethics Committee of Shanghai Jiaotong University School of Medicine.
Funding: National Natural Science Foundation of China.

Automated assessment of image quality in digital breast tomosynthesis in a screening setting: more positioning errors for women with large breasts

G. G. Waade, A. S. Danielsen, S. Hofvind*; Oslo/NO (gugi@oslomet.no)*

Purpose: To analyse mammographic image quality criteria related to positioning among women in a screening setting.
Methods and materials: An automated software assessed the left mediolateral oblique mammogram from 5,668 women participating in the tomosynthesis trial in Bergen, January 2018-May 2019, to obtain information about image quality. Image quality criteria were defined as nipple in profile, pectoral muscle shape, and inframammary fold (IMF) appearance (its visibility and/or presence of skin folds). We investigated proportions of image quality errors and used a log-binomial regression model to produce adjusted risk ratios (RR) with 95% confidence intervals (95%CI) of image quality errors for women with small (<700cm^3), relative to medium (700-1200cm^3), and large (>1200cm^3) breasts, adjusted for mammographic density (dense versus non-dense) and age.
Results: A total of 3,913 (69%) of the 5,668 mammograms included one or more image quality errors: nipple not in profile (20.1%, 1138/5668), pectoral muscle not straight (32.8%, 1857/5668), and issues with IMF appearance (42.9%, 2434/5668). Women with medium-sized or large breasts had a higher RR of image quality errors compared to women with small breasts (RR: 1.06, 95%CI: 1.01-1.11 and RR: 1.22, 95%CI: 1.17-1.29, respectively).
Conclusion: A large proportion of images contained positioning errors. Women with large breast are more likely to have mammograms of suboptimal image quality compared to women with small breasts.
Limitations: Further research is needed to investigate the clinical implications of these findings.
Ethics committee approval: The Regional Committee for Medical and Health Research Ethics approved the trial (2015/424).
Funding: The trial received funding by the Norwegian Cancer Society (190184-2017).

RPS 1402a-5 11:39

Reading breast tomosynthesis examinations with an AI decision support system: improving cancer detection accuracy

R. M. Mann, A. Rodriguez Ruiz, A. Gubern Merida, N. Karssemeijer, I. Sechopoulos*; Nijmegen/NL (alejandro.rodriguezruiz@screenpointmed.com)*

Purpose: To compare the breast cancer detection accuracy of radiologists reading breast tomosynthesis (DBT) examinations unaided versus supported by an artificial intelligence (AI) system.
Methods and materials: A cancer-enriched, retrospective, fully-crossed, multi-reader, multicase, HIPAA-compliant study was performed. Four-view DBT examinations from 240 women were included. All examinations (in total 71 breasts with cancer lesions, 70 breasts with benign findings, and 339 normal breasts) were interpreted by 9 qualified radiologists (median experience 8 years, range 4-23), once with and once without AI support (Transpara, ScreenPoint Medical). The readers provided a level of suspicion for each breast. When using AI support, radiologists were shown an examination-based cancer likelihood score as well as marked lesions and lesion-based cancer likelihood scores. The area under the receiver operating characteristic curve (AUC) was compared between both reading conditions at a per breast-level, using mixed-models analysis of variance for multiple repeated clustered measurements. Reading time differences for normal examinations were also measured.
Results: On average, the AUC was higher with AI support than with unaided reading (0.861 vs 0.820, respectively; P = .001). The AUC of the stand-alone AI system was similar to the average AUC of the radiologists unaided (0.840 vs 0.820, 95% CI: -0.038, +0.078). Reading time per normal case showed an average reduction of -21% when using AI, with 8 of 9 readers having shorter reading time.
Conclusion: Radiologists improved their cancer detection in breast tomosynthesis examinations when using an AI system for support, while simultaneously reducing reading time.
Limitations: Retrospective laboratory study. Single vendor of AI and DBT images.
Ethics committee approval: HIPAA-compliant.
Funding: Study sponsored by ScreenPoint Medical.

RPS 1402a-6 11:45

Predicting malignant mass in digital breast tomosynthesis using a multi-objective feature selection radiomics model

Z. Fengxia, W. Xu, C. Wen, W. Chen, G. Qin*; Guangzhou/CN (3425262945@qq.com)*

Purpose: To apply a multi-objective feature selection radiomics model that considers sensitivity and specificity simultaneously for predicting the malignancy of the mass-like lesions in digital breast tomosynthesis (DBT).
Methods and materials: A total of 963 cases with diagnosed mass-like lesions were retrospectively used for model training and testing. Patients with infiltrating ductal carcinoma (IDC), ductal carcinoma in situ (DCIS), invasive lobular carcinoma (ILC), adenofibroma, cystic hyperplasia, cyst, and hyperplasia were included. The follow-up time was about 24 months and malignant cases were confirmed by biopsy or surgical pathology. DBT images were contoured and reviewed by 3 radiologists each with more than 5 years' experience in breast diagnosis. For MO-FS, we developed a modified entropy-based termination criterion (METC) that stops the algorithm automatically and used the evidential reasoning approach (SMOLER) to automatically select the optimal solution from the Pareto-optimal set.87. Image features including intensity features, textural features, and geometric features were extracted and selected based on the multi-objective model. Support vector machine (SVM) with radial basis function kernel was used for building the predictive model.
Results: In the prediction model, accuracy, area under the receiver operating characteristic curve (AUC), sensitivity, and specificity were used as the evaluation criteria. The multi-objective radiomics model shows a diagnostic accuracy of 75.6%, AUC of 81.9%, a sensitivity of 76.4%, and a specificity of 81.5%.
Conclusion: This study demonstrated the feasibility of using a multi-objective radiomics model on DBT images to predict the malignancy of the mass-like lesions. The model can handle many mass-like lesions in breast cancer screening and allow for improving the accuracy of diagnosis and increasing the radiologists' work efficiency.
Limitations: This is not a multi-centere study.
Ethics committee approval: n/a

Radiomic standardisation of breast MRI to predict pathological complete response to neoadjuvant chemotherapy

P. Akl[1], F. Khalid[2], D. Sebbag-Sfez[1], F. Frouin[2], C. Malhaire[1]; [1]*Paris/FR,* [2]*Orsay/FR (piaakl@gmail.com)*

Purpose: To optimise and standardise breast MRI texture measurements performed as part of a neoadjuvant chemotherapy (NAC) protocol by defining a data preprocessing method before radiomic index extraction, then testing the ability of textural analysis to predict a pathologic complete response (pCR).
Methods and materials: A clinical dataset of 76 patients, acquired using two scanners and three coils with locally advanced breast tumour diagnosis treated at Institut Curie, were analysed retrospectively. A bias field correction was systematically applied and evaluated through a mean relative difference parameter between left and right ROIs in normal tissues: breast parenchyma (BP) and pectoral muscles (PM). Images were then standardised using the sternum as reference tissue. Tumours were segmented and 48 radiomic features (RF) were extracted from 3D corrected and standardised images using the LIFEx software.
Results: Relative differences in normal breast and pectoral muscles were significantly reduced (p-value < 0.001 for both BP and PM) using bias field correction. Pathological analysis indicated that 35 (46%) patients were complete responders. The most robust RF for pCR prediction was “GLCM correlation”, showing an AUC under the ROC curve equal to 0.68. In addition, multivariate analysis taking into account different coils and scanners type and molecular subtypes showed no significant difference for this RF.
Conclusion: This study showed that retrospective bias field correction in breast MRI could improve regional quantitative analyses. This correction was combined with image standardisation on T2 weighted MR images and showed that "GLCM_correlation" is a promising and robust predictor of pCR in breast cancer.
Limitations: This study should be confirmed on a larger number of patients.
Ethics committee approval: The Institutional Review Committees approved this retrospective study and waived informed consent.
Funding: No funding was received for this work.

RPS 1402a-8 11:57

Radiomics-based MR features in HER2 overexpressing breast cancer receiving neoadjuvant chemotherapy: correlation with pathologic response

A. Bitencourt[1], P. Gibbs[2], C. Rossi[1], I. Daimiel Naranjo[3], R. Lo Gullo[2], K. Pinker-Domenig[2], E. A. Morris[2], M. Morrow[2], M. S. Jochelson[2]; [1]*Sao Paulo/BR,* [2]*New York, NY/US,* [3]*Madrid/ES (almirgvb@yahoo.com.br)*

Purpose: To use magnetic resonance (MR)-based radiomic features to assess tumour heterogeneity in HER2 overexpressing breast cancer patients receiving neoadjuvant chemotherapy (NAC) and correlate these findings with a pathologic response.
Methods and materials: This retrospective single-centre study included 311 patients with HER2 overexpressing invasive breast carcinoma who received NAC following pretreatment MRI. Pathologic complete response (pCR) was defined as no residual invasive carcinoma in the breast (ypT0/is) after surgical resection. A breast radiologist performed 3D segmentations of the tumour in the first minute post-contrast sequence using ITK-SNAP software. Enhancement maps were calculated as the percentage increase in signal from the pre-contrast image to the first post-contrast image. Radiomics and statistical analysis were performed using publicly available CERR software and MATLAB.
Results: Mean tumour size by MRI was 4.7 cm (range: 0.9-14.8 cm). The index tumour presented as mass in 47.3%, non-mass enhancement (NME) in 10.9%, and both mass and NME in 41.8%. Most tumours were multifocal on MRI (65.9%). Overall pCR rate was 62.7% (195/311). 12 radiomics parameters demonstrated significant differences between pCR and non-pCR groups. After ROC and correlation analysis 3 radiomic parameters were retained and advanced to modelling alongside clinical parameters, including lesion type (mass/NME/both), multifocality, size, and nodal status. A robust model was developed utilising coarse decision trees and 5-fold cross-validation. The final model utilised 5 parameters (2 clinical and 3 radiomic) for a diagnostic accuracy of 86.2% (268/311).
Conclusion: A model including both clinical and radiomics-based MR features can be used to assess tumour heterogeneity and predict pCR after NAC in HER2 overexpressing breast cancer patients.
Limitations: Retrospective design.
Ethics committee approval: IRB approved.

Combined contrast-enhanced magnetic resonance and diffusion-weighted imaging radiomic signatures for the assessment of breast cancer molecular subtypes

D. Leithner[1], M. S. Jochelson[1], J. V. M. Horvat[2], M. A. Marino[3], D. B. Avendano[4], D. Martinez[5], S. Thakur[6], E. A. Morris[1], K. Pinker-Domenig[1]; [1]*New York, NY/US,* [2]*002, SP/BR,* [3]*Messina, AT/IT,* [4]*Monterrey, NUEVO LEON/MX,* [5]*New york/US,* [6]*New York/US (doris.leithner@gmail.com)*

Purpose: To investigate the clinical value of radiomic features derived from contrast-enhanced magnetic resonance imaging (CE-MRI) and diffusion-weighted imaging (DWI) for the assessment of breast cancer receptor status and molecular subtypes.
Methods and materials: 91 patients with biopsy-proven breast cancer (luminal A, n=49; luminal B, n=8; HER2-enriched, n=11; triple-negative (TN), n=23) who underwent 3T CE-MRI and DWI were included in this IRB-approved study. Radiomic features (co-occurrence and run-length matrix, absolute gradient, autoregressive model, Haar wavelet transform, and geometry) were extracted from manually drawn ROIs (total number of features per lesion, n=704) on initial CE-MR images and ADC maps. The 5 best features for the differentiation of subtypes were selected separately for CE-MRI and ADC using the probability of error and average correlation coefficients. Following principal component analysis, a multi-layer perceptron feed-forward artificial neural network (MLP-ANN) was used for radiomics-based classification, with 10 iterations, and histopathology as a reference standard. 70% of the cases were used for training, and 30% for validation.
Results: MLP-ANN yielded an overall median area under the receiver-operating-characteristic curve (AUC) of 0.80 (0.77-0.85) for separation of TN from other cancers, with accuracies of up to 81.3% in the training and 84.0% in the validation datasets. The separation of luminal A and TN cancers yielded an overall median AUC of 0.76 (0.71-0.90), with up to 83.3% for training, and 79.2% for validation. All other AUCs were below 0.75.
Conclusion: Combination of radiomic features extracted from CE-MRI and DWI may aid in the non-invasive differentiation of TN and luminal A cancers from other breast cancer subtypes.
Limitations: Manual delineation of cancers.
Ethics committee approval: Approved by the Institutional Review Board; informed consent was waived.
Funding: NIH/NCI Cancer Center Support Grant, Susan G. Komen Foundation, Breast Cancer Research Foundation, Austrian Nationalbank "Jubiläumsfond".

Radiomic features of axillary lymph nodes based on pharmacokinetic modelling DCE-MRI allow preoperative diagnosis of their metastatic status

H. B. Luo, Y. Y. Liu, J. Ren, P. Zhou; *Chengdu/CN (rohbin@163.com)*

Purpose: To study the feasibility of radiomic features extracted from axillary lymph nodes in diagnosing their metastatic status of breast cancer.
Methods and materials: 176 axillary lymph nodes in breast cancer, consisting of 87 metastatic axillary lymph nodes（ALNM) and 89 negative axillary lymph nodes proven by surgery, were retrospectively reviewed. Each selected axillary lymph node's 106 radiomic features based on pharmacokinetic modelling DCE-MRI and 5 conventional image features were obtained. The LASSO regression was used to select useful radiomic features. Logistic regression was used to develop diagnostic models for ALNM. Delong test was used to compare the diagnostic performance among different models.
Results: The 106 radiomic features were reduced to 4 ALNM diagnosis-related features by LASSO. 4 diagnostic models including the conventional model, pharmacokinetic model, radiomic model, and combined model were developed and validated. The Delong test showed that the combined model had the best diagnostic performance, with an AUC of 0.972 in the training cohort and 0.979 in the validation group. The diagnostic performance of the combined model and radiomic model were better than that of the pharmacokinetic model and the conventional model.
Conclusion: The radiomic features of axillary lymph nodes demonstrated promising application in diagnosing ALNM of breast cancer.
Limitations: There might be some selection bias in the study as it is difficult to accurately match the selected axillary lymph nodes visible on DCE-MRI with the metastatic nodes proved by the resection and biopsy. The semi-automatic features extraction approach may cause some interobserver heterogeneity. This was only a single-centre study.
Ethics committee approval: Our institutional review board approved this study and waived the need for informed consent.
Funding: The Key R&D Projects of the Science and Technology Department in Sichuan Province (grant number 2018SZ0183).

Parenchymal radiomics in cone-beam breast CT: comparison with mammography and implication for cancer risk estimation

Y. Zhu, Y. Zhang, Y. Ma, Z. Ye; *Tianjin/CN (zhuyueqiang1985@126.com)*

Purpose: To investigate the potential advantage of parenchymal radiomics in cone-beam breast CT (CBBCT) compared to mammography (MG) for breast cancer risk estimation.
Methods and materials: Bilateral CBBCT and MG from 233 women (147 malignant and 86 benign patients who had unilateral disease) were retrospectively collected from a CBBCT clinical trial (NCT01792999) between May 2012 to November 2014. Parenchymal radiomic features were computed from retroareolar region in contralateral normal breast parenchyma. Principal component analysis (PCA) was applied to obtain orthogonal radiomic components. Breast percent density (PD) was evaluated with software. Correlation analysis and linear regression were performed to determine the association between radiomic features and breast PD with increasing levels of risk. Age was also considered as an additional predictor in multivariate models.
Results: Overall, CBBCT radiomic features demonstrated stronger correlations with breast PD than MG. When dividing population into groups of increasing levels of risk according to breast PD, CBBCT radiomic features appeared to be more discriminative, having regression lines with overall steeper slopes, higher R^2 estimates, and lower P values. Linear regression of PCA radiomic features as predictors of PD also demonstrated significantly stronger associations with CBBCT (R^2 = 0.375) than with MG (R^2 = 0.069). The association was strongest when age was combined (R^2 = 0.439).
Conclusion: Parenchymal radiomic features were more strongly correlated to breast PD in CBBCT than in MG. CBBCT parenchymal radiomics could provide a more accurate characterisation of breast parenchymal patterns, which could ultimately improve breast cancer risk estimation.
Limitations: Our study cohort was a diagnostic population.
Ethics committee approval: The institutional review board approved this study and written informed consent was obtained from all patients.

Artificial intelligence breast cancer risk estimation from CT thorax scans

S. de Buck[1], J. Bertels[1], C. van Bilsen[2], T. Dewaele[2], C. van Ongeval[1], H. Bosmans[1], J. Vandevenne[2], P. Suetens[3]; *[1]Leuven/BE, [2]Genk/BE, [3]Leuven - Heverlee/BE*

Purpose: Breast glandularity is associated with breast cancer risk. Systematic scoring of glandularity on CT thorax examinations performed for another clinical reason could find patients at risk, but it is currently cumbersome and not standard practice. Automated scoring would give access to this information. We propose a novel method to automatically segment the breast volume on CT thorax examinations and estimate glandularity.
Methods and materials: We used an artificial neural network with a U-Net-like architecture to automatically segment the breast region. A retrospective study was conducted on a dataset of 23 postmenopausal women that had a CT thorax examination for another clinical reason. The images were manually segmented to serve as a gold standard. The image/segmentation pairs were randomly separated in a training (15 patients) and a testing (8 patients) set. We computed 2 risk scores in the segmented breast: the glandular fraction (HU>40) and volumetric breast density (VBD), based on the average HU in comparison to pure fat and gland. Segmentation accuracy was validated by Dice overlap between predicted and manually segmented regions. Risk score correlation was assessed by the Pearson coefficient.
Results: We obtained a Dice overlap score of 0.84±0.03. The Pearson coefficient between predicted and ground-truth values of the glandular fraction and VBD amounted to 0.99 and 0.98 respectively.
Conclusion: We present a first, novel artificial intelligence-based approach to automatically compute the volume of the breast by a convolutional neural network and determine cancer risk scores based on CT thorax examinations performed for another reason. Results show excellent correspondence between the automated method and expert observers.
Limitations: Despite a limited population, good results are shown.
Ethics committee approval: A retrospective study on anonymised images, waived by the ethical committee (ZOL).
Funding: No funding was received for this work.

Flow-controlled angiography for the assessment of vascular patency, permeability, and leakage in bioengineered kidneys

S. Cohen[1], S. Hirschberg[2], S. Partouche[1], M. Gurevich[1], V. Tennak[1], V. Mezhybovsky[1], E. Nesher[1], E. Mor[3], E. Atar[1]; *[1]Petah Tikva/IL, [2]Salit/IL, [3]Ramat Gan/IL (sarit.soffer@gmail.com)*

Purpose: Perfusion decellularisation is a promising method for the generation of non-immunogenic organs from allogeneic and xenogeneic donors. A number of imaging modalities are used to assess vascular integrity in bioengineered organs, including fluoroscopic angiography, with no consistency in the method used. None of these techniques addressed changes in permeability, while the demonstration of patency was limited to visualisation of arterial tree. The goal of this study was to evaluate the use of fluoroscopic angiography performed under

controlled flow conditions for the assessment of vascular integrity in bioengineered kidneys.
Methods and materials: Porcine kidneys underwent ex vivo fluoroscopy before and after perfusion decellularisation, under controlled flow conditions. Arterial and venous patency were defined as the visualisation of contrast medium (CM) in distal capillaries and the renal vein, respectively. For permeability assessment, grey-scale intensity within the parenchyma was measured and the washout index (W_{index}) was calculated at several time points during a washout phase. Extravasation of CM was documented following iatrogenic injury.
Results: No differences in patency were detected in decellularised kidneys compared with native kidneys. However, a significantly lower W_{index} was calculated for decellularised kidneys, indicating a delayed CM clearance and increased vascular permeability. Focal opacities representing extravasation of CM into the parenchyma were only detected in decellularised kidneys. Iatrogenic leakage was equally detectable in both groups, with DSA scans revealing even minimal CM leakage.
Conclusion: Quantitively assessment of permeability should be coupled with patency when studying the effect of perfusion decellularisation on kidney vasculature. Flow-controlled fluoroscopic angiography based on the proposed methodology is an accessible, accurate, and sensitive method that should be adopted as the method-of-choice for vascular assessment in bioengineered organs.
Limitations: Larger sample sizes are needed to confirm our findings.
Ethics committee approval: Performed in accordance with IRB guidelines.
Funding: No funding was received for this work.

