## 114 Introduction

115 Secondary progressive multiple sclerosis (SPMS) is characterized by progressive accrual of  
116 neurological disability independent of clinical relapses(1). Compartmentalized inflammation within  
117 the brain parenchyma(2–4) the leptomeninges(5) and the cerebrospinal fluid(6) represents a key  
118 driver of disability worsening in SPMS. Persistent inflammation within the CNS, in terms of clinical  
119 relapses or MRI activity, has been repeatedly associated with accelerated disability progression (7,8).  
120 Although first randomized controlled clinical trials did not reveal the efficacy of disease-modifying  
121 therapies (DMT) for disability progression during SPMS(9,10), a recent randomized clinical trial  
122 established some benefits of siponimod(11,12) in reducing the risk of disability worsening compared  
123 to placebo. In line with this result, observational studies have suggested that the use of available DMT  
124 in SPMS may be therapeutically beneficial(13,14), especially in active SPMS(13). However, the overall  
125 risk reduction in disability worsening with available DMT is only modest and it is still unclear whether  
126 the effect of treatment persists over time.

127 Ablation of the immune system followed by autologous hematopoietic stem cell transplantation  
128 (AHSCT) has been gain increasing evidence as a therapeutic strategy