The evaluation of early haemodynamic changes in rabbit aorta atherosclerosis by high frame rate V-flow imaging

Y. Dong, Y. Qiu, Q. Zhang, D. Yang, W. Wang*; Shanghai/CN (dr_mimi@163.com)*

Purpose: To evaluate the change of V Flow and wall shear stress (WSS) parameters in the evaluation of early-stage aorta atherosclerosis (AS) in rabbit models.
Methods and materials: Rabbit AS models were established by feeding high-fat forage in healthy New Zealand rabbits (n=7). Ultrasound evaluations were performed once per week since the 14th week. A Mindray Resona 7s ultrasound system equipped with a L9-3U linear array transducer (3-9 MHz) and updated V Flow imaging function was used. The maximum WSS (WSSmax) value and mean WSS (WSSmean) value were compared with the blood flow volume (BFV) and peak systolic velocity (PSV) value measured by colour Doppler flow imaging (CDFI). Histopathological results after 34 weeks were used as the gold standard to make a correlation analysis with the WSS value.
Results: On the 34th week, pathological results showed typical fatty streak changes on the wall of the aorta. Since the 37th week, AS plaques could be detected. The WSS values of the aorta changed with the progression of AS, which began to decrease at the 14th week, increased between the 20th-27th week, and gradually decreased after the 27th week. A significant difference was found between the WSS values and the baseline values ($P<0.05$). Statistical results showed earlier statistical changes of WSSmax and WSSmean values while comparing with PSV and BFV values.
Conclusion: The WSS value measured by V Flow technology changed dynamically during the progress of aorta AS in rabbit models. WSS values might have potential clinical value in the evaluation of early haemodynamics changes in AS.
Limitations: The number of animals were limited.
Ethics committee approval: This animal study was approved by the ethics committee of Zhongshan Hospital, Fudan University.
Funding: Shanghai Municipal Science and Technology Innovation Action Plan Clinical Medicine Project (Grant No. 17411954200).

RPS 1415-3 11:27

The detection of shear stress in haemodialysis arteriovenous fistulae by ultrasound vector flow imaging

J. Ding[1], R. Zhao[1], Q. Yang[1], Y. Du[2], L. Zhu[2], H. Gan[1], M. Wang[1]*; [1]Beijing/CN, [2]Shenzhen/CN (yigang1982@gmail.com)*

Purpose: Altered blood flow and wall shear stress (WSS) in arteriovenous fistulae (AVF) might make the access stenosis, causing the dialysis procedure to become ineffective. The stenosis of AVF commonly occurs in three specific sites: the anastomosis floor (Type-I), on the inner wall of the swing segment (Type-II), and after the curved region when the vein straightens out (Type-III). WSS in these sites could be measured by V Flow, which is a high-frame-rate ultrasound vector flow imaging (VFI) implemented based on multi-directional Doppler techniques.
Methods and materials: This study established the first quick measurement of vascular WSS by V Flow in AVF (available on a clinical system, Resona 7 manufactured by Mindray, Shenzhen, China). 15 haemodialysis patients were included; 9 males and 6 females. The dialysis age was 38.0±25.1 months. The mean age of the fistula was 21.4±18.6 months. Each fistula was functioning for dialysis access at the time of our examination.
Results: The level of mean WSS in Type-I, -II, and -III sites were 0.9±0.6Pa, 1.2±0.5Pa, and 0.8±0.4Pa. The level of max WSS was 2.7±1.3Pa, 4.2±2.5Pa, and 1.7±0.7Pa in these sites. It was found that the WSS level of Type-III was significantly lower than the others ($P<0.05$), except the mean WSS in Type-I and -III ($P=0.6$). The level of fistulae flow rates was about 559±126.5 ml/min measured by V Flow.
Conclusion: The ultrasound VFI technique is convenient to study the changes of WSS and flow in AVF. The lowest WSS in Type-III might explain that this site is the most susceptible site for stenosis. WSS is expected to be a sensitive and non-invasive method for the early prediction stenosis of AVF.
Limitations: A pilot study.
Ethics committee approval: Approved by the Hospital Review Board.

Ferumoxytol MR angiography: a novel imaging technique for vascular mapping before haemodialysis arteriovenous fistula creation

A. Tan, S. Stoumpos, P. Hall Barrientos, A. Radjenovic, D. Kingsmore, R. S. Kasthuri, G. Roditi, P. Mark*; Glasgow/UK (alfred.research@gmail.com)*

Purpose: Doppler ultrasound (DUS) is routinely performed for vascular mapping prior to haemodialysis arteriovenous fistula (AVF) creation but has the disadvantage of not visualising the central vasculature. Ferumoxytol, an iron oxide nanoparticle, provides an alternative to gadolinium contrast for magnetic resonance angiography (MRA). We assessed the clinical utility of ferumoxytol-enhanced MRA (FeMRA) before autogenous upper limb AVF creation compared with DUS.
Methods and materials: In a prospective comparative study, paired FeMRA and DUS were obtained the same day. Vessels were evaluated for diameter, stenosis or occlusion, arterial disease, and central stenosis by independent readers. Interclass correlation coefficients (ICC) and Bland-Altman plots examined inter- and intra-reader variability. Based on accepted standards for AVF creation, an algorithm was designed to predict the AVF outcome relying on mapping findings. Logistic regression models were created with AVF success as the dependent variable and age, sex, and DUS or FeMRA mapping as the independent variables.
Results: 59 patients (mean age 59 years) had FeMRA and DUS, and 51 AVF were created. FeMRA showed excellent inter- and intra-reader repeatability (ICC 0.84-0.99). In addition to identifying 15 central vasculature stenoses, FeMRA explicitly characterised anatomical abnormalities and variants in arm vessels. On multivariable regression analyses, FeMRA mapping independently predicted AVF success in models including [OR: 6.49 (95% CI 1.70-24.79); p=0.006] and excluding central stenoses [OR: 4.58 (95% CI 1.25-16.83); p=0.02].
Conclusion: FeMRA better predicted the AVF successful outcome compared to DUS and has the added advantage of identifying central vessels pathology.

Limitations: The translation of study protocol to clinical practice. Ferumoxytol is not yet licensed as a contrast agent for MRI and used off-label.
Ethics committee approval: The study was approved by the institutional review board [Research Ethics Committee (REC) reference: 16/NS/0099, NCT02997046].

A magnetic micro-robot for aneurysm coiling with magnetic particle imaging
A. C. Bakenecker, F. Wegner, H. Schwenke, K. Lüdtke-Buzug, T. Friedrich, J. Barkhausen, T. M. Buzug*; Lübeck/DE (bakenecker@imt.uni-luebeck.de)*

Purpose: To introduce a new approach for aneurysm coiling by using a magnetic micro-robot, which is steered by the magnetic fields of a magnetic particle imaging (MPI) scanner in an in vitro study.
Methods and materials: For in vitro phantom experiments, a high precision model of a middle cerebral artery was used, which was 3D-printed and filled with water. For the micro-robot, we used a 3D-printed helically shaped swimmer, which can be navigated by magnetic fields. The required homogeneous magnetic fields of low amplitude (about 10 mT) and rotating field vector are generated by a commercial MPI scanner (Bruker BioSpin, Ettlingen, Germany). Low rotation frequencies (around 10 Hz) are applied and the swimmer follows the rotation. Due to the swimmers' shape, a forward movement is induced. The magnetic fields are pre-calculated according to the pathway the swimmer has to cope. The swimmer has a length of 3.0 mm and a width of 1.2 mm, fitting the blood vessels of the phantom. It is coated with magnetic nano and microparticles to introduce magnetic properties. The magnetic nanoparticles could serve as tracer material for visualisation with MPI.
Results: The swimmer can be navigated by external magnetic fields through a blood vessel towards an aneurysm within a vessel phantom. The magnetic fields were applied with an MPI scanner, which allowed the visualisation of the swimmer.
Conclusion: The first in vitro experiments demonstrate the feasibility of steering a micro-robot by pre-calculated magnetic fields of an MPI scanner through a vessel phantom towards an aneurysm, which paves the way for an untethered coiling procedure.
Limitations: In vitro experiments were performed without flow.

The safety of a new stent design during magnetic particle imaging and magnetic resonance imaging
U. Grzyska[1], T. Friedrich[1], J. Haegele[2], T. M. Buzug[1], J. Barkhausen[1], F. Wegner[1]; *[1]Lübeck/DE, [2]Neuss/DE (ulrike.grzyska@gmx.de)*

Purpose: To evaluate the heating of a recently developed re-dilatable stent for the treatment of aortic coarctation in neonates and small children during magnetic particle imaging (MPI) and magnetic resonance imaging (MRI).
Methods and materials: All measurements were performed using a recently developed cobalt-chromium stent (BabyStent, Osypka) with a new stent design which allows for re-dilatation and adjustment of the diameter from 6 to 16 mm. At a diameter of more than 12 mm, the stent loses radial integrity while fracturing at dedicated breaking points. Temperature measurements were performed with fibre-optic thermometers during 7-minute MPI and MRI scans. 6 different stent diameters (6, 8, 10, 12, 14, and 16 mm) were evaluated in this study.
Results: In MPI, all stents with continuous struts showed a temperature increase (max. 2.3 K). The measured temperature differences increased with growing diameters up to 12 mm, whereas the stents with discontinuous struts at 14 and 16 mm showed nearly no heating. In contrast to MPI, the investigated stents showed no heating during the MRI measurements.
Conclusion: The stents showed no heating during MRI and only clinically insignificant heating during MPI and can safely be examined with both modalities. However, in MPI, the stent diameter and the strut design influence the temperature difference.
Limitations: The absence of flow could be a potential limitation of our study. To prevent potential cooling effects, we consciously created a worst case scenario study with static conditions and stents surrounded by air.

The identification of intra-individual flow variation of intracranial aneurysms on phase-contrast MR and the influence on computational haemodynamics
Y. Wang[1], X. Liu[2], E. Kao[3], H. Haraldsson[3], M. Ballweber[3], M. Alastair[3], D. Saloner[3]; *[1]Chengdu/CN, [2]Beijing/CN, [3]San Francisco/US (wangyuting_330@163.com)*

Purpose: Patient-specific inlet artery flow has been applied in intracranial aneurysm simulations. This study aims to identify the intra-individual flow variation in phase-contrast MR (PCMR) and how it influences the following computational haemodynamics.
Methods and materials: 2D PCMRs were performed in a longitudinal patient cohort of intracranial aneurysms to determine the inlet flow boundary condition. The intraclass correlation coefficient (ICC) and the coefficient of variance (CV) across 3 time points were used to identify reproducibility and variation. Computational fluid dynamics were performed using the original flow and flow with the corresponding variation, respectively. The wall shear stress (WSS), low shear area (LSA), time-averaged wall shear stress (TAWSS), and oscillatory shear index (OSI) were compared.
Results: 51 patients (14 males; mean age: 62 years; mean follow-up interval: 7.2 months) were included. The reproducibility of the flow and velocity was good, with ICCs of 0.71-0.90. A 10% CV of mean flow was identified. The variation of flow data was smaller than the velocity data ($p<0.05$). The variation of flow and velocity at the end-diastolic phase was larger than that of the mean and systolic phase ($p<0.01$). A 10% of flow variance would lead to haemodynamic changes including 20% of WSS at the systolic phase, 19.6% of WSS at diastolic phase, 5.0% of LSA at systolic phase, 5.2% of LSA at diastolic phase, 20.1% of TAWSS, and 4.6% of OSI.
Conclusion: The flow should be preferred rather than the velocity in choosing inlet boundary conditions due to a smaller variance. A 10% of flow variation could lead to a series of haemodynamic changes. LSA is a more stable parameter than WSS.
Limitations: n/a
Ethics committee approval: Under IRB approval of UCSF. All subjects gave informed written consent.

The potential of ferumoxytol as a contrast media in computed tomography: a phantom study
A. Parakh, A. O'shea, M. Harisinghani, A. Kambadakone, R. Gupta, B. Ghoshhajra, S. Hedgire*; Boston, MA/US (aoshea1@mgh.harvard.edu)*

Purpose: To investigate the potential of ferumoxytol as a vascular contrast agent using dual-source dual-energy CT (DECT).
Methods and materials: 10 10-ml syringes were filled with increasing dilutions of ferumoxytol with saline in increments of 3 mg/ml ranging from 0-27 mg/ml. The syringes were placed within an attenuation phantom that was scanned using single-energy CT (SECT) at 120 kVp and DECT (100/Sn150) protocols. Attenuation (HU) for all syringes was measured on SECT and virtual monoenergetic images (VME) at 40-190 keV on DECT. Generally, an

intravascular attenuation of 250 HU is deemed acceptable for evaluating vasculature on CT. Therefore, the attenuation of different concentrations of ferumoxytol at varying energy levels was compared with 250HU.
Results: The maximum attenuation observed for the syringe containing 27 mg/ml ferumoxytol was 146HU at SECT and 435HU at 40keV-DECT. Attenuation values higher than 250 HU were observed for concentrations of 18 mg/ml at 40-42keV, 21 mg/ml at 40-44keV, 24 mg/ml at 40-50keV, and 27 mg/ml at 40-55keV. For concentrations between 18-27 mg/ml, HU at SECT were 96, 104, 122, and 146 HU, respectively. Compared to SECT, 40keV, and 50keV images increased the attenuation of ferumoxytol two-to-three-folds.
Conclusion: Use of low keV (40-50keV) monoenergetic images using 100/Sn150 kVp spectra on a dual-source dual-energy CT platform increases the attenuation of ferumoxytol compared to 120-kVp SECT substantially. CT imaging with this agent may be feasible for assessing vasculature in selected patient populations who can not receive iodinated or gadolinium contrast media for vascular CTA/MRA studies.
Limitations: This setup was a phantom without circulation dynamics. Further studies using clinically appropriate concentrations of ferumoxytol and simulated haemodynamics are required to assess the feasibility of using this contrast agent.

Virtual monochromatic images in low tube current dual-energy spectral imaging combined with adaptive statistical iterative reconstruction V in head CT angiography: a phantom and clinical study

T. Song, Z. Li*; Chengdu/CN*

Purpose: To analyse the value of combining virtual monochromatic spectral (VMS) image and adaptive statistical iterative reconstruction V (ASiR-V) in low tube current dual-energy spectral imaging in head computed tomography angiography (CTA), and to explore the optimal VMS and ASiR-V levels.
Methods and materials: An anthropomorphic PBU-60 angiographic head phantom and 40 patients (randomly divided into two groups with 20 patients in each group) were examined on a revolution CT with spectral imaging mode at two different tube currents. Images of different energy levels in the low tube current group (with 280mA) were reconstructed with the combination of filtered back projection (FBP), 20%, 40%, 60%, and 80% ASiR-V. VMS images at 70keV in the routine tube current group (with 445mA) were reconstructed with FBP only.
Results: The SNR and CNR of the simulated cerebral vessels and subjective scores of the 55 keV VMS images with ASiR-V 60% and ASiR-V 80% in the low tube current patient group were higher than that of the 70 keV FBP images in the routine tube current group. The radiation dose of group A was lower than group B.
Conclusion: VMS images in low tube current spectral imaging combined with ASiR-V can significantly reduce the radiation dose and ensure image quality in head CTA. The 55 keV VMS images with ASiR-V 60% and 80% provide higher image quality.
Limitations: A single-centre study.
Ethics committee approval: This study was approved by the biomedical ethics committee of our hospital.

The effectiveness of dual-layer spectral detector CT for reducing the amounts of contrast agents and injection flow rate

T. E. Kim[1], Y. H. Chung[2], T. H. Nam[1], S. A. Kwon[1]; *[1]Seongnam/KR, [2]Seoul/KR, (20309@snubh.org)*

Purpose: To investigate the utility of a method for dual-energy computed tomography (DECT) using a low flow-rate and volume of contrast when the aorta CT angiography is progressed.
Methods and materials: 64 patients who underwent aorta CT angiography with 256MDCT and 128DECT were enrolled in this study. In cases of 256MDCT, we administered 130 mL of contrast at a rate of 3.0 mL/sec. In cases of 128DECT, we administered 50 mL of contrast at a rate of 1.5 mL/sec. Additional MonoE (60keV) images were reconstructed from a DECT examination. For quantitatively evaluation, two radiographers measured the CT number, standard deviation, and CNR. The measurement regions were two points as descending aorta and SMA. For qualitative evaluation, two radiologists evaluated the level of aortic enhancement based on three-point scaling at the region of the brachiocephalic artery, SMA, and IMA.
Results: Results in quantitative evaluation from the average CNR results, the MDCT cases were shown as 93±11 and 76±7 from the descending aorta and SMA. The DECT cases were shown as 108±14 and 86±13 from the descending aorta and SMA, respectively. The results of qualitative evaluation, the good results (over 3.5 points with P>0.05) at the evaluation have been reported. This means there are few statistical differences between the two methods.
Conclusion: Image reconstruction based on the spectral method using DECT for the scanning of aorta angiography reduced the dosage of the contrast agent by 62.5% and the injection flow rate by 50% without a decrease of the image quality. Therefore, the DECT aorta protocol is a useful technique in patients with kidney failure and poor IV.
Limitations: The lack of experiments with varying amounts of contrast agents.

The validation of iodine contrast flow velocity quantification from time-resolved CT-angiography in a flow phantom

P. T. Boonen[1], N. Buls[1], J. Vandemeulebroucke[2], G. van Gompel[1], Y. J. F. de Brucker[1], D. Aerden[1], T. Leiner[3], J. de Mey[1]; *[1]Jette/BE, [2]Brussels/BE, [3]Utrecht/NL (pieter.thomas.boonen@vub.be)*

Purpose: To demonstrate the feasibility and reliability of flow velocity measurements using time-resolved CT-angiography in a dynamic flow phantom.
Methods and materials: All experiments were performed with a single lumen flow phantom with a 6 mm inner diameter. Saline was infused at varying injection rates with a contrast injector (Dual Shot GX 7-Nemoto) and the contrast bolus (2 mL iomeprol 350 at 0.33 mL/s) was subsequently injected using a syringe injector (Alaris GH Syringe Pump). The two injectors were connected to a silicone tube which was contained within a solid 2% agar-agar solution to mimic soft tissue.
Saline was injected at 6 flow rates to achieve the following reference velocities: 21.2 mm/s, 38.9 mm/s, 60.1 mm/s, 81.4 mm/s, 99.0 mm/s, and 120.3 mm/s. For each velocity, 6 consecutive time-resolved CTA acquisitions were performed (Revolution CT, GE Healthcare), each consisting of 20 repeated axial acquisitions with an interscan delay of 1.2s at 160 mm (256x0.625 mm) collimation. The mean centerline flow velocities were automatically assessed and differences and correlations with reference settings were evaluated with the Wilcoxon signed-rank test and the Pearson correlation.
Results: From the CT image data, the average obtained velocities were 21.6±5.6 mm/s, 34.5±6.8 mm/s, 61.5±3.1 mm/s, 76.3±14.5 mm/s, 104.9±27.0 mm/s, and 143.6±42.1 mm/s. No significant difference was observed with the reference velocities ($p=0.912$) and a significant linear correlation was found ($r=0.903$, $p<0.01$). Up to 99.0 mm/s, the measurement error was confined within 12%.
Conclusion: The results of this study suggest that mean flow velocities within the range of typical blood flow velocities (40 mm/s-70 mm/s) can be accurately measured with high precision in a 6 mm flow phantom using time-resolved CTA.
Limitations: Of minor importance.

DKI evaluation of crossed cerebellar diaschisis after MCAO cerebral infarction in rats
Z. Ma, X. Zhao; *Zhengzhou/CN (11430884@qq.com)*

Purpose: To observe the expression of NMDA, apoptosis, and the effect on nerve function recovery in a rat model of middle cerebral artery occlusion (MCAO). Diffusion kurtosis imaging (DKI) was used to evaluate crossed cerebellar diaschisis (CCD) to provide an experimental and theoretical basis for clinical treatment.
Methods and materials: MCAO models were established in rats. Every 12 rats were randomly divided into a control group, 6-hour group, 12-hour group, 24-hour group, 48-hour group, 7-day group, and 14-day group. The rats were scanned by MRI at the above time points. Rats were sacrificed for H&E staining, immunohistochemical staining, and TUNEL staining to detect the expression of NMDA in the core infarct area and cerebellum, and to analyse the relationship between the parameters of MRI and molecular biology.
Results: The values of MD, ADC, and FA in MCAO rats were all lower than those of the control group and the parameters of contralateral cerebellum were lower than those of ipsilateral cerebellum ($P<0.05$), reaching the lowest value at 12 hours, while the values of MK were opposite. The expression of NMDA showed an upward trend, higher than that of the control group, which reached the maximum in 24 hours ($P<0.05$, and that in the contralateral cerebellum was higher than that in the ipsilateral cerebellum.
Conclusion: NMDA can be a novel treatment target for CCD and the parameters of MRI can predict the occurrence and development of CCD.
Limitations: Continuous dynamic scanning has not yet been used in the experiment.

Cost awareness of interventional radiology devices among radiology trainees
M. Courtney[1], D. Mulholland[1], D. O'Neill[1], C. Redmond[2], M. J. Lee[1], T. Farrell[1]; *[1]Dublin/IE, [2]Tullamore/IE (michael.courtney@tcd.ie)*

Purpose: Numerous disposable devices are consumed daily in interventional radiology (IR) suites globally. Trainees receive no formal training or assessment on the cost and identification of these devices. Educating specialists on disiposable devices has shown to reduce costs in other disciplines. This study aims to assess radiology trainees' ability to identify and estimate the costs of common disposable interventional radiological devices and identify deficiencies in postgraduate radiology teaching in terms of healthcare economics.
Methods and materials: The postgraduate radiology training body of a European country was consulted to obtain numbers of all current radiology trainees. Trainees were invited to partake in a questionnaire via email. An anonymous online survey consisting of 26 multiple-choice questions (MCQs) was administered. Respondents were asked to provide their year of training and subspecialty of interest. Respondents were asked to identify 13 devices, using in vivo and ex vivo images. The devices were a PICC line, Angioseal closure device, tunnelled dialysis catheter, Port-A-Cath, pigtail drainage catheter, guidewire, biopsy needle, micropuncture kit, angioplasty balloon, IVC filter, covered metal vascular stent, gastrostomy tube, and an EVAR graft. They were asked to estimate the cost of each device. Trainees were deemed correct if they responded within 25% of true cost.
Results: The questionnaire was delivered to 82 radiology trainees; the response rate was 60% (49/82). No trainee accurately estimated the cost for all 13 devices assessed. The cost of devices was underestimated by trainees 48.9% of the time and overestimated 32.3% of the time.
Conclusion: Radiology trainees are deficient in cost awareness of a number of common IR devices used. A health economics module in postgraduate radiology training may improve the efficiency of healthcare expenditure within radiology departments.

A pilot study to compare the perception of image quality using smart glasses and a conventional monitor
S. Dorey[1], S. Al-Islam[2], J. D. Thompson[1], A. England[1]; *[1]Manchester/UK, [2]Blackburn/UK (shaun.dorey@tgh.nhs.uk)*

Purpose: Due to the hands-free nature of smart glasses, they have the potential to be useful in interventional environments where sterility has to be ensured and where the clinician has both hands occupied with surgical tasks. A visual grading analysis (VGA) study was performed to compare the perceived image quality of fluoroscopy images using smart glasses and a conventional monitor.
Methods and materials: 10 observers (3rd-year student radiographers) evaluated 4 anonymised fluoroscopic images for 4 criteria (representation of soft tissue structures, bone, contrast filled structures, and clear definition of a guidewire). Each criterion was rated on a scale of 1-5, with a higher number representing a more positive response.
The evaluation was completed with a pair of prototype Epson BT-35E smart glasses (Epson, Japan) in a controlled environment (dimmed ambient lighting with no adjustments made to the brightness, contrast, or magnification settings). The same images were also displayed on an Iiyama ProLite B2206WS monitor (Iiyama, Japan) within the same controlled environment. The area under the visual grading characteristic (AUC_{VGC}) was used as the figure of merit (FOM). The image evaluation would be considered statistically different if the 95% confidence interval (CI) of the AUC_{VGC} did not include 0.5.
Results: The AUC_{VGC} and 95% CI was 0.519 (0.425, 0.618), p=0.610, for the comparison of the image evaluation with smart glasses and a conventional monitor. This means that no significant difference was detected for the evaluation of image quality in this pilot data.
Conclusion: There were promising early results for the image quality provided by smart glasses in comparison to a conventional monitor. A larger-scale study, also considering dynamic imaging, is now required.

Endovascular simulation training: a tool to increase enthusiasm for interventional radiology among medical students
F. Stoehr[1], S. Schotten[1], M. B. B. Pitton[1], C. Düber[1], F. Schmidt[1], N. L. Hansen[2], B. Baessler[2], R. Kloeckner[1], D. Pinto Dos Santos[2]; *[1]Mainz/DE, [2]Cologne/DE (fabianstoehr@hotmail.de)*

Purpose: Interventional radiology (IR) is a growing field but is underrepresented in most medical school curricula. We tested whether endovascular simulator training improves attitudes towards IR among medical students.
Methods and materials: We conducted this prospective study at two university medical centres, where 4th-year medical students completed a 90-minute IR course. The class consisted of a theoretical part and a practical part, involving endovascular simulators. Using smartphones/tablets, students completed questionnaires before the course, after the theoretical part, and after the practical part. On a 7-point Likert scale, they rated their interest in IR, knowledge

about IR, the attractiveness of IR, and the likelihood to consider IR as a subspecialty. We used a crossover design to prevent position-effect bias.
Results: The seminar/simulator parts led to higher scores for all items compared to baseline: interest in IR (pre-course 5.2 vs post-seminar/post-simulator 5.5/5.7), knowledge of IR (pre-course 2.7 vs post-seminar/post-simulator 5.1/5.4), attractiveness in IR (pre-course 4.6 vs post-seminar/post-simulator 4.8/5.0), and the likelihood of choosing IR as a subspecialty (pre-course 3.3 vs post-seminar/post-simulator 3.8/4.1). Although the seminar and simulator both led to a significant improvement, the effect was significantly stronger for the simulator training compared to the seminar for all items (all $p<0.05$).
Conclusion: Endovascular simulator training in medical school significantly increases students' interest in IR, knowledge about IR, positive attitude toward IR, and the likelihood of potentially choosing IR as a subspecialty. Implementing dedicated IR courses that include practical simulator training might ease recruitment problems in the field.
Limitations: We minimised response bias by using an anonymous, untraceable survey design and ad-hoc completion of each questionnaire during the course.

Augmented reality in training: can CT-guided intervention be simulated accurately?
D. Amiras[1], P. Pratt[1], T. Hurkxkens[1], C. Watura[1], B. Pitrola[1], S. Rostampour[2], M. Hammady[1]; [1]*London/UK,* [2]*Luton/UK (bhavnapitrola@gmail.com)*

Purpose: Computed tomography (CT)-guided interventions are taught across the world mostly using a traditional mentored approach on real patients. However, it is well established that simulation is a valuable training tool in medicine. This project assessed the feasibility and acceptance of replicating a CT-guided intervention using a bespoke software application within an augmented reality head-mounted display (ARHMD): the Microsoft HoloLens.
Methods and materials: A bespoke application was written to simulate the process of performing a CT-guided procedure using augmented reality. Virtual patients were generated using CT datasets obtained from the cancer imaging archive. A mesh of a virtual patient was projected into the field of view of the operator and a virtual CT slice simulating the needle position generated on voice command. In order to provide tactile feedback, a mock biopsy phantom was made using agar jelly. ChArUco markers were used to track both the needle and phantom using RGB cameras built into the ARHMD.
The application was trialled by senior international radiologists and radiology registrars-in-training with a structured feedback questionnaire evaluating face validity and technical aspects.
Results: Good feedback was received from participants regarding realism, usability, and the accuracy of the application.
Conclusion: The study showed it is possible to replicate a CT-guided procedure with augmented reality and that this could be used as a training tool.
Limitations: There is no comparison made to traditional CT training techniques, although a further study will address this. A limited CT dataset was used to simulate patient subjects and this could be increased with further study.
Ethics committee approval: The CT datasets from the cancer imaging archive have ethical approval for re-use. No other ethical approval was required.
Funding: No funding was received for this work.

RDIM software for patient peak skin dose assessment: comparison with radiochromic film measurements
M. M. J. Felisi[1], P. E. Colombo[1], S. Riga[1], F. Rottoli[1], F. Barbosa[1], A. Rampoldi[1], C. Dillion[2], S. Massey[2], A. Torresin[1]; [1]*Milan/IT,* [2]*Scottsdale, Arizona/US (marco.felisi@unimi.it)*

Purpose: To evaluate the accuracy of the algorithm for calculating the skin dose distribution in interventional radiology procedures, provided by the radiation dose index monitoring software NEXO[DOSE]® (Bracco Injeneering SA, Lausanne).
Methods and materials: To obtain the skin dose distribution, the software uses exposure parameters taken from the radiation dose structured report (primary/secondary angles, source-to-isocenter distance, kV, Kerma-Area Product (KAP), air-Kerma at interventional reference point, and additional filters), angiographic system information (table attenuation and KAP correction factor), and other factors, such as the backscatter factor and ratio of mass-energy absorption coefficients. The software had been previously validated on a geometrical phantom. GafChromic® XR-RV3 films were positioned under the patient's back to evaluate the software accuracy in clinical conditions. The interventional procedures (18 cases including prostatic artery embolisation, uterine fibroid embolisation, transjugular intrahepatic portosystemic shunt, and transarterial chemoembolisation) were performed with two Philips Integris Allura FD20 and a Siemens Artis Zeego.
Results: The peak skin dose (PSD) values were in a range from 0.2 Gy to 10 Gy. The differences between estimated and measured PSD were lower than 25%, except in one case where a discrepancy of 65% was probably due to an uncorrected geometric evaluation or to the film positioning. The mean deviation is 0.7%±20.6%.
Conclusion: We observed a good correlation ($r=0.980$, $p<0.0001$) between film measurements and software estimates. This study suggests that NEXO[DOSE]® software can be considered as a valuable dose calculation tool to optimise existing practices and monitor the follow-up required for patients who have received high doses, without using radiochromic films which are expensive and time-consuming.
Limitations: The analysis of a limited number of cases due to incorrect film positioning.

RPS 1409a-6 11:55
Monte Carlo study of 3D stray radiation during interventional procedures
K. S. Alzimami*; Riyadh/SA (kalzimami@ksu.edu.sa)*

Purpose: In interventional medical procedures, other than the highly important issue of optimising image quality and patient exposure in use of the primary beam, there remains a continuing need for the study of staff exposures from the scattered radiation. Herein, an investigation is made of the 3D stray radiation distribution, the simulation being made of a realistic interventional scenario through the use of the Monte Carlo code Geant4 (version 10.3).
Methods and materials: The simulation was conducted based on the HDRK-Man computational phantom and a GE Infinia 3/8" C-arm machine, focusing on the effect of variation of kVp and field of view (FoV) on the scattered particles spatial distribution. Scatter fraction distributions were simulated for x-ray tube outputs (and half-value layers, HVL) of 60 kVp (2.3 mm Al), 80kVp (3.2 mm Al), and 120 kVp (4.3 mm Al), and FoV of 15, 20, 25, and 30 cm. The distributions are obtained for different height levels, corresponding to the lens of the eye, lung and prostate, and all radiosensitive organs.
Results: At fixed FoV, results reveal an inverse relationship between ESAK and kVp. A change in kVp from 60 to 80 has a greater effect than from 80 to 120. For a change in FoV at fixed kVp, the scatter fraction remains constant. For a given value of FoV, ESAK is seen to increases with a decrease in kVp, supporting existing literature.
Conclusion: The typically adopted locations of the various members of staff during interventions, in accordance with their role, is found to be an optimal choice. From such findings, we urge for the implementation of appropriate in-house protocols in seeking to mitigate the potential deleterious effects of radiation to members of staff.

RPS 1409a-7 12:01

The eye lens dose of the interventionalist: measurement in practice

E. J. Meijer[1], D. van Zandvoort[1], J. W. H. Kruimer[2], C. V. Pul[3]; [1]*Eindhoven/NL,* [2]*Woerden/NL,* [3]*Veldhoven/NL (e.meijer@mmc.nl)*

Purpose: Early in 2018, the new eye lens dose limit of 20 mSv per year for occupational exposure to ionising radiation was implemented in the European Union. Dutch guidelines state that monitoring is compulsory above an expected eye lens dose of 15 mSv/year. In this study, we assess whether the eye lens dose of interventionalists in the Máxima Medical Centre, the Netherlands, would exceed 15 mSv/year and whether the measured eye lens dose measurements can be individually related to regular personal dosimeter measurements.
Methods and materials: The eye lens dose, Hp(3), of interventional radiologists (n=2), cardiologists (n=2), and vascular surgeons (n=3) was measured during six months, using thermoluminescence dosimeters (Mirion dosimetry services) on the forehead. Simultaneously, the surface dose, Hp (0.07), and whole-body dose, Hp (10), were measured using regular dosimeters outside the lead skirt at chest level. The dosimeters were simultaneously refreshed every four weeks. The observed dose data was extrapolated to one year to check compliance with the year limit.
Results: A clear relation was observed between the two dosimeters: Hp(3)≈0,25 Hp(0,07). The extrapolated year dose for the eye lens did not exceed 15 mSv for any of the interventionalists (average 3 to 10 studies/month).
Conclusion: The eye lens dose can be monitored indirectly through regular dosimeter at chest level. Additionally, all interventionalists remain below the dose limit and compulsory monitoring limit for the eye lens dose. We cannot generalise our findings to other hospitals because of too many variables involved, such as procedure type, the orientation of the tube, and the position of the interventionalist. Nevertheless, a limited monitoring period can give substantial information on the yearly eye lens dose.
Limitations: Findings are not generalisable to other hospitals due to many variables.

Endovascular technologies for radiation oncology: how to protect patients from potential bleeding during radiotherapy and proton therapy in cases of vessel tumour invasion

M. Cherkashin, I. Sonkin, N. Vorobyov, N. Martynova, N. Berezina, A. Oleynik, A. Mikhaylov*; St. Petersburg/RU (mikhail.a.cherkashin@gmail.com)*

Purpose: To evaluate individual approaches of different endovascular techniques for bleeding prevention during conventional external beam or proton radiotherapy in patients with a pelvic tumour mass and vessel invasion.
Methods and materials: This is an ongoing case study. In 2018-2019, 3 patients (colorectal cancer, chondrosarcoma, and locoregional ovarian cancer) with vessel tumour invasion were included. 1 patient has an invasion into the internal iliac vein (IIV) and 2 have an invasion into external and common iliac veins (ECIV). Vein involvement was confirmed by CT and MR-angiography and conventional contrast angiography. Venous tumour invasion was characterised by a high bleeding risk during irradiation. Every case was discussed by the tumour board with intervention radiologists. The IIV patient underwent selective vein embolisation by coils and the ECIV patients underwent endovascular stenting by stent graft. Radiation therapy (2 external beam VMAT, 1-proton therapy) was performed.
Results: All patients were irradiated without bleeding complications. 2 patients with stent-grafts during the first follow-up (months 3) had no signs of venous insufficiency i.e. endovascular devices also prevent vein occlusion in postradiation period. For outcome tracking the individual, a program was developed; visits and control MRI at 3, 6, and 12 months and angiography on demand (by the decision of an interventional radiologist). From an oncology perpective, these patients are still under surveillance.
Conclusion: Internal bleeding during radiotherapy is a rare but potentially life-threatening complication. Multidisciplinary discussion with an interventional radiologist allows identification and risk minimisation endovascular technologies. Coil embolisation may be useful for internal iliac vein tumour invasion and angioplasty and stenting by stent-graft for external and common iliac vein involvement.
Limitations: A small number of subjects. Heterogeneous data sampling. The uncommon incidence of these types of clinical cases.
Ethics committee approval: The study was approved by a local ethical board.
Funding: No funding was received for this work.

Monte Carlo study of scattered radiation during CBCT studies

Y. Toufique, J. Goracy, I. Delakis, C. E. Kelly, N. Apps, V. Bahun, W. Mubarak, O. Bouhali*; Doha/QA (yassine.toufique@qatar.tamu.edu)*

Purpose: Staff exposure to radiation during an interventional procedure with cone-beam CT (CBCT) can be higher than standard interventional fluoroscopic studies. This dose is due to scattered radiation during the operation. In this work, we study the origin and the impact of scatter using a GATE (GEANT4 application for tomographic emission) simulation toolkit. First, we validate a numerical model of a C-arm x-ray system from Siemens named ARTIS ZEEGO by the estimation of the computed tomography dose index (CTDI) using two polymethylmethacrylate (PMMA) phantoms. In addition, we present the validation of the GATE-modelled x-ray tube named MEGALIX Cat Plus by comparing the simulated energy spectrum with the calculated one by the SpekCalc software.
Methods and materials: Radiation doses (CTDI) were measured using PMMA head and body phantoms with diameters of 16 and 32 cm, respectively, and a height of 15 cm. Both phantoms contain five different positions (at centre and 3h, 6h, 9h, and 12h positions in the phantoms). Radiation measurements were performed at the 5 holes using a 100 mm long pencil chamber.
Results: For various voltage (kVp) levels of the x-ray tube, the results of simulated x-ray spectrums show a good agreement with calculated ones (SpekCalc). A difference in the K-characteristic x-ray intensity was observed. The relative difference between simulated and measured CTDI value for Siemens ARTIS ZEEGO at different kVp were less than 5%. Simulations demonstrated the distribution of scatter in the equipment and highlighted areas of potential high occupational doses.
Conclusion: In this study, we demonstrated the feasibility of modelling a complete CBCT study from the x-ray tube to the absorbed dose and the scattered one.
Limitations: A limitation in Monte Carlo tools and a lack of details about some CBCT components.

Leveraging technology to build an interventional oncology practice

S. H. Shah*; New York, NY/US (shahs1@mskcc.org)*

Purpose: Telemedicine has been utilised in primary care to increase access for patients. As the patient acceptance of this practice has grown, specialists have also begun to utilise telehealth visits. We tested the feasibility of starting an IR TeleHealth practice and studied the impact with a focus on days from IR referral to consult and from IR referral to biopsy.
Methods and materials: Telehealth visits were performed either by a physician or advanced practice provider at a single academic medical centre. The total patient encounters were analysed from 2017-2019. Visit types were categorised by standard documentation criteria. Time saved by the patient and physician not having to travel between locations was studied. Days from IR referral to consult and days from IR referral to biopsy were studied.
Results: In our experience, there were 325 telehealth encounters. Patients saved a total of $10,524 in travel costs and 279 hours of travel time. A total of 521 hours of travel time was saved by physicians and a total of $76,000 was saved by the practice. Days from IR referral to a clinic consult decreased from 2.7 days to 0.33 days and days from IR referral to biopsy decreased from 17.2 days to 12.2 days.
Conclusion: Leveraging telehealth can increase access to care for patients and allow for more efficient use of physician resources. In addition, telehealth could decrease the time from the referral to the initial office consult and could decrease

both the time to the clinic consultation and the IR procedure since many of these patients could potentially be seen on the same day as the referral.
Limitations: The equipment cost and regulations/compliance issues.

Does interventional radiology undergraduate exposure hold the key to workforce shortage? A multicentre/cross-sectional study in the United Kingdom
M. E. E. R. Elsakka[1], Y. Al-Obudi[1], H. M. A. Elgendy[2], M. Zamir[1]; [1]*London/UK,* [2]*Leicester/UK (Mohamed.elsakka@doctors.org.uk)*

Purpose: Interventional radiology (IR) is an evolving sub-speciality, although its representation in the undergraduate curriculum is not. This has prompted the cardiovascular and interventional radiology society of Europe (CIRSE) to introduce an undergraduate curriculum. With a shortage of 500 IR consultants, we aim to assess IR representation in the undergraduate curriculum across the United Kingdom.
Methods and materials: An 18-question questionnaire, influenced by the CIRSE undergraduate curriculum, was circulated across 18 hospitals in the United Kingdom. Recently graduated doctors were targeted to assess their understanding of IR given that they would have theoretically been exposed to the entire undergraduate curriculum and only have limited postgraduate experience.
Results: 280 replies were received. One-third of the cohort demonstrated poor exposure to general radiology, although this figure soared to 76% for IR. Only 13% of the respondents experienced a dedicated IR section in their undergraduate curriculum. Only two students were aware of international/national IR undergraduate curricula. More than 80% of respondents did not consider a career in radiology for various reasons, with 30% citing a lack of exposure. 40% of junior doctors were not aware of radiation exposure in IR. Similarly, less than half of the cohort correctly identified both the training route for IR and the imaging modalities used. Nonetheless, 80% of the respondents thought coronary stenting was being performed by IRs. Finally, the majority of the cohort welcomed radiology attachments and IR lectures as preferred teaching methods, the inclusion of IR undergraduate curriculum, and a two-week postgraduate exposure.
Conclusion: Despite current efforts, radiology, especially IR, is still falling behind in undergraduate curriculum representation. This study confirms that improved IR undergraduate exposure is a key factor in tackling national shortages of IRs.
Limitations: National, not international, study.

An externally validated prognostic model based on CT radiomics to improve risk-stratification in head and neck cancer patients
S. A. Keek[1], F. Wesseling[2], L. Licitra[3], K. Scheckenbach[4], T. Hoffmann[5], M. Ravanelli[6], R. Leemans[7], T. Poli[8], P. Lambin[2]; [1]*Maastricht, LIMBURG/NL,* [2]*Maastricht/NL,* [3]*Milan/IT,* [4]*Düsseldorf/DE,* [5]*Ulm/DE,* [6]*Brescia/IT,* [7]*Amsterdam/NL,* [8]*Parma/IT (s.keek@maastrichtuniversity.nl)*

Purpose: Patients with locoregionally advanced head and neck squamous cell carcinoma (HNSCC) have high relapse and mortality rates. Imaging-based decision support could help improve prognosis by preventing unnecessary treatment or escalating treatment for suitably stratified patients. We investigate whether a CT radiomics-based prognostic model for TNM-7 stage-III and –IV HNSCC improves risk-stratification compared to the new gold standard of TNM-8.
Methods and materials: 699 retrospective (training) and 138 prospective (validation) stage III-IV (M0) HNSCC patients from 6 European hospitals were collected from the BD2Decide database (ClinicalTrials: NCT02832102). Patients were treated with surgery and/or (chemo-) radiotherapy. TNM-8 guidelines occasionally restaged III-IV into stage I-IV, depending on HPV status. A multivariable Cox regression model was trained to predict overall survival (OS) based on radiomics features derived from the gross tumour volume (GTV) of the primary tumour. ComBat harmonisation was used to improve the interchangeability of features between the different centres. Patient stratification was assessed through Kaplan-Meier (KM) survival curves and a log-rank test for significance (p-value<0.05). The accuracy of the prediction was reported through the concordance-index (CI).
Results: A 4-feature radiomics signature (four-filtered texture) can significantly group the validation cohort into two distinct risk groups ($p < 0.05$), with a CI of 0.69. TNM-8 staging can determine two risk groups ($p < 0.05$), albeit with a higher CI of 0.70. A model built on volume can also stratify the validation cohort ($p<0.05$, CI of 0.719).
Conclusion: A model based on radiomics significantly predicts OS in TNM-7 Stage-III and -IV HNSCC patients, but is not able to outperform TNM-8 staging.
Limitations: The radiomics model does not take HPV status into account and further analysis within subgroups may yield better results.

Test-retest reproducibility of radiomics features in the computed tomography of interstitial lung disease: a pilot study
F. Prayer, J. Hofmanninger, S. Röhrich, J. Pan, A. Willenpart, M. Weber, G. Langs, H. Prosch*; Vienna/AT*

Purpose: To investigate the reproducibility of publically available radiomics features in prospective test-retest chest CT data of patients with fibrosing interstitial lung disease (fILD). To provide libraries of robust features with regard to reconstruction protocol.
Methods and materials: 30 fILD patients received repeated CT scans on a single scanner. Image data was reconstructed using sharp/i70f, intermediate/i50f, and soft/i30f kernels, and 1/3 mm slice thickness. Radiomics features (n=86) were extracted from fibrotic and healthy lung tissue, ROIs and ROCs obtained. Test-retest feature intra-class correlation (ICC) using unchanged reconstruction parameters and a fILD radiomics feature performance score (RFPS) (ROC*ICC) were calculated. The impact of altered reconstruction parameters was investigated using ICCs of features between test CT reconstructed using a sharp kernel and thin slices, and test and retest CT reconstructed using different parameters.
Results: Median ICCs (constant parameters) for i70f/1mm, i50f/1mm, i30f/1mm, i70f/3mm, i50f/3mm, and i30f/3mm were 0.927, 0.929, 0.938, 0.929, 0.923, and 0.929, respectively. Median RFPS for i70f/1mm, i50f/1mm, i30f/1mm, i70f3mm, i50f3mm, and i30f/3mm were 0.893, 0.895, 0.912, 0.892, 0.903, and 0.903, respectively. Median ICCs (altered parameters: i70f/1mm vs. rest) for i50f/1mm, i30f/1mm, i70f/3mm, i50f/3mm, and i30f/3mm were 0.829, 0.537, 0.621, 0.425,

and 0.242, and 0.752, 0.483, 0.576, 0.412, and 0.263, for test and retest, respectively.
Conclusion: Altered reconstruction parameters, particularly slice thickness, for retest CT may reduce radiomics feature reproducibility. RFPS and ICCs provided may facilitate robust, reconstruction protocol-specific feature selection in future studies.
Limitations: This pilot study included a limited sample size.
Ethics committee approval: This prospective study was approved by the institutional review board.
Funding: This work was kindly supported by a research grant from Boehringer Ingelheim.

CT high-resolution images-based radiomics analysis for differentiating lung cancer from tuberculosis
C. Tian[1], X. Chunchao[1], X. Li[2], X. Wang[2]; [1]Chengdu/CN, [2]Shanghai/CN
(tianchuan101995@163.com)

Purpose: To establish and validate a CT high-resolution images-based radiomics model for differentiating lung cancer from tuberculosis.
Methods and materials: 243 patients with lung cancer and 243 patients with tuberculosis who underwent CT examinations one month before pneumocentesis biopsy were respectively included in this study. The pneumocentesis biopsy was regarded as the golden standard. ITK-SNAP was used to segment draw the region of interest and generate the 3D volume of the lesion. All data was divided into a training cohort (ncancer=ntuberculosis=170) and validation cohort (ncancer=ntuberculosis=73) by using stratified sampling and 10-fold cross-validation with proportion 7:3. The texture features extracted by artificial intelligent kit (A.K.) were selected by using Spearman and Support vector machine recursive feature elimination feature selection method. The remaining features were included in the model developed by logistic regression analysis and presented with a radiomics nomogram. The receiver operator characteristics (ROC) analysis was performed to validate the radiomics model curves.
Results: There were a total of 696 features extracted. After data redundancy and dimension reduction, 17 features were used to develop the prediction model. A nomogram for distinguishing these two diseases, with an AUC of 0.894 (accuracy, 0.826; precision, 0.81; SE, 85.3%; and SP, 80%) for training set and 0.856 (accuracy, 0.767; precision, 0.767; SE, 76.7%; and SP, 76.7%) for the validation data was successfully plotted.
Conclusion: A CT high-resolution image-based radiomics has the potential for distinctions between lung cancer and tuberculosis, indicating that radiomics could play an important role in before-pneumocentesis biopsy.
Limitations: This is a retrospective, single-centre cohort study.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Biological validation with gene expression profiling of a CT-radiomics signature for predicting response to immunotherapy
M. Ligero, A. Garcia-Ruiz, C. Rubio-Perez, P. Nuciforo, J. Seoane, M. Escobar Amores, R. Dienstmann, E. Garralda, R. Perez Lopez; Barcelona/ES (mligero@vhio.net)

Purpose: To biologically validate the CT-radiomics signature predictive of response to immune-checkpoint-inhibitors by correlating the CT-radiomics score with gene expression profiling data from tumour samples and to compare the performance of radiomics only and combined with clinical data to predict response to immune-checkpoint-inhibitors in patients with advanced solid tumours.
Methods and materials: In this retrospective study, a predictive signature was derived from 239 metastases of 85 consecutive patients treated with immune checkpoint inhibitors (monoclonal anti-PD-1/anti-PD-L1 antibodies) monotherapy in phase I clinical trials from August 2012 to May 2018. Validation was performed in 112 lesions from 46 consecutive patients with urinary bladder cancer treated with anti-PD-1/PD-L1 monotherapy (Cohort 2). Radiomics variables were extracted from all lesions per patient in the pre-treatment CT scan and an elastic-net model was implemented. Biological validation was pursued studying the association (Mann-Whitney analyses) of the CT-radiomics score with RNA signatures of cytotoxic cells in an independent cohort of 20 patients. A regression model was applied to combine radiomics and clinical variables.
Results: In Cohort 1 (training), the radiomics signature associates with a response (area under the curve [AUC] 0.74;$P=2.96x10^{-10}$). In Cohort 2 (validation), the radiomics signature predicts a response with AUC=0.70 ($P=1x10^{-3}$). A high radiomics score associates with cytotoxic-enriched immunophenotype (P=0.035). The model combining radiomics and clinical variables slightly improve the capacity for predicting response AUC=0.76 ($P=1.02x10^{-5}$) in the training set and AUC=0.78 ($P=5x10^{-4}$) in the validation set.
Conclusion: CT-radiomics signature at baseline predicts the response to immune checkpoint inhibitors and, likely, reflects tumour immunophenotype. Integrating radiomics and clinical data improve the prediction performance.
Limitations: The biological validation was performed in a relatively small cohort.
Ethics committee approval: Approved by the institutional review board. Informed consent was waived.
Funding: Funded by BBVA, La Caixa-Foundation,Prostate Cancer Foundation.

Radiomics of small renal masses on multiphasic CT: accuracy of machine learning-based classification models for the differentiation of RCC and AML without visible fat
R. Yang, J. Wu, L. Sun, S. Lai, Y. Xu, X. Liu, Y. Ma, X. Zhen; Guangzhou/CN
(yangrm0708@gmail.com)

Purpose: To investigate the discriminative capabilities of different machine-learning based classification models on the differentiation of small (< 4 cm) renal angiomyolipoma without visible fat (AMLwvf) and renal cell carcinoma (RCC).
Methods and materials: This study retrospectively collected 163 patients with pathologically proven small renal mass, including 118 RCC and 45 AMLwvf patients. Target region of interest (ROI) delineation, followed by texture feature extraction, were performed on a representative slice with the largest lesion area on each phase of the four-phase CT images. 15 concatenations of the four-phasic features were fed into 224 classification models (built with 8 classifiers and 28 feature selection methods), classification performances of the 3,360 resultant discriminative models were compared, and the top-ranked features were analysed.
Results: Image features extracted from the unenhanced phase (UP) CT image demonstrated dominant classification performances over features from the other three phases. The two discriminative models 'SVM + t_score' and 'SVM + relief' achieved the highest classification AUC of 0.90. The top-10 ranked features from UP included 1 shape feature, 5 first-order statistics features, and 4 texture features, where the shape and first-order statistics features showed superior discriminative capabilities in differentiating RCC versus AMLwvf through the t-SNE visualisation.
Conclusion: Image features extracted from UP is sufficient to generate accurate differentiation between AMLwvf and RCC using a machine-learning-based classification model.
Limitations: The present study included only three RCC subtypes. Texture features were extracted from two-dimensional (2D) ROI on each representative axial section rather than from three-dimensional (3D) ROI. Kinetic pattern was not analysed in the current study.
Ethics committee approval: This case-control retrospective study was institutional review board approved and HIPAA compliant, with a waiver of informed patient consent.

Repeatability and reproducibility of radiomics features in spectral CT using an anthropomorphic abdomen phantom

L. Caldeira, J. Holz, S. Lennartz, D. Maintz, N. Grosse Hokamp; *Cologne/DE (liliana.caldeira@uk-koeln.de)*

Purpose: To evaluate repeatability and reproducibility of radiomics features in spectral CT using an anthropomorphic abdomen phantom.
Methods and materials: The phantom was scanned repetitively using different radiation doses ($CTDI_{vol}$ of 10, 15, and 20 mGy) using a spectral detector computed tomography scanner (SDCT). Scanning was repeated three times each. Different spectral results were reconstructed: conventional, virtual non-contrast (VNC), iodine density, iodine no-water, MonoE 50KeV, electron density, and Z-Effective. 34 three-dimensional regions-of-interest (ROIs) were defined analytically and fully-automated. 93 radiomics features were extracted employing the pyradiomics-package. In total, 93x7x3x3 extracted features were analysed. Repeatability and reproducibility were assessed using the concordance correlation coefficient (CCC).
Results: Features with excellent and moderate reproducibility, as indicated by a CCC>0.8 and CCC>0.6, respectively, for the different image reconstructions were identified. Percentage of features with CCC>0.8 varied between 16% (Z-Effective with 10 mGy) and 89% (iodine no-water with 15 mGy). Furthermore, the total number of features with CCC>0.8 and CCC>0.6 increases with dose. In total there were 205 features with excellent repeatability and reproducibility, but only 13 features for all image reconstructions were identified. Among all reconstructions, first-order features show the best reproducibility and repeatability (~50%). CCCs between different radiation doses were further assessed showing good reproducibility (>80% of features).
Conclusion: This study comprises the first systematic evaluation of repeatability and reproducibility using spectral reconstruction images from SDCT. While first-order features show a good repeatability and reproducibility, care has to be taken when using features with medium and poor reproducibility for classification tasks.
Limitations: Only phantom images were assessed; a translation onto patients is desirable. Images did not undergo pre-processing which holds potential to improve repeatability and reproducibility.
Ethics committee approval: n/a
Funding: No funding was received for this work.

Multicentre validation of a radiomics-based model for the diagnosis of idiopathic pulmonary fibrosis

T. Refaee[1], B. Bondue[2], G. van Simaeys[2], A. Ibrahim[1], G. Wu[1], H. C. Woodruff[1], P. A. Gevenois[2], S. Goldman[2], P. Lambin[1]; [1]*Maastricht/NL,* [2]*Brussels/BE (t.refaee@maastrichtuniversity.nl)*

Purpose: The most common idiopathic interstitial lung disease (ILD) is idiopathic pulmonary fibrosis (IPF), which is determined by the presence of usual interstitial pneumonia (UIP) in high resolution computed tomography (HRCT). If a patient diagnosed with ILD of an unknown cause is suspected of having IPF with a UIP pattern, an invasive biopsy is recommended. We investigated the ability of machine learning models based on radiomic features to identify IPF patients using thin-section CT, aiding in diagnostic and treatment selection towards precision medicine.
Methods and materials: A total of 259 patients from two separate collections were available for this study. 158 patients from the Lung Tissue Research Consortium consisted of two groups: group A (n=80) included patients with IPF/UIP and group B (n=78) included patients with non-IPF ILDs, both confirmed by biopsy. 101 patients collected retrospectively from Erasmus University Hospital consisted of two groups with identical clinical findings as group A and B respectively (n=52 and n=49). Each lung was automatically contoured and divided into four sectors. A random forest classifier model was created and the performance was assessed using the area under the receiver operator characteristics curve (AUC).
Results: Feature selection yielded one clinical (age) and seven radiomic features as inputs for the model. The AUC of the classification model, when applied to the basal sector of the lung, was 0.75 in training and 0.80 in testing. The positive predictive value was 73% and the negative predictive value was 75%.
Conclusion: Quantitative image analysis could potentially decrease the need for biopsies, providing a low-cost, non-invasive, observer-independent, and reproducible classification of fibrotic lung diseases. Future work includes adding further datasets for model validation and feature harmonisation methods.
Limitations: The sample size is low. There is a big variation in image acquisition and CT parameters.
Ethics committee approval: Was not needed (retrospective study).

Prediction of tumour progression and recurrence in patients with hepatocellular carcinoma undergoing transarterial chemoembolisation as a bridge to transplant using CT radiomics features

E. Salinas-Miranda, K. Namdar, F. Khalvati, D. Deniffel, P. Abreu, T. Ivanics, G. Sapisochin, M. A. Haider, P. Veit-Haibach; *Toronto/CA (emmanuels7@gmail.com)*

Purpose: To evaluate the performance of an arterial phase CT radiomics model in predicting tumour progression prior to transplant or post-transplant recurrence in patients with hepatocellular carcinoma (HCC) who underwent pre-transplant transarterial chemoembolisation (TACE)
Methods and materials: In this retrospective study, we analysed the baseline contrast-enhanced CTs of 91 patients with HCC listed for liver transplantation prior to bridging therapy with TACE. Using the PyRadiomics library (v2.2), 1,441 radiomic features were extracted from the largest HCC volume in the arterial phase. After removing features with variance below 0.05, 762 features remained. Principal component analysis (PCA) was applied for feature reduction and the first 22 components were kept in the model. The binary classification task was done using a support vector machine (SVM) classifier. The performance of the model was evaluated by area under the receiver operating characteristic curve (AUC) using 5-fold cross-validation. The primary endpoint of the radiomics classifier was the combined event of tumour progression prior to transplant or post-transplant recurrence.
Results: The combined event occurred in 37% of patients (34/91) with 21.9% of patients (20/91) having tumour progression and1 5% of patients (14/91) having tumour recurrence. The mean time from listing to transplant, listing to progression, and listing to recurrence was 182, 335, and 670 days, respectively. The mean follow-up time was 1,308 days. The mean AUC for the prediction of pre-transplant tumour progression or post-transplant tumour recurrence was 0.81 (95% confidence interval: 0.76-0.85). The best radiomic model at a threshold of 0.387 achieved a sensitivity and specificity (at maximum Youden index) of 85% and 83%, respectively.
Conclusion: An arterial phase-based radiomics model can predict tumour progression and recurrence in HCC-patients listed for transplant who undergo TACE
A machine-learning driven radiomics algorithm may provide a useful tool for risk stratification of HCC patients listed for transplant. Further prospective validation is required.
Limitations: A retrospective study and single institution cohort. Radiomic features were obtained from single arterial-phase.
Ethics committee approval: An IRB approved study.
Funding: No funding was received for this work.

CT-radiomics quantification towards a more accurate immunotherapy response assessment
A. Antón Jiménez[1], M. Ligero[1], S. Roche[1], R. Mast Vilaseca[2], N. Roson[1], M. Escobar[1], R. Perez Lopez[1]; [1]Barcelona/ES, [2]Hospitalet de Llobregat/ES (alba.antonj@gmail.com)

Purpose: To develop an immunotherapy response model based on the change of radiomic features from baseline to follow-up for a more accurate response assessment.
Methods and materials: This retrospective study included 67 consecutive patients with metastatic solid tumours treated in phase I clinical trials with immune checkpoint inhibitors (anti-PD1/PD-L1). Baseline contrast-enhanced CT and follow-up CT after 8 weeks of treatment were evaluated. One target lesion per patient was delineated and radiomics features were extracted using pyradiomics. An analysis of variance (ANOVA) was implemented as a feature selector. Featured differences between baseline and follow-up that showed significant differences for clinical benefit were selected and a logistic regression model was generated. Log-rank analysis of Kaplan-Meier data was conducted to determine associations between the radiomics score and overall survival.
Results: From 105 radiomic features from first-order, shape, and texture matrices, four features differed between baseline and follow-up (total energy, small area low grey-level emphasis, coarseness, and surface) associated with a response in the validation set ($p<0.05$). Prediction capacity of the radiomics model showed an AUC of 0.79 (95% CI 0.69-0.90; $p<0.05$). Patients with a higher radiomics score showed longer survival ($p<0.05$).
Conclusion: The change in radiomics features from baseline to follow-up after treatment classifies responder and non-responder patients and associates with overall survival.
Limitations: A retrospective study with a limited number of patients.
Ethics committee approval: Approved by the ethics committee.
Funding: No funding was received for this work.

A preliminary study of radiomic classifiers for identifying small cell lung cancer from non-small cell lung cancer
C. Y. Zhang, S. H. Liu, H. L. Yu, S. L. Liu, Z. X. Zhang; Qingdao/CN (shihe528@126.com)

Purpose: To establish a radiomics model and a nomogram for identifying small cell lung cancer from non-small cell lung cancer based on enhanced CT images.
Methods and materials: From January 2014 to June 2018, 202 cases of small cell lung cancer and 266 cases of non-small cell lung cancer were enrolled into our primary cohorts. All patients underwent enhanced CT scan and all lesions were pathologically confirmed. Our primary cohorts were randomly divided into a training group (n=327) and a verification group (n=141) according to 7:3. 396 radiomics features were automatically extracted by AK software. Data reduction and feature selection were performed using the LASSO regression model. Logistic regression analysis was used to establish a multivariate predictive model for identifying small cell lung cancer and non-small cell lung cancer. In addition, a nomogram model combining the radiomics features and clinical information was established in order to raise the diagnostic efficiency.
Results: The established radiomics label contained 14 omics features. The diagnostic efficiency of the radiomics label performed well in differentiating small cell lung cancer and non-small cell lung cancer. The area under the ROC curve (AUC) was 0.86 (training group, 95%CI:0.834～0.889) and 0.82 (verification group, 95%CI:0.802～0.851), respectively. Compared with the clinical parameter prediction model (AUC=0.86, 95%CI:0.836～0.890) and the image histology label (AUC=0.82, 95%CI:0.802～0.851) in the validation group, the AUC of the nomogram was 0.94 (95%CI:0.895～0.991) in the validation group and the accuracy was 86.2%.
Conclusion: The radiomics label and the nomogram have good diagnostic efficiency for identifying small cell lung cancer from non-small cell lung cancer.
Limitations: This study is a single-centre, retrospective study.

A comparison between routine and targeted CT-based radiomics classification models for predicting malignant pulmonary nodules
G. Tao[1], Y. Chen[1], J. Ye[1], H. Yu[1], X. Ye[1], X. Li[2], Z. Zhou[2]; [1]Shanghai/CN, [2]Beijing/CN (121058820@qq.com)

Purpose: To compare the results of conventional and targeted CT-based radiomic classification models distinguishing benign and malignant pulmonary nodules.
Methods and materials: The two datasets were comprised of routine and targeted lung CT images of 349 patients with pathological results respectively. We built classification models to predict the malignancy of pulmonary nodules based on a radiomics method. To achieve the best result on both datasets, we used diverse feature selection methods and machine learning algorithms.
Results: The AUC, accuracy, sensitivity, and specificity of the radiomic model based on routine lung CT images were 0.77, 60.16%, 58.15%, and 78.79%, respectively. By contrast, the AUC, accuracy, sensitivity, and specificity of the radiomic model based on targeted lung CT images were 0.84, 75.72%, 76.36%, and 69.70%, respectively. The result showed that targeted CT images have an edge over routine CT images on predicting malignancy of pulmonary nodules.
Conclusion: Because of the use of target scanning, we obtain more sufficient and more accurate image data, and the large matrix, small FOV, and thin layer thickness reduce the voxel, making the quantitative analysis results more accurate. We have demonstrated that a radiomic classification model based on targeted CT images has better performance compared to a model based on routine CT images. Therefore, target CT combined with radiomic classification models can provide a more accurate diagnosis of pulmonary nodules, thus helping select proper treatment or follow-up strategies.
Limitations: This work has not been verified by a multicentre trial, which is considered to be our future work.
Ethics committee approval: This retrospective study was approved by the institutional review board of Shanghai Chest Hospital (KS1956).

The clinical efficacy of second-look ultrasound (SLUS) following breast MRI in breast cancer imaging: does SLUS change management?
A. J. Jameel, A. S. Mehdi, K. Edmonds, D. Khafaf, T. Seaton, D. Cunningham; London/UK (aia.s.mehdi@gmail.com)

Purpose: To evaluate our institutional experience of second-look ultrasound (SLUS) for targeted breast lesions identified on breast MRI. To determine our SLUS lesion detection rate (LDR), positive predictive value (PPV), and the effect on patient management (PM).
Methods and materials: A retrospective review of SLUS at our institution between January 2016-2017 identified 316 patients who underwent breast ultrasound following breast MR. All non-SLUS cases were excluded and 66 patients with 73 target lesions were included. The index lesion (inital ultrasound identified/ MR indication), the target lesion (MR identified/ SLUS indication), and the SLUS were analysed with regard to imaging characteristics (location, size, morphology, enhancement), histopathology, and MDT outcomes to assess the efficacy of SLUS and its LDR, PPV, and PM.

Results: 57 of 73 target lesions were identified on SLUS: LDR 78.1%.
The MR imaging characteristics of the 73 target lesions were: 74.0% <10mm, 26.0% > 10mm, 84.2% mass-like enhancement, 14.0% non-mass enhancement, 1.8% no enhancement.
Of the 57 target lesions detected on SLUS: 42.1% were biopsy-proven malignant (n=24) - PPV of 63.4%. 29.8% were biopsy-proven benign (n=17) - NPV 93.6%. 28.1% were not biopsied due to stable benign radiological features or patient refusal (n=16).
SLUS confirmed suspected findings in 71.9% (n=41) and changed management in 36.8% (n=21), causing upstaging to WLE or mastectomy.
Conclusion: Our study demonstrates the utility of SLUS breast imaging with 78.1% LDR, PPV 63.4%, and NPV 93.6%. SLUS changed patient management in 71.9% upstaging to WLE or mastectomy. SLUS is a pivotal imaging tool in the radiological assessment of breast lesions.
Limitations: 1 year data, limited sample size.

Evaluation of additional MR-detected breast mass using quantitative analysis of contrast-enhanced ultrasound and its comparability to MR findings
S. Y. Lee, O. Woo, H. S. Shin, S. E. Song, K. R. Cho, B. K. Seo, S. Y. Hwang; *Seoul/KR (adimsum@gmail.com)*

Purpose: To evaluate the diagnostic performance of contrast-enhanced ultrasound (CEUS) in evaluating breast mass and to determine whether kinetic pattern results comparable to dynamic contrast-enhanced MRI (DCE-MRI) can be obtained using quantitative analysis of CEUS.
Methods and materials: In this single-centre prospective study conducted from January 2016 to December 2018, a total of 71 breast cancer participants who had additional MR-detected mass with 2nd look US correlation were included. For these masses, a single radiologist performed the CEUS exam. Two radiologists then reviewed all the images for quantitative and qualitative analysis and were subsequently categorised according to BIRADS by consensus. The diagnostic performance of CEUS was analysed by comparing the BIRADS category to the final pathology results. The degree of agreement between kinetic patterns shown by CEUS and DCE-MRI was evaluated using weighted kappa analysis.
Results: Of the 71 US-correlated additional MRI-detected masses, 53 (75%) were malignant and 18 (25%) were benign. The diagnostic performance of CEUS for these masses was excellent with 84.9% sensitivity, 94.4% specificity, and 97.8% positive predictive value. Among the 53 malignant masses, there were 37 (71%) IDC, 8 (15%) DCIS, and 7 (13%) ILC. A total of 57/71 (80%) masses had correlating kinetic patterns and showed good agreement (weighted kappa = 0.66) between CEUS and DCE-MRI evaluations. Benign masses showed excellent agreement (0.84) while agreement in malignant masses was fair (0.38). Among different malignant types, IDC showed good agreement (0.62) while DCIS and ILC showed no agreement (0.14 and 0.10).
Conclusion: Diagnostic performance of CEUS for additional MR-detected breast mass was excellent. Accurate kinetic pattern evaluation that is fairly comparable to DCE-MRI can be obtained for benign and IDC masses by using CEUS.

Clinical utility of second-look ultrasound with prone MRI virtual navigation in breast lesions detected on MRI alone: a preliminary study
R. Qi, L. Bao; *Hangzhou/CN (qirx1816@126.com)*

Purpose: To evaluate the clinical utility of second-look ultrasound (US) with MRI virtual navigation in the prone position for MRI-detected incidental breast lesions.
Methods and materials: Between June 2016 and February 2019, 24 consecutive patients with 26 additional BI-RADS category 4 or 5 lesions that were detected on MRI but occult on second-look US were enrolled in the study. All suspicious lesions were located with US/MRI fusion virtual navigation in the prone position and then underwent US-guided biopsy or surgical excision. The detection rate was calculated compared with pre/postoperation MRI and pathological results. The MRI features and pathological types of these lesions were analysed.
Results: A total of 24 lesions were successfully located with virtual navigation and performed with US-guided biopsy or localisation, and the detection rate of virtual navigation was 92.3% (24/26). 21 (87.5%, 21/24) proved to be benign lesions and 3 (12.5%, 3/24) malignant lesions at pathology. The remaining 2 lesions exhibited no abnormal findings on second-look US with virtual navigation and could be judged to be benign as there was no change during MRI follow-up after 6 months. Of the 26 MRI-detected lesions, 24 (92.3%, 24/26) were non-mass enhancements and 2 (7.6%, 2/26) were masses.
Conclusion: The lesions detected on MRI but not visible on US tend to be benign. Second-look US with virtual navigation in the prone position can be an effective method for the evaluation of such lesions and can significantly increase the rate of US-guided interventional procedures which are preferable for MRI-guided ones.
Limitations: Accurate alignment is difficult between different imaging modalities.
Ethics committee approval: The study was approved by our hospital's institutional review board.

Ultrasound evaluation of breast ductal carcinoma in situ
S. Paolicelli[1], N. Troiano[2], M. Carbone[1], M. Telegrafo[1], M. Moschetta[1]; *[1]Bari/IT, [2]Modugno/IT (simonapaolicelli@gmail.com)*

Purpose: To evaluate the role of ultrasound (US) for detecting and characterising breast ductal carcinoma in situ (DCIS) of the breast.
Methods and materials: US features of 178 preoperative lesions in 170 patients affected by DCIS were retrospectively evaluated by using the BIRADS ultrasound lexicon considering the lesion pattern (mass type, non-mass type, or occult), the presence of microcalcifications, architectural, and ductal distortions. For "mass-like" lesions, shape, margins, and echogenicity were considered. The ultrasound recognition rate of lesions and the distribution of ultrasound patterns was calculated, evaluating any statistically significant differences among the different lesion patterns.
Results: 63/178 lesions (35%) were detected by ultrasound; 52 (83%) were "mass-like" type and 11 (17%) "non-mass-like" type (6 architectural distortions, 5 ductal distortions) ($p < 0.05$). In 10 patients (6%), breast lesions were identified only by US. The most common US appearance of DCIS finding in mass-type lesions was an irregular shape (79%), indistinct margins (87%), and hypoechogenicity (94%) ($p < 0.05$). Microcalcifications associated with mass-type lesions were found in 23 cases (37%).
Conclusion: US can allow a diagnosis of DCIS of the breast in case of mass-type lesions. The most common US finding is represented by mass-type, hypoechogenic lesion, and indistinct margins. Microcalcifications and architectural distortions are the most frequent US findings in non-mass lesions.
Limitations: A limited number of patients.
Ethics committee approval: Yes.
Funding: No funding was received for this work.

Assessment of NACT response in locally advanced breast cancer patients: a prospective comparison of grey scale ultrasound and contrast-enhanced ultrasound

A. Sharma, S. B. Grover, A. Katyan, .. Chintamani, D. C. Ahluwalia*; New Delhi/IN (anante266@gmail.com)*

Purpose: To compare the role of grey scale ultrasound and contrast-enhanced ultrasound (CEUS) in evaluating the response to neoadjuvant chemotherapy (NACT) in patients with locally advanced breast cancer (LABC).
Methods and materials: This prospective IRB approved study comprised of 40 patients of LABC receiving NACT. Both studies were performed in 4 stages: before each of the 3 cycles of LABC and immediately prior to surgery. Grey scale ultrasound was done to evaluate tumour size. This was followed by contrast-enhanced ultrasound using a 4.8 ml bolus intravenous injection of second-generation ultrasound contrast agent. The CEUS quantitative parameters recorded were time to peak (TTP), mean transit time (MTT), and area under curve (AUC). Pathological tumour response (pTR) was evaluated after modified radical mastectomy, using the Miller Payne grading system. Statistical analysis was done for sensitivity, specificity, PPV, and NPV of each technique.
Results: In the series of patients evaluated, 28 patients showed good pTR and 12 patients showed poor pTR. Grey scale ultrasound changes for size of tumour demonstrated sensitivity of 71.5%, specificity of 79.3%, PPV of 78.5%, and NPV of 73.8%, whereas quantitative CEUS parameters showed a sensitivity of 87.6%, specificity of 88.3%, PPV of 91.1%, and NPV of 82.4% in patients with good pTR. An increase in time to peak (TTP) after each cycle of NACT was the most accurate quantitative parameter.
Conclusion: CEUS study using quantitative parameters was more sensitive and specific as compared to grey scale ultrasound changes of size measurements. CEUS quantitative parameters can be very useful for modifying individualised patient based NACT regimens.
Limitations: Single-centre study.
Ethics committee approval: Informed consent was taken from all patients. Animal Board approval n/a.
Funding: No funding was received for this work.

False-negative axillary ultrasound in patients with newly diagnosed invasive breast cancer: is there a correlation with preoperative findings?

C. Manzone, M. Durando, L. Bergamasco, E. Regini, G. Bartoli, G. Mariscotti, P. Fonio*; Turin/IT (chiaramanzone@hotmail.it)*

Purpose: To investigate false-negative results of preoperative axillary ultrasound (AUS) in patients with breast cancer and to identify features related to false-negatives.
Methods and materials: 124 consecutive patients with newly diagnosed invasive breast cancer who underwent preoperative AUS between January-June 2018 were retrospectively included. All patients underwent sentinel lymph node biopsy or axillary lymph node dissection and pathology outcomes were considered as a gold standard. True and false-negative AUS groups were statistically compared in terms of age, BMI, tumour size, subtype, grade, estrogen receptor (ER), progesterone receptor (PR), HER2 status, proliferation index, lymphovascular invasion (LVI), and growth pattern (unifocal or multifocal).
Results: Out of the 106 patients with normal AUS, 27 (25%) were found to be node-positive on pathologic assessment. On univariate analysis, LVI was found to be significantly different between true and false-negative groups [24%(19/79) versus 89%(24/27), p<0.0001]. Breast tumour size was smaller in the true-negative group with an average size of 14.0±9.0mm (versus 19.6±8.6mm, p=0.01). The presence of a higher grade and a multifocal growth pattern were more likely in the false-negative group [40%(32/79) versus 15%(4/27), p=0.03 and 90%(71/79) versus 67%(18/27), p=0.015]. There was no significant difference in age, BMI, subtype, ER, PR, and HER2 status and proliferation index. On multivariate analysis, only the presence of LVI achieved statistical significance [p<0.0001, OR 21.81(CI 95% 5.61–84.83)].
Conclusion: Our results suggest that patients with false-negative AUS are more likely to have larger (>20mm) multifocal and higher grade (G2-G3) invasive cancers. In this setting, preoperative AUS results should be interpreted cautiously.
Limitations: Small sample size. Retrospective, single-centre study. Low number of lobular subtype (18%).

Comparison between execution and reading time of 3D automatic breast ultrasound (ABUS) versus hand-held ultrasound (HHUS): results from the TOMUS study

N. Brunetti, S. de Giorgis, J. P. Zawaideh, F. Rossi, S. Tosto, A. Tagliafico, M. Calabrese*; Genoa/IT (nicole.brunetti.1992@gmail.com)*

Purpose: Breast density is an independent risk factor for breast cancer. Mammography is supplemented with hand-held ultrasound (HHUS) to increase sensitivity. Automatic breast ultrasound (ABUS) is an alternative to HHUS. Our study wanted to assess the difference in execution and reading time between ABUS and HHUS.
Methods and materials: N=221 women were evaluated consecutively between January 2019 and June 2019 (average age 53 years; range 24-89) within a multicentric comparative prospective trial between tomosynthesis and HHUS. The execution and reading time of ABUS and HHUS was calculated with an available stop watch. Time started for both procedures when the patient was ready on the examination table to be examined to the end of image acquisition and interpretation.
Results: No patients interrupted the exam due to pain or discomfort. N=221 women underwent ABUS and HHUS, n=11 patients refused to undergo both procedures due to time constraints and refused ABUS, therefore 210 patients were enrolled with both ABUS and HHUS available. The average time to perform and read the exam was 5 minutes for HHUS (DS ±1.5) with a maximum time of 11 minutes and a minimum of 2 minutes. The average time with ABUS was 17 minutes (DS ±3.8, with a maximum time of 31 minutes and a minimum time of 9 minutes). The ABUS technique took longer to be performed in all patients, with an average difference of 11 minutes (range 3-23 minutes) per patient, p<0,001.
Conclusion: A significant difference was observed in the execution and reading time of the two exams, where the US method was more rapid and tolerated.
Limitations: A potential sources of bias.
Ethics committee approval: The study received IRB approval and informed consent was obtained from all participating patients.
Funding: No funding was received for this work.

Could conventional US and contrast-enhanced US be helpful for breast cancer prediction based on MR imaging BI-RADS category 4 lesions?

J.-M. Xu*; Shanghai/CN (junmei_510@126.com)*

Purpose: To prospectively estimate the predicting value of US and CEUS for breast cancer in MR imaging BI-RADS 4 lesions and to determine whether the integration of US and CEUS into MR imaging BI-RADS 4 lesions improves the diagnostic performance.
Methods and materials: A total of 163 breast MR imaging BI-RADS 4 lesions in 163 women who underwent US and CEUS simultaneously before ultrasound-guided core biopsy or surgery were included. A multivariate logistic regression analysis was performed to assess 26 independent variables for prediction of malignancy. ROC curve analysis was used to evaluate the diagnostic performance.
Results: Of the 163 MR imaging BI-RADS 4 lesions, 49 (30.1%) were benign and 114 (69.9%) were malignant. Enhancement area enlargement (OR: 64.28) was the strongest independent predictor for breast malignancy, followed by hyperechoic halo sign (OR: 33.75), fast-in and/or fast-out patterns (OR: 27.76), and spiculation (OR: 20.38)(all P<0.05). The areas (Az) under the ROC curve for enhancement area enlargement and fast-in and/or fast-out patterns were greater than those for the significant independent variables of hyperechoic halo sign and spiculation. The Az, sensitivity, and specificity were 0.70-0.85, 53.5%-76.4%, and 85.7%-95.7% on US, respectively, and 0.86-0.89, 90.4%-95.6%, and 75.5%-87.8% on CEUS, respectively.
Conclusion: Conventional US and CEUS are both promising for breast cancer prediction in MR imaging BI-RADS 4 lesions, with higher sensitivity on CEUS and higher specificity on US. They can be used as a meaningful supplement to MR imaging in the diagnosis of BI-RADS 4 breast lesions and thus has the potential to avoid unnecessary biopsy.

Limitations: Our study only enrolled patients with MR imaging BI-RADS 4 lesions, so selection bias may be present.
Ethics committee approval:
This study was institutional review board-approved and informed consent was obtained from all patients.

The role of automated breast ultrasound (ABUS) in correlation to contrast-enhanced spectral mammogram (CESM) in the staging of breast cancer

M. H. Helal, S. A. Mansour, R. Hussien*; Cairo/EG (r_hkhaled@hotmail.com)*

Purpose: To evaluate the role of ABUS in correlation to CESM in the loco-regional staging of breast cancer.
Methods and materials: The study is a prospective analysis that included 75 female patients with proved breast cancers. Evaluation was in regard to the size, multiplicity, and the stromal invasion around the tumour. Cases were subjected to automated breast ultrasound and contrast-based mammography, which was performed using low and high exposures following i.v. injection of a contrast agent.
Results: Eligible cases were 62 in number. CESM and ABUS showed high accuracy of assessment of the tumour multiplicity (82.2%). ABUS showed a higher accuracy of the stromal involvement (93.5%) than CESM (66.1%). There was no significant difference in the size between the pathology and the CESM. The latter showed a percentage of agreement of 38.7%. Yet, there was a statistical significance ($p < 0.001$) between the ABUS and the pathology in the detection of the size of the tumour.
Conclusion: ABUS is a non-invasive modality that can be used for the staging of breast cancer. It provided accurate assessment of the stromal involvement and multiplicity of the cancer. CESM outperformed ABUS in the measurement of the size of the index cancer.
Limitations: Not all cases performed mastectomy, which may affect the study outcome.
Ethics committee approval: The study had an Ethics committe approval and patients gave informed written consent.
Funding: No funding was received for this work.

Influence of breast density on patient's compliance during conventional hand-held breast ultrasound (US) or automated breast ultrasound (ABUS)

S. de Giorgis, N. Brunetti, J. P. Zawaideh, F. Rossi, A. Garlaschi, M. Calabrese, A. Tagliafico*; Genoa/IT (degiorgis.sara@libero.it)*

Purpose: To study the influence of breast density on patient's compliance during conventional hand-held breast ultrasound (US) or automated breast ultrasound (ABUS).
Methods and materials: Between January 2019 and June 2019, n=221 female patients (mean age: 53; age range: 24-89) included in a multicentric prospective comparative trial comparing digital breast tomosynthesis and US underwent both US and ABUS. All participants had independently interpreted US and ABUS regarding patient's compliance. The diagnostic experience with US or ABUS was described with a modified testing morbidities index (TMI), a validated instrument for assessing the short-term quality of life related to diagnostic testing. The scale ranged from 0 (the worst possible experience) to 5 (an acceptable experience). Pain or discomfort before and during testing, fear or anxiety before and during testing, and embarrassment during testing were recorded. Standard statistics were used to compare data of US and data of ABUS.
Results: None of the patients interrupted the ABUS exam. The mean TMI score was 4.6 (SD ± 0.5) for US and 4.3 (SD ± 0.8) for ABUS. The overall difference between the patient's experience on US and ABUS was statistically significant with $p<0.0001$. The difference between the patient's experience in women with BI-RADS 4 for breast density was statistically significant with $p<0.02$ in favour of US (4.7 ± 0.4) vs 4.5 (SD ± 0.6) for ABUS. Patients' experience with breast density 1 was better for US (4.7 ± 0.4) vs 4.3 (SD ± 0.6) for ABUS, $p<0.01$. Pain or discomfort during testing was higher in patients >40 years.
Conclusion: Compliance of ABUS was lower than US, especially in women <40 years. Breast density did not influence the ABUS experience.
Limitations: A potential sources of bias.
Ethics committee approval: The study received IRB approval.
Funding: No funding was received for this work.

A non-invasive differential diagnosis of breast cancer by the new concept of full breast ultrasonography: improvements of the initial assessment of the disease's extension

A. C. Georgescu, S. Bondari, E. Andrei, A. Manda*; Craiova/RO (acgeorges.radiology@gmail.com)*

Purpose: The non-invasive radiological-imaging differential diagnosis of breast cancer (BC) is still unsatisfactory due to the less specific descriptors and the non-anatomical scanning and interpreting. We aimed to improve sonomorphology for a better differential diagnosis and a better assessment of the initial extension of breast diseases through the new integrative concept of full breast ultrasonography (FBU), represented by the radial ductal scanning, colour Doppler, and strain sonoelastography.
Methods and materials: We conducted a retrospective study of 1,223 consecutive FBU in 944 patients, referred for screening, diagnostic, or follow-up in two imaging centres with different equipments, and we compared the initial US BI-RADS assessment with the pathological reports or the follow-up exams for the benign findings. Statistical analysis included the evaluation of the sensibility and specificity of the technique and other correlations of the findings.
Results: The US BI-RADS assessment was in accordance with the pathological reports in 99.2% cases. We found no significant correlation between BC-Density-Age, but significant association of BC + Benign pathology. The benign findings were multiple, combined, and with unpredictable evolution (regression or progression to the atypia or DCIS). The suspect infra-centimetric findings had short-interval follow-up (2-3 months). BC represented unifocal lesion in 60% of cases, multifocal and lobar type in 38% of cases, and multicentric lesions in 2% of cases. The most important descriptor for BC was the incident angle of the plunging artery and, when associated with a score 4 or 5 Ueno, the accuracy was close to 100%.
Conclusion: FBU offered a new hierarchy of the US descriptors, useful differential diagnosis of breast tumours, and anatomical redefinition of the multifocality and multicentricity of BC, with better initial evaluation of the disease's extension.
Limitations: Initial study.

Is US-texture analysis a useful instrument to discriminate fibroadenomas from complex fibroadenomas and benign phyllodes tumours?

I. Başara Akin, H. A. Özgül, M. K. Şimşek, C. Altay, M. Seçil, P. Balci*; Izmir/TR (haozgul@hotmail.com)*

Purpose: Although BIRADS 4A refers lesions with low malignancy suspicion, benign pathologic diagnoses such as fibroadenomas, complex fibroadenomas (CF), and benign phyllodes tumours (BPT) are commonly expected in this category lesions. Fibroadenomas are the most frequent benign tumours of the breast. CFs are subgroups of fibroadenomas with additional histopathologic features. The risk of developing breast carcinoma was found to be higher in patients with CF than in those with fibroadenomas. BPTs have a potential of malignant transformation. There is substantial overlap in sonographic features between phyllodes tumours and fibroadenomas. In this study, we aimed to use US texture analysis (USTA) to discriminate fibroadenomas from CFs and BPTs.
Methods and materials: We analysed the texture of 95 patients with histologically proven 32 fibroadenomas, 32 BPTs, and 31 CFs. Texture analysis was performed using LIFEx software on the largest slice of each lesion in B-mode US. First order texture histogram parameters (skewness, kurtosis, entropy) were evaluated. A comparison was made with an unpaired t-test.
Results: There were statistical significances in all lesions in terms of skewness ($p=0.00$) and kurtosis ($p=0.003$). In the evaluation of sub-groups with each other, there was statistical significance between fibroadenomas and both CFs and BPTs in terms of both skewness ($p=0.001$) and kurtosis ($p=0.009$). However, there was no statistical significance between CFs and BPTs according to all parameters.

Conclusion: In benign BIRADS 4A lesions, USTA is a potential biomarker to discriminate fibroadenomas from CFs and BPTs, which have a higher possibility of malignant transformations than fibroadenoma. USTA could have a contribution to US examination in the distinction of fibroadenoma.
Limitations: The number of patients was limited. Additionally, texture analyses were performed by one observer.

Application of post labeling delay time in 3D-pseudo continuous arterial spin labeled perfusion imaging in normal children

S. Tang*; Chongqing/CN (sltang66@163.com)*

Purpose: To explore the application value of PLD in 3D-pcASL perfusion imaging in normal children and to find the optimal PLD values for children at each age group.
Methods and materials: 5 groups of children, with 50 patients in each group, who underwent routine MRIs with normal results were included. The patients were stratified according to the following ages: <1 month, 1 to 6 months, 6 to 12 months, 1 to 3 years, 3 to 6 years, and 6 to 18 years. All patients received 3D-pcASL scanning. The PLD values were set to 1,025 ms, 1,525 ms, or 2,025 ms. In subjective evaluations, the SNR and CBF of 3D-pcASL perfusion images under different PLD values were compared and analysed.
Results: For patients in the < 1 month group and 1 to 6 months group, when the PLD value was 1,025 ms, the brain CBF values and SNR values were higher than those of the images with PLD values of 1,525 ms and 2,025 ms. For patients in the 6 to 12 months group, 1 to 3 years group, 3 to 6 years group, and 6 to 18 years group, when the PLD value was 1,525 ms, the brain CBF values and SNR values were higher than those of the images with PLD values of 1,025 ms and 2,025 ms.
Conclusion: The optimal PLD value for infants who are aged ≤6 months is 1,025 ms. The optimal PLD value for children >6 months to 18 years old is 1,525 ms.
Limitations: The deficiency of this study is that some children used sedatives during the examination.
Ethics committee approval: Ethics committee approval obtained.
Funding: No funding was received for this work.

Is multi-delay arterial spin labelling a better biomarker of cerebral perfusion in sickle cell cerebral vasculopathy?

C. Y. Provost[1], S. Lion[1], R. M. Lebel[2], J. Benzakoun[1], L. Legrand[1], D. Calvet[1], P. Bartolucci[3], M. Edjlali-Goujon[1], C. Oppenheim[4]; *[1]Paris/FR, [2]Calgary/CA, [3]Créteil/FR, [4]Paris Cedex 14/FR (cyprovost@gmail.com)*

Purpose: Arterial spin labelling (ASL) is a promising non-invasive MRI perfusion technique but remains challenging to use in sickle cell disease (SCD) cerebral vasculopathy, which results in long arterial transit times (ATT) through collateral pathways. We aimed to validate multi-delay ASL for cerebral blood flow (CBF) measurements in SCD patients with cerebral vasculopathy.
Methods and materials: We performed single-delay ASL (labelling duration=1,500 milliseconds, post-labelling delay=2,025 milliseconds) and multi-delay ASL (labelling duration=4,000 milliseconds, 7 post-labelling delays: 2,000-5,000 milliseconds) on a 3-Tesla MRI scanner in 21 patients with SCD cerebral vasculopathy. Dynamic susceptibility contrast MRI was used to assess the disease severity and to identify cortical regions with normal (<2 seconds), moderate (2-4 seconds), and severe (>4 seconds) Tmax. Normalised relative CBF (rCBF), ATT, and Tmax values were automatically extracted from 20 cortical regions.
Results: Single-delay ASL measured lower rCBF that were 93%, 89% ($p<0.001$), and 84% ($p=0.011$) of the multi-delay ASL values in cortical regions of normal, moderate, and severe Tmax, respectively. Compared to multi-delay ASL, single-delay ASL underestimated rCBF by 16% in regions with severe Tmax ($p=0.014$), especially in anterior and middle cerebral artery perfusion territories. ATT was correlated with Tmax in cortical regions with severe Tmax ($\rho=0.56$, $p<0.001$). ATT maps were visually comparable to that of Tmax.
Conclusion: Non-invasive multi-delay ASL improves CBF assessment in SCD cerebral vasculopathy, particularly in cortical regions with long ATT. It could reduce the need for contrast injection in patients difficult to infuse.
Limitations: No reference standard such as [^{15}O]-water positron emission tomography was available to validate the accuracy of rCBF measurement from ASL.
Ethics committee approval: The study was approved by the Comité de Protection des Personnes Île-de-France Saint-Louis Ethics Committee.
Funding: The Agence Régionale de Santé Ile-de-France.

Multi-delay ASL with reduced-resolution pre-scan transit time maps for the assessment of cerebral perfusion in Moyamoya disease: a comparison with conventional 3D-ASL

Y. Zeng, S. Zhou, X. Zhang, Y. Chen, J. Fu, S. Duan, J. Qu, D. Geng, J. Zhang*; Shanghai/CN (18211220088@fudan.edu.cn)*

Purpose: The cerebral haemodynamics of Moyamoya disease (MMD) is complex and conventional arterial spin labelling (ASL) with a fixed post-labelling delay (PLD) time can easily misestimate the cerebral perfusion. We aimed to explore the value of a multi-delay ASL with reduced-resolution pre-scan transit time (TT) maps in obtaining cerebral perfusion information in MMD compared to the conventional 3D-ASL.
Methods and materials: 46 patients with MMD underwent both multi-delay ASL and 3D ASL-MRI. All brain regions based on the automated anatomical labelling (AAL-90) atlas were divided into 5 groups according to the TT values measured in TT maps from multi-delay ASL-MRI. The cerebral blood flow (CBF) values in 4,140 brain regions in all patients were also measured.
Results: The CBF values in multi-delay ASL and 3D-ASL were significantly different ($p<0.001$). At TT≤1,000 ms, 1,000 ms$<$TT≤1,500 ms, and 1,500 ms $<$TT≤2,000 ms, the respective CBF values in multi-delay ASL were lower than the corresponding CBF values in 3D-ASL value ($p<0.001$ for all comparisons). However, at 2,000 ms$<$TT≤2,500 ms, the multi-delay ASL value was higher than the 3D-ASL value ($p<0.001$). Although the fifth group (TT$>$2,500 ms) included only 5 brain regions of 3 patients, the CBF values from multi-delay ASL were all higher than those from 3D-ASL.
Conclusion: The CBF can be corrected by using a series of low-resolution TT maps from the multi-delay ASL-MRI. This approach possibly provides more accurate cerebral perfusion information for the assessment of MMD.
Limitations: The application of the multi-delay ASL was not explored in more depth.
Ethics committee approval: The study was approved by ethics committee of our hospital and written informed consent was obtained.
Funding: The National Key Research and Development Program of China (Grant No.2016YFA0203700).

Cerebrovascular reserve derived from ASL may differentiate between affected and unaffected vascular territories in patients with Moyamoya disease

M. Fahlström, P. Enblad, A. Lewén, J. Wikström*; Uppsala/SE (markus.fahlstrom@radiol.uu.se)*

Purpose: To compare cerebrovascular reserve (CVR) in affected and unaffected vascular territories in patients with Moyamoya disease (MMD) using ASL.
Methods and materials: 9 patients with MMD were included before or after revascularisation surgery of unilaterally or bilaterally affected vascular territories. All patients were examined on a 3T MR scanner. CBF maps, based on 3D-pCASL acquisition, were acquired before and 5, 15, and 25 minutes after an i.v. acetazolamide (ACZ) injection and registered to each patient's 3D-T1-weighted image. A vascular territory template was spatially normalised to the patient-specific space. CBF values were extracted from regions supplied by the middle and anterior cerebral arteries and categorised as affected or unaffected based on DSA. CVR was calculated as CBF augmentation post-ACZ injection relative to baseline. A post label delay of 2,500 ms and large regions-of-interests were used to account for possible arterial transit time artefacts.
Results: A total of 19 examinations were analysed, generating 76 vascular territories (12 unaffected and 64 affected). Average CVRs (CI95%) in unaffected vascular territories were 60% (46-73%), 54% (44-64%), and 46% (38-54%) at 5, 15, and 25 minutes after ACZ injection, respectively. Corresponding values in affected vascular territories were 42% (38-47%), 40% (36-45%), and 38% (34-42%). Differences between unaffected and affected vascular territories were significant at 5 minutes (p=0.006) and 15 minutes (p=0.017), but not at 25 minutes (p=0.095).
Conclusion: CVR derived from ASL can differentiate between unaffected and affected vascular territories. ASL has potential as a non-invasive diagnostic method in patients with MMD.
Limitations: The small number of unaffected vascular territories is a potential source of bias.
Ethics committee approval: Approved by the regional ethics committee (DNR 2019/01316). Written informed consent was given.
Funding: No funding was received for this work.

RPS 1411a-5 11:39

Establishing a potential imaging biomarker in spinocerebellar ataxia type 3: the application of voxel-based morphometry and ASL

M. Hu, J. Zhao, H. Qiu, J. Chu, C. Wu*; Guangzhou/CN (humanshi_may@163.com)*

Purpose: To uncover the changes of whole-brain grey-matter (GM) based on voxel-based morphometry (VBM) and to obtain cerebral blood flow (CBF) maps of the significantly altered regions in VBM. Further, to establish a potential imaging biomarker for the diagnosis of spinocerebellar ataxia type 3 (SCA3).
Methods and materials: 20 symptomatic SCA3 patients (mean age: 39.7y), 5 pre-symptomatic SCA3 patients (mean age: 27.3y), and 20 age- and gender-matched healthy controls (HCs) (mean age: 37.6y) were included in this study and underwent whole-brain T1-MPRAGE and pASL. Their clinical information was also collected.
Results: Compared with HCs, SCA3 symptomatic patients had a significantly reduced GM volume in the right anterior cerebellum lobe (RACL) (P<0.001, FWE correction). However, no significant GM volume differences were found between pre-symptomatic and symptomatic SCA3 patients or was found between the HCs and pre-symptomatic SCA3 group. Further, when the extracted RACL CBF values in symptomatic SCA3 and HCs were compared, CBF values were significantly higher in symptomatic SCA3 patients ($CBF_{symptomatic\ group}$: 56.0±31.7 (mL/(100g×min) vs CBF_{HCs}: 29.6±22.0 (mL/(100g×min); P <0.05). ROC analysis showed that the CBF values of RACL had high diagnostic value (AUC=0.75) and the specificity, sensitivity, and cut-off value for the diagnosis of symptomatic SCA3 were 75%, 84.2%, and 29.8 mL/(100 g×min).
Conclusion: Compared with HCs, the GM volume had significantly reduced in the RACL of SCA3 symptomatic patients, whereas the CBF values of the same patients in RACL had complementary increased. The CBF value in RACL might serve as a non-invasive and promising diagnostic biomarker for SCA3 patients with a high sensitivity.
Limitations: The sample size is relatively small.

ASL MRI brain imaging studies in patients with diabetic retinopathy

Q. He*; Kunming/CN (ynheqian@163.com)*

Purpose: To evaluate cerebral perfusion in diabetic retinopathy patients by magnetic resonance ASL imaging.
Methods and materials: 10 diabetic retinopathy patients without hypertension selected from June 2017-March 2019 were included in study group A, 24 non-retinopathy patients were included in study group B, and 22 healthy volunteers were included in control group C. Magnetic resonance head scanning, MRA, and ASL scanning were performed on the three groups of subjects at rest. SPM software based on MATLAB was used to convert and preprocess the obtained images and the activation points of each brain region were calculated. The ROI was manually marked in the activated brain region. According to the ROI activation diagrams of different brain regions obtained by preprocessing, an area of approximately 20 mm^2 and the average CBF value of the corresponding ROI and its mirror ROI were measured.
Results: The average CBF values of the left cerebellar hemisphere, left cerebellar tonsil, bilateral inferior temporal gyrus, left straight gyrus, left cingulate gyrus, and bilateral medial frontal gyrus in group A were lower than those in group B and group C (P<0.05), and the average CBF values of the pons and left anterior central gyrus in group A were higher than those in group B and group C (P<0.05).
Conclusion: MRI brain ASL imaging showed abnormal perfusion in the cerebral motor centre, visual projection area, limbic system, and other areas in patients with diabetic retinopathy, indicating that changes in cerebral microcirculation may occur simultaneously in diabetic retinopathy.
Limitations: Few cases were enrolled.
Ethics committee approval: Ethics committee approval obtained.
Funding: Supported, in part, by Core Grant 2018FE001(-267) from a special joint fund from Yunnan Provincial Department of Science and Technology and Kunming Medical University, Kunming, Yunnan, China.

Perfusion abnormalities detected by MR pseudo-continuous arterial spin labelling (pCASL) in patients with porphyria

G. Castorani[1], D. Vergara[2], D. Grasso[3], C. Borreggine[4], G. Valle[5], C. C. Guida[5], A. Simeone[5], T. Popolizio[5], G. Guglielmi[6];
[1]Foggia/IT, [2]Naples/IT, [3]Manfredonia/IT, [4]Casamassima/IT, [5]San Giovanni Rotondo/IT, [6]Andria/IT (giulia.castorani90@gmail.com)

Purpose: Acute intermittent porphyria (AIP) is a rare inherited disorder presenting with abdominal, neurologic, and psychiatric symptoms.
Several studies documented brain perfusion defects by single-photon emission tomography (SPET) in subjects affected by AIP. PCASL is a non-invasive MRI technique for measuring tissue perfusion with a lot of potential clinical applications. Our purpose is to evaluate the role of pCASL and to compare it with SPET findings in this cohort of patients.
Methods and materials: 50 patients (26 group; 24 control) with AIP were included in the study. All subjects underwent MR examination using a 3T MR scanner with conventional sequences and pCASL, and had been studied by single-photon emission computed tomography. Two blinded neuroradiologists evaluated MR images and two experienced observers (20 years and 25 years) reviewed by consensus all SPECT images.
Results: Conventional MRI showed no significant findings in all patients. All presented a variable pattern of SPECT including multiple mild to moderate perfusion cortical defects, bilateral or asymmetric. The most involved regions

were temporal, frontal, and parietal lobes. We found a similar pattern of hypoperfusion with pCASL in 20 patients. 2 patients were excluded because of movement artefacts. 3 subjects didn't manifest any significative perfusion alteration.
Conclusion: pCASL represents an important and reliable alternative to others more expensive or invasive techniques, like PET or SPECT, for measuring cerebral perfusion in AIP patients. It could become a useful tool in research and clinical practice.
Limitations: The retrospective nature of the study; difficult in the control group.
Ethics committee approval: Patient consent was obtained.
Funding: No funding was received for this work.

The use of arterial spin labelling in acute ischaemic stroke and transient ischaemic attack

C. B. Brito[1], P. Vilela[1], X. Golay[2]; [1]*Lisbon/PT,* [2]*London/UK*
(catarinaborgesbrito@gmail.com)

Purpose: Arterial spin labelling (ASL) is a non-invasive and quantitative imaging method to evaluate brain perfusion and angiography (4D-MRA ASL) using magnetically labelled arterial blood water as an endogenous tracer. The aim of this review is to discuss the applications of ASL in the setting of acute ischaemic stroke (AIS) and transient ischaemic attack (TIA).
Methods and materials: A literature review was conducted searching the electronic databases PubMed and SCOPUS from inception to May 2019 to identify relevant peer-reviewed English publications. Qualitative and quantitative ASL imaging data were extracted.
Results: After screening 404 titles and abstracts, and 41 full-text articles, 34 studies were included. ASL is an accurate and fairly versatile technique that provides useful imaging information required by the current AIS treatment guidelines. ASL has a high sensitivity (>85%) and accuracy for the detection of the arterial occlusion site. This technique is successful in depicting the ischaemic penumbra, with a tendency to show larger volumes than dynamic-susceptibility contrast MRI perfusion. ASL can reliably rule-out stroke by recognising its mimics and may even help to sustain the diagnosis of minor stroke/TIA, monitor clinical evolution, and stratify the risk of future stroke. The new 4D-MRA ASL defines the arterial occlusion site and collateral circulation status, which helps to predict the clinical outcome.
Conclusion: ASL has proven to be an accurate alternative for stroke evaluation, allowing quantitative brain perfusion analysis, the definition of occlusion site, and collateral delineation with 4D-MRA. This technique is especially important when contrast agents are contraindicated, repeated image is needed, or the paediatric population is implicated. It is very effective for TIA/minor stroke evaluation.
Limitations: Available studies have small sample sizes and use different approaches to evaluate perfusion, limiting the comparability of results.
Ethics committee approval: n/a
Funding: No funding was received for this work.

MRI spectroscopy and arterial spin labelling in migraine patients

G. Singla[1], D. S. Thakur[2], D. S. Sharma[2]; [1]*Karnal/IN,* [2]*Shimla/IN*
(drgazalsingla2212@gmail.com)

Purpose: A migraine is a common disabling primary headache disorder of high prevalence. We tried to evaluate the neuro-imaging findings in patients with migraines with conventional and advanced MRI sequences.
Methods and materials: 44 patients with migraines and 14 well-matched controls received conventional MRI brain scanning, 3D multi-voxel spectroscopy, and arterial spin labelling. Ratios of N-acetyl aspartate (NAA)/choline (Ch), NAA/creatine(Cr), Cho/Cr, lactate(Lac)/NAA, and myoinositol(mI)/NAA were taken in each thalamus.
ASL images were analysed for any blood flow related abnormalities. Values were taken in both cerebral hemispheres in the frontal cortex, in both thalami, and in both cerebellar hemispheres.
Results: Few migraine patients showed T2/FLAIR white matter hyperintensities ($p>0.05$). There was reduced NAA/Cho and NAA/Cr ratios in the thalamus of the contralateral side of migraine headache ($p<0.05$).
NAA/Cho and NAA/Cr ratios were decreased in migraine patients when compared to controls ($p< 0.05$). Increased duration of illness was associated with decreased NAA/Cho and NAA/Cr ratios ($p<0.05$).
A significant decrease in perfusion in the ipsilateral brain in patients with ipsilateral migraine headache was noted.
Conclusion: MRS and ASL can help detect changes that are not readily detected on conventional MRI. MR spectroscopy can detect changes in the mean metabolite concentration in the thalami of migraine patients, which can predict the severity of the disease. MR perfusion using ASL can evaluate the perfusion changes. From such data, biomarkers can be developed in the future for early diagnosis. Also, medications can be developed targeting the thalamus for managing this disease more precisely.
Limitations: n/a
Ethics committee approval: n/a

Arterial spin labelling-based MR perfusion in epilepsy: an imaging tool in the presurgical evaluation in epilepsy (a 50 case study)

A. Joshi, S. Jagtap, N. Kurwale, S. Patil*; Pune/IN*
(draniruddha.joshi@gmail.com)

Purpose: Accurate identification of the epileptogenic zone is an important prerequisite in the presurgical evaluation of refractory epilepsy.
The arterial spin labelling (ASL) non-contrast perfusion technique not only provides structural abnormalities but also a functional characterisation of abnormalities, and may play a vital role in structural MRI negative epilepsy.
Methods and materials: We examined 50 patients with intractable epilepsy. On the basis of their clinical and electrophysiological findings, 32 patients had temporal lobe epilepsy, 3 had post-ischaemic scar lesions, 9 had focal seizures, and 6 had dysplastic lesions.
MRI was performed using a 3.0-T Skyra (Siemens). ASL was performed with a pulsed sequence using a QUIPSII perfusion mode. Relative cerebral blood flow maps for ASL were calculated for contrast-enhanced perfusion-weighted imaging using Syngo perfusion (MR) software.
An epilepsy protocol was used: axial T2W, sagittal T1W and sagittal 3D FLAIR, SWI, and diffusion-weighted imaging with 62-direction scanning. Interictal FDG PET/CT was used for comparison with ASL.
Results: All cases with temporal lobe epilepsy showed hypoperfusion in the affected temporal lobe on both the interictal PET and ASL maps. In those cases where a cortical lesion was visible on imaging and corresponded with an alteration seen on PET, the same result seen on ASL perfusion.
Conclusion: The perfusion maps obtained with ASL corresponded well with the PET perfusion and EEG results in patients with intractable epilepsy.
ASL not only allows the localisation of the epileptogenic focus but also provides the functional characterisation of abnormalities identified by MRI. ASL is a non-contrast, non-radiation useful supplementary investigation. It has the potential to make MRI a one-stop-shop in epilepsy evaluation.
Limitations: Despite a slightly reduced resolution with ASL, we found a correlation between ASL, PET, and electrophysiological data.

CT-perfusion and MR-ASL in the differential diagnosis of glioblastomas and primary CNS lymphomas

A. Batalov, R. Afandiev, N. Zakharova, E. Pogosbekian, S. Goriainov,
A. Bykanov, I. Pronin, A. Potapov*; Moscow/RU (batalov89@gmail.com)*

Purpose: To study the possibilities of MR-ASL and CT-perfusion (CTP) in the differential diagnosis of glioblastomas (GB) and primary CNS lymphomas (PCNSL).
Methods and materials: On the basis of ASL, we measured the tumour blood flow (TBF) in 119 patients with GB and 16 patients with PCNSL. All patients were examined on a 3T MR-scanner. The pseudo-continuous ASL (pcASL) technique was used to calculate TBF. Post-processing of ASL data was conducted on the workstation using the ReadyView program. Using CT perfusion, we estimated haemodynamic parameters (CBF, CBV, MTT, and PS) in 23 patients with GB

and 15 patients with PCNSL. Post-processing was done using a CT-perfusion 4D program (AW Server 3.2 GE). All parameters (ASL and CTP) were normalised to intact white matter.
Results: ASl-TBF in GB was significantly higher than in PCNSL (p<0.001). The cut-off=109 ml/100g/min, AUC=0.885, sensitivity=93.8%, and specificity=73,1%. CTP-CBF and CBV in GB was significantly higher than in PCNSL (p<0.0001). The cut-off for CBF was 56.5 ml/100g/min (AUC=0.942, sensitivity=73.3%, and specificity=100%) and the cut-off for CBV was 4.4 ml/100g (AUC=0.965, sensitivity=100%, and specificity=82,6%). MTT and PS in GB was significantly lower than in PCNSL (p=0.008 for MTT, p<0.0001 for PS). The cut-off for MTT was 4.6s (AUC=0.759, sensitivity=80%, and specificity=69,6%) and the cut-off for PS was 7.6 ml/100g/min (AUC=0.968, sensitivity=86.7%, and specificity=100%).
Conclusion: ASL and CTP are reliable quantitative techniques for the differential diagnosis between GB and PCNSL. The study was supported by RFBR №18-29-01018.
Limitations: A small number of patients in the study group.
Ethics committee approval: n/a
Funding: The study was supported by Russian Foundation for Basic Research №18-29-01018.

RPS 1407a-1 11:15

Substantial radiation dose reduction with consistent image quality using a novel low-dose stone composition protocol
P. Apfaltrer[1], A. Dutschke[1], P. A. T. Baltzer[1], C. Schestak[1], M. Özsoy[1], C. Seitz[1], T. H. Helbich[1], H. Ringl[1], G. Apfaltrer[2]; *[1]Vienna/AT, [2]Graz/AT*

Purpose: To assess a novel low-dose CT-protocol, combining a 150kV spectral filtration unenhanced protocol (Sn150kVp) and a stone targeted dual-energy CT (DECT) in patients with urolithiasis.
Methods and materials: 232 (151 male, 49±16.4 years) patients with urolithiasis who had received a low-dose non-contrast enhanced CT (NCCT) for suspected urinary stones either on a third-generation dual-source CT system (DSCT) using Sn150kVp (n=116, group 1) or on a second-generation DSCT (n=116, group 2) using single-energy (SE) 120kVp. For group 1, a subsequent dual-energy CT (DECT) with a short stone-targeted scan range was performed. Objective and subjective image quality was assessed. Radiation metrics were compared.
Results: 534 stones (group 1: n=242 stones; group 2: n=292 stones) were found. In group 1, all 215 stones within the stone-targeted DECT-scan range were identified. 11 calculi (5.12%) were labelled as uric acid (UA) while 204 (94.88%) were labelled as non-UA calculi. DE analysis was able to distinguish between UA and non-UA calculi in all collected stones. There was no significant difference in the overall signal-to-noise ratio between group 1 and group 2 (p=0.819). On subjective analysis, both protocols achieved a median Likert rating of 2 (p=0.171). The mean effective dose was significantly lower for combined Sn150kVp and stone-targeted DECT (3.34±1.84mSv) compared to singe-energy 120kVp NCCT (4.45±2.89mSv) (p<0.001), equaling a 24.9% dose reduction.
Conclusion: The evaluated novel low-dose stone composition protocol allows substantial radiation dose reduction with consistent high diagnostic image quality.
Limitations: A retrospective design.
Ethics committee approval: Institutional review board approved.
Funding: No funding was received for this work.

Comparison of ultra-low-dose CT with standard-dose CT for urolithiasis
Y. S. Shim, S. H. Park, J. Lee; *Incheon/KR (peaceilv@naver.com)*

Purpose: To evaluate the radiation dose exposure, diagnostic performance, and image quality of ultra-low-dose non-contrast CT using an advanced modelled iterative reconstruction (ADMIRE) algorithm with spectral filtration for the detection of urolithiasis.
Methods and materials: 145 consecutive patients underwent non-contrast CT using third-generation dual-source scanner to obtain two datasets: 16.7% (ultra-low-dose CT) and 100% (standard-dose CT) tube loads with spectral filtration. The performance of ultra-low-dose CT for detection of stones was analysed by two readers and compared with that of standard-dose CT. Image quality was measured subjectively and objectively.
Results: 171 stones were detected in 79 patients. The mean effective radiation doses of ultra-low-dose CT was 0.3 mSV. The sensitivity and specificity values for the diagnosis of stones measuring ≥3 mm was 95.1% and 100% for ultra-low-dose CT. The sensitivity and specificity for all stone detection was 74.9% and 97.8% for ultra-low-dose CT. The image quality was lower for ultra-low-dose CT than for standard-dose CT (P<0.01).
Conclusion: Ultra-low-dose CT can be achieved with radiation doses close to KUB radiography. Ultra-low-dose CT with spectral filtration can be used to detect stones measuring ≥3 mm and be used as a follow-up imaging modality as an alternative to KUB radiography.
Limitations: The small number of obese patients and the relatively small number of ureteric stones. Due to the difference in image quality between ultra-low-dose and standard-dose CT scans, there was a limit to the extent that the readers could be blinded. The 3 mm slice thickness might impact the ability to detect small stones.
Ethics committee approval: Approval for the study was obtained from the institutional review board of Gil Medical Center.
Funding: No funding was received for this work.

RPS 1407a-3 11:27

Variations in CT protocols and radiation doses for haematuria and renal colic: comparing practices in 20 European countries
F. Homayounieh[1], V. Gershan[2], R. Singh[1], M. Kalra[1], J. Vassileva[3]; *[1]Boston, MA/US, [2]Skopje/MK, [3]Vienna/AT (vgersan@gmail.com)*

Purpose: CT is commonly used for evaluating patients with haematuria and renal colic. We assessed variations in radiation doses and CT protocols for the evaluation of haematuria and renal colic in 20 European countries.
Methods and materials: IAEA surveyed practices in 51 hospitals from 20 European countries and obtained information for three CT protocols (haematuria, renal colic, and routine abdomen-pelvis CT) for 1,276 patients: patient information (weight and clinical indication), scanner information (vendor, scanner name, and number of detector rows), parameters (number of phases, scan start and end locations, mA, and kV), and radiation dose descriptors (CTDIvol and DLP). Two radiologists assessed the appropriateness of clinical indications and scan phases using the ESR referral guidelines and ACR appropriateness criteria. Descriptive statistics and Student's t tests were performed.
Results: Most institutions used 3-6 phase CT haematuria protocols (80%, median DLP 1,793-3,618 mGy.cm) which were associated with 2.4-4.9-fold higher dose compared to 2-phase protocol (20%, 740 mGy.cm) (p<0.0001). Likewise, 52% patients were scanned with 3-5 phase routine CT protocol (1,574-2,945 mGy.cm) as opposed to 37% single-phase routine CT (676 mGy.cm). The median DLPs for renal colic CT (516 mGy.cm; 77% had single-phase CT and 23% acquired 2-5-phases for renal colic protocol) were significantly lower than median DLPs with the other two CT protocols (p<0.0001). Most institutions did not change scan parameters (such as kV, mA, scan length) for multiphase protocols.

Conclusion: Although most institutions use low-dose CT for renal colic, large variations in haematuria and routine abdomen-pelvis CT protocols result in huge radiation doses (up to 2,945-3,618 mGy.cm). Scan parameters are not adjusted when acquiring CT with multiple phases.
Limitations: Most of the data came from developing nations with a heterogeneous number of patient studies.

RPS 1407a-4 11:33
The efficacy of CT urography using low-osmolar reduced-dose contrast agent and reduced radiation dose in patients with chronic kidney disease
H. S. Park, S. H. Kim, S. H. Cho, M. Kim*; Daegu/KR (mirank1210@naver.com)*

Purpose: To prospectively compare the image quality of CT urography with IOHEXOL 240 at 80-kVp to that with IOBITRIDOL 350 at 120-kVp in patients with or without chronic kidney disease.
Methods and materials: Among 400 patients > 60 years who underwent CT urography, 200 patients with eGFR < 45 mL/min scanned using IOHEXOL 240 at 80-kVp, and in eGFR < 45 mL/min with IOBITRIDOL 350 at 120-kVp were selected. Two radiologists measured quantitative (SNR, CNR, and CT value ratio of the bladder) and qualitative image quality (urinary tract opacification, visual image noise, artefact, and overall image quality) between the two groups with the same inclusion criteria.
Results: There were significantly higher SNR in IOHEXOL 240 at 80-kVp (renal cortex, liver parenchyma, and psoas muscle) except for the abdominal aorta ($P < 0.05$ for all). There were no significant differences in CNR and CT value ratio of the bladder between two groups ($P > 0.05$ for all). There were significant differences in the opacification score, visual image noise, artefacts, and overall image quality between the two groups ($P > 0.05$ for all).
Conclusion: CT urography with the use of IOHEXOL 240 at 80-kVp showed a dose reduction and no significant differences regarding the image.
Limitations: There are some technical parameters that have a significant impact on contrast agent enhancement, such as the rate of infusion, amount of iodine injected, and body composition and cardiac output
We did not use the techniques of abdominal compression or intravenous hydration because these techniques may be a burden for the patient.
The study suffers from selection bias, as patients were selected to perform CT urography by various referring clinicians that had a high clinical suspicion for urinary tract pathology.

Effective radiation dose reduction in CT with iterative reconstruction in patients with urinary stones
S. H. Kim, H. S. Park, S. H. Cho*; Daegu/KR (warpaludin@gmail.com)*

Purpose: To prospectively compare the image quality and visibility of urinary stones on CT images to obtain multiple radiation exposures within the same patient reconstructed with SAFIRE.
Methods and materials: This prospective observational study included 760 patients (45.5 years ± 12.8, 452 men and 248 women) known to have urinary stones between January 2016 and December 2018. Patients underwent CT with simultaneous acquisition of 6 exposures per patient from the same patient (100% FBP, 75%, 50%, 37.5%, 25%, and 12.5% SAFIRE). Two radiologists independently assessed qualitative measurement, including overall image quality, noise, and visibility of the stones using a five-point scale. Quantitative measurement, including CT number, image noise, SNR, CNR, and corresponding FOM, were compared by using the Student t-test for comparison of 100% and 5 other radiation doses.
Results: Qualitative overall image quality, noise, and visibility of the stones by location at 37.5% dose were rated as non-inferior to those at 100% exposure, except for the visualisation of smaller stones < 3 mm. The CT images with 50% exposure had increased SNR and CNR compared with those of 100% exposure. The CT images with 37.5% exposure reconstructed with SAFIRE had significantly more noise and lesser CNR than CT images reconstructed with FBP compared with FOMnoise and FOMCNR. The size-specific dose estimation was 4.1m Gy±0.8 at 37.5% exposure.
Conclusion: CTs performed at 37.5% exposure reconstructed with SAFIRE prove diagnostically acceptable for the detection of clinically relevant stones.
Limitations: We did not use the techniques of abdominal compression because the technique may be a burden for patients, especially those with chronic heart failure or diabetes.
Ethics committee approval: n/a
Funding: No funding was received for this work.

RPS 1407a-6 11:45
Iodine parameters in triple-bolus dual-energy CT correlate with perfusion CT biomarkers of angiogenesis in renal cell carcinoma
D. Manoharan, A. Netaji, C. J. Das, S. Sharma*; New Delhi/IN (dineshkimi@gmail.com)*

Purpose: To determine the degree of relationship between PCT parameters and iodine concentration metrics derived from triple-bolus DECT and to compare the radiation dose delivered.
Methods and materials: This single-centre, IRB approved, prospective study was conducted from October 2015 to September 2017. 23 consenting adults (15 men, 8 women; mean age: 56 ± 13 [range, 25–78] years) with RCCs underwent consecutive PCT and triple-bolus DECT. Triple-bolus DECT consisted of synchronous corticomedullary, nephrographic, and delayed-phase scans acquired using a dual-source DECT scanner. Two readers independently analysed blood flow (BF), blood volume (BV), and permeability (PMB) from the PCT, and iodine density (ID) and the iodine ratio (IR) from the triple-bolus DECT. Size-specific dose estimates (SSDE) of both groups were calculated.
Results: Inter-reader agreement was good for PMB (intraclass correlation coefficient [ICC]=0.812) and BF (ICC=0.849) and excellent for BV (ICC=0.956), ID (ICC=0.961), and IR (ICC=0.956). Very strong positive correlations were found between BV and ID ($P < 0.001$) and BV and IR ($P < 0.001$). Strong positive correlations were found between BF and ID ($P < 0.001$) and BF and IR ($P < 0.001$). The correlations between PMB and ID (P=0.01) and PMB and IR (P=0.02) was moderate. The mean SSDE of triple-bolus DECT was significantly lower than that of PCT ($P < 0.001$).
Conclusion: Quantitative iodine metrics derived from triple-bolus dual-energy CTs showed a significant correlation with CT parameters in renal cell carcinoma, with a significantly lower radiation dose.
Limitations: Low dose perfusion protocols were not used. Volume ROI was not taken.
Ethics committee approval: IRB approval and patient consent was obtained.
Funding: No funding was received for this work.

A normalised dual-energy iodine ratio best differentiates renal cell carcinoma subtypes among quantitative imaging biomarkers from perfusion CT and dual-energy CT
D. Manoharan, A. Netaji, K. Diwan, C. J. Das, S. Sharma*; New Delhi/IN (dineshkimi@gmail.com)*

Purpose: To compare diagnostic performances of PCT and DECT in differentiating RCC subtypes.
Methods and materials: After IRB approval, this retrospective study included 51 patients (mean age, 49.7 ± 13.2 years; range, 19–71 years; 11 women and 40 men) with different RCC subtypes (36, 9, and 7 with clear-cell, papillary, and chromophobe subtypes, respectively) who underwent both PCT and DECT before surgery/biopsy between January 2014 and December 2018. Three independent readers measured blood flow, blood volume (BV), and permeability using PCT, and iodine concentration and iodine ratio (IR) using DECT. Multivariable logistic regression analysis was performed to assess PCT and DECT models. Inter-reader agreement was calculated using the intraclass correlation (ICC) coefficient. Size-specific dose estimates of the two methods were compared.
Results: BV (ICC, 0.929) and IR (ICC, 0.850) were the most reproducible parameters. PCT and DECT were significant models ($p<.05$, all) for differentiating clear-cell RCC from papillary and chromophobe RCC, whereas neither model was significant in differentiating papillary RCC from chromophobe RCC ($p>.05$). There was no significant difference in diagnostic accuracy between PCT and DECT ($p>.05$). IR was the only independent predictor of non-clear-cell RCC in models from all readers ($p<.05$). It had an AUC of 0.95, and

sensitivity, specificity, and accuracy with IR cut-off of 63.72% were 0.88, 0.87, and 0.87, respectively. The mean size-specific dose estimate was lower with DECT than with PCT (p<.001).
Conclusion: Perfusion CT and dual-energy CT had comparable and high diagnostic accuracy in differentiating renal cell carcinoma subtypes, with the iodine ratio being the best independent predictor. Further, dual-energy CT involved significantly lower radiation dose.
Limitations: n/a
Ethics committee approval: IRB approval was obtained and informed consent was waived.

A retrospective evaluation of pathologic CT findings in a fast-track haematuria program

O. Graumann[1], J. Madsen[1], M. C. Kobel[2], C. B. Ipsen[3], J. B. Jensen[4], A. Makki[4]; [1]Odense/DK, [2]Vejle/DK, [3]Herning/DK, [4]Aarhus/DK (olegraumann@dadlnet.dk)

Purpose: Asymptomatic microscopic haematuria is one of the most common clinical findings requiring urological evaluation in adults. Often, no pathologic CT findings are seen among younger patients. Thus, CTs expose them to potential unnecessary radiation. The purpose of this study was to systematically evaluate pathologic CT findings for patients under primary investigation in the fast-track program for cancer in the urinary tract (UT) and other patients with haematuria, focusing mainly on findings of cancer in the UT.
Methods and materials: Using the radiology information system (RIS) as well as electronic patient records, data was obtained for all patients undergoing CT urography after referral in the fast-track program for cancer in the UT due to haematuria from 11 March, 2013, to 30 June, 2015, at a large university hospital.
Results: The study material was 2,365 CT urographies performed in 2,314 patients. In the group of patients with unexplained macroscopic haematuria, 101 cancers (8.77 %) were found in 1,152 CT urographies. In the group of patients older than 40 years with recurrent microscopic haematuria and relevant symptoms, 8 cancers (2.40 %) were found in 326 CT urographies. For the same patient group but with no relevant symptoms, 10 cancers (1.81 %) were found in 551 CT urographies.
Conclusion: The majority of pathologic CT findings for patients under primary investigation for haematuria were found in the group of macroscopic haematuria. Our study, therefore, supports a narrowing of the indication criteria for haematuria fast-track programs for cancer in the UT and in patients with asymptomatic haematuria.
Limitations: The study was retrospective and carried out in a single centre.

Size of kidney stones in computed tomography: the influence of acquisition and image reconstruction parameters

R. P. Reimer[1], J. Salem[1], M. Merkt[2], S. Lennartz[1], D. Zopfs[1], K. Sonnabend[1], A. Heidenreich[1], D. Maintz[1], S. Haneder[1], N. Grosse Hokamp[1]; [1]Cologne/DE, [2]Coblenz/DE (robert.reimer@uk-koeln.de)

Purpose: Computed tomography (CT) is the imaging modality of choice in suspected urolithiasis. Information obtained from CT includes the presence, location, and size of the stones, with the latter frequently determining treatment decision. While there is a consensus regarding how to perform measurements, the influence of other factors possibly impairing accurate measurement, including radiation dose and reconstruction techniques, is unknown.
Methods and materials: 47 kidney stones of different composition were scanned using a 256 row MDCT using a 3D-printed, semi-anthropomorphic phantom. The size was measured manually with a digital caliper (Man-M). Stones were imaged with 2 and 10 mGy. Images were reconstructed using filtered-back-projection, hybrid-iterative, and model-based iterative reconstruction algorithms (FBP, HIR, and MBIR) with different kernels and denoising levels. All stones underwent semi-automatic, threshold-based segmentation for computation of maximum diameter. Statistics were conducted using ANOVA ± correction for multiple comparisons.
Results: Overall stone size as compared to manual measurements was overestimated in CT (8.8±2.9 vs 10.0±3.1 mm, p<0.05) showing a good correlation (R^2=0.66). Radiation dose and denoising levels did not significantly influence measurements (p>0.05). MBIR and sharp kernels showed the closest agreement with Man-M (9.3±3.1 vs 8.8±2.9 mm, p<0.05). Differences within single stones were as high as 40% (e.g. Man-M: 5.9 mm, CT: 7.3-12 mm).
Conclusion: CT-based measurements tend to overestimate stone size as compared to manual measurements. CT-based measurements appear independent of radiation dose and denoising, however, reconstruction algorithms and kernels demonstrate a relevant impact on size measurements. The smallest differences were found when using model-based iterative reconstruction algorithms with a sharp kernel.
Limitations: This is a retrospective single-centre study only investigating reconstruction techniques of one vendor. Comparisons between reconstruction techniques of different vendors were beyond the scope of this study.
Ethics committee approval: IRB-approval given.
Funding: No funding was received for this work.

Imaging protocols for CT urography: results from a consensus conference of the French Society of Genitourinary Imaging

R. Renard Penna; Paris/FR (raphaele.renardpenna@gmail.com)

Purpose: To develop technical guidelines for computed tomography urography.
Methods and materials: The French Society of Genitourinary Imaging organised a Delphi consensus conference with a two-round Delphi survey followed by a face-to-face meeting. Consensus was strictly defined using a priori criteria.
Results: 42 expert uro-radiologists completed both survey rounds with no attrition between the rounds.
96 (70%) of the initial 138 statements of the questionnaire achieved a final consensus. An intravenous injection of 20 mg of furosemide before iodinated contrast medium injection was judged mandatory. Improving the quality of excretory-phase imaging through oral or intravenous hydration of the patient, or through the use of an abdominal compression device, was not deemed necessary. The patient should be imaged in the supine position and placed in the prone position only at the radiologist's request. The choice between single-bolus and split-bolus protocols depends on the context, but split-bolus protocols should be favoured whenever possible to decrease patient irradiation. Repeated single-slice test acquisitions should not be performed to decide the timing of excretory phase imaging; instead, excretory phase imaging should be performed 7 minutes after the injection of the contrast medium. The optimal combination of unenhanced, corticomedullary phase and nephrographic phase imaging depends on the context. Suggestions of protocols are provided for 8 different clinical situations.
Conclusion: This expert-based consensus conference provides recommendations to standardise the imaging protocol for computed tomography urography.
Limitations: This consensus meeting did not address all clinical situations and did not take into consideration dual-energy CT
Ethics committee approval: n/a
Funding: Société d'Imagerie Génito-Urinaire.

Urinary calculi detection with CT-urography: our experience using the nephro-pyelographic phase alone

R. Ciabattoni[1], I. Campo[2], L. Basso[3], C. Sachs[1], M. A. A. Cova[1]; [1]Trieste/IT, [2]Conegliano/IT, [3]Genoa/IT (ciabattoni.riccardo@gmail.com)

Purpose: To evaluate whether the nephro-pyelographic phase of CT-urography alone, without the unenhanced phase, is sufficient to identify and localise urinary calculi.

Methods and materials: In this single-centre retrospective study, images were acquired using a 64-slice Toshiba multidetector CT scanner. Patients who underwent a CT-urography with split bolus or triphasic technique between 2016 and 2019 were included. Images were evaluated randomly and independently by two radiologists with 7 and 25 years of urogenital imaging experience. Patients with no urinary calculi identified or missing one of the CT-urography phases were excluded. The number of calculi identified on each phase was recorded.
Using Cohen's method, the intra-reader agreement was calculated comparing the unenhanced and the nephro-pyelographic phases analysed by each radiologist. The inter-reader agreement was calculated comparing the unenhanced phases and the nephro-pyelographic phases analysed by the two radiologists
Results: Of the 479 enrolled patients, 65 were included in the study (47 M, 18 F). The first radiologist identified 64 calculi in the unenhanced phases and 66 in the nephro-pyelographic phases. The second radiologist identified 76 calculi in the unenhanced phases and 74 in the nephro-pyelographic ones.
The intra-reader agreements were 0.912 and 0.963, respectively. The inter-reader agreements were 0.772 and 0.713, with comparable and reproducible statistical results
Conclusion: The use of a nephro-pyelographic phase alone has greater sensitivity and specificity than the unenhanced phase in localising urinary calculi and in differentiating them from other calcifications while delivering a lower radiation dose to the patient.
Limitations: The main limitation of the nephro-pyelographic phase, which occurred in one patient in our series, is in detecting calculi with the same density of iodinated urine, visible only in the unenhanced phase.

Automated detection of kidney stones on CT images using a pre-trained ResNet
C. E. S. Zaeske, K. Bousabarah, J. Salem, D. Maintz, A. Heidenreich, S. Haneder, N. Grosse Hokamp*; Cologne/DE*

Purpose: A deep learning-based algorithm was developed to assist radiologists in detecting kidney stones. We demonstrates how the availability of pre-trained neural networks and the optimisation of the training process allow for the rapid development of powerful algorithms with low sample sizes.
Methods and materials: CT images from 52 patients with 114 kidney stones were labelled by a radiologist in training and used to train a ResNet50 pre-trained on ImageNet. To compensate for the small sample size and class imbalance, image augmentations and weighted sampling were used. Images were clipped using Hounsfield Units [-100, +1000] and normalised based on ImageNet statistics. The algorithm was trained using the one-cycle policy and the results were validated using 5-fold cross-validation.
Results: Classifications were evaluated per slice (2d) for the whole image series (3d). The mean accuracy, sensitivity, and precision of the classifier per slice were 0.94, 0.67, and 0.43, respectively. In 3d, we considered a kidney stone as detected if any slice containing the stone was correctly classified. Using this method, the mean sensitivity was measured to be 0.87.
Conclusion: Since most kidney stones were identified by the algorithm, it may allow for faster detection of kidney stones and thus a reduction of workload once implemented in clinical routine. Using pre-trained models and optimised training methods such as the used one-cycle policy allow for the rapid training of clinically useful decision support systems.
Limitations: The specificity of the algorithm regarding distractors such as phleboliths is yet to be determined. A specific comparison between radiologists using and not using the algorithm in the diagnostic setting to determine the time saving effect was out of the scope of this study.

Volume doubling times of lung adenocarcinomas: correlation with predominant histologic subtypes and prognosis
S. Park, S. M. Lee*; Seoul/KR*

Purpose: To investigate differences in VDT between the predominant histologic subtypes of lung adenocarcinomas and to assess the correlation between VDT and prognosis.
Methods and materials: This retrospective study included patients who underwent at least two serial CT scans before surgery between July 2010 and December 2018. Three-dimensional tumour segmentation was performed on two CT scans and VDTs were calculated. VDTs were compared between predominant histologic subtypes and lesion types using Kruskal–Wallis tests. Disease-free survival (DFS) was obtained from patients undergoing surgery before July 2017. A Cox proportional hazards model was used to determine predictors of DFS.
Results: Out of 268 patients (mean age, 64 years; 143 men), there were 30 lepidic, 87 acinar, 109 papillary, and 42 solid/micropapillary predominant subtypes. The median VDT was 528.8 days (range, 30.9–2,911.4 days) for all lung adenocarcinomas. VDTs differed significantly across subtypes (P<0.001), being shortest in solid/micropapillary subtypes (229.2 days). In terms of lesion type, solid lesions had significantly shorter VDTs than subsolid lesions (P<0.001).
In the 148 patients included in the survival analysis, 35 had disease recurrence or died. The multivariate analysis identified VDT (≥400 or <400 days) as an independent risk factor for DFS (hazard ratio, 2.310; P=0.024), as well as TNM stage and lesion type. Adding VDT to TNM stage and lesion type led to significant improvement in model performance (C-index, 0.767 vs. 0.795; P=0.037).
Conclusion: VDTs varied significantly according to the predominant histologic subtypes of lung adenocarcinoma, and VDT had additional prognostic value for DFS.
Limitations: Retrospective in nature. A selection bias.
Ethics committee approval: Informed patient consent was waived by the institutional review board.
Funding: Funding from the Basic Science Research Program through the National Research Foundation of Korea funded by the Ministry of Science, ICT & Future Planning.

RPS 1404a-2 11:21
Identifying participant subgroups in a lung cancer CT screening setting based on competing risks at the baseline scan
A. Schreuder[1], C. Jacobs[1], N. Lessmann[1], M. Broeders[1], M. Silva[2], I. Isgum[3], P. A. de Jong[3], N. Sverzellati[2], M. M. Prokop[1], U. Pastorino[4], C. M. M. Schaefer-Prokop[5], B. van Ginneken[1]*; [1]Nijmegen/NL, [2]Parma/IT, [3]Utrecht/NL, [4]Milan/IT, [5]Amersfoort/NL (antoniusschreuder@gmail.com)*

Purpose: Cardiovascular disease (CVD) and COPD are the main competing causes of death which diminish the benefits of lung cancer (LC) CT screening. Being able to identify participants at risk may encourage a multidisciplinary preventative approach towards reducing overall mortality.
Methods and materials: The model derivation (n=23,096) and validation cohorts (n=2,287) were formed using data from the NLST and MILD trials, respectively. CT measures of CVD and COPD were extracted using computer algorithms, and nodule features were provided by the trials. Risk models were developed to predict four outcomes: LC incidence, LC mortality, CVD mortality, and COPD mortality. For each outcome, a Cox regression model was derived from combining patient characteristics and CT features from the baseline scans.
Results: In the NLST, 756 were diagnosed with LC (3.4%) and 259 (1.2%), 435 (2.0%), and 0.5% died of LC, CVD, and COPD, respectively, after five years' follow-up. 34.2% (259/756) of the LC patients died. Among those who also had a CVD and COPD mortality risk above the 0.9 quantile, this proportion increased to 48.4% (45/93) (Figure 1). In participants with a low LC risk and high CVD and COPD mortality risks, respectively, 0.8% were diagnosed with LC (3/362) and 7.5% died (27/362) ("high" and "low" risk defined in Figure 2). Among those with

a high LC risk and low CVD and COPD mortality risks, 16.0% were diagnosed with LC (150/940) and 2.1% died (20/940).
Conclusion: LC screening participants can be stratified into groups based on LC, CVD, and COPD risk and may benefit from personalised follow-up protocols. Participants with a high LC risk and low risk of CVD or COPD deaths may benefit most from screening.
Limitations: A retrospective design. Recalibration required.

RPS 1404a-3 11:27
Variation in LungRADS™ scoring for screen detected lung nodules
H. C. Schmidt[1], M. McInnis[1], C. Dennie[2], D. Langer[1], M. Ang[1], A. Khan[1], P. Jain[1], M. Tammemagi[3], G. Darling[1]; [1]*Toronto, ON/CA,* [2]*Ottawa/CA,* [3]*Thorold/CA (heidi.schmidt@uhn.ca)*

Purpose: To determine the Canadian feasibility of a provincial scale roll-out of an organised lung cancer screening program, Cancer Care Ontario (CCO) implemented the multicentre High Risk Lung Cancer Screening Pilot (HRLCSP) in 2017. One of the integral components of the HRLCSP is radiology quality assurance (QA) to support consistency in performing and interpreting screening scans. Participating radiologists were required to attend a workshop, including a pre-workshop quiz.
Methods and materials: Before the HRLCSP workshop, 43 participating radiologists (chest radiologist without specific experience in lung cancer screening) received the LungRADS™ classification chart and a PowerPoint presentation with 20 questions regarding the scoring and follow-up of 16 different examples of CT images with screen-detected nodules. They were asked to score the nodule examples according to the LungRADS™ classification system. Responses were compared to the consensus of expert radiologists, which served as the reference standard.
Results: The LungRADS™ scores assigned by the participating radiologists varied significantly and were different from the reference standard. For the 20 questions, the correct answers ranged from 42% to 93%, with a mean of 74%. Nodule scores were both overestimated as well as underestimated.
Conclusion: Scoring screen-detected nodules using LungRADS™ does vary significantly and radiologist training before reading for a screening program is important for quality and consistency. The application of a pre-workshop quiz allows for the tailoring of the workshop content to address specific knowledge gaps.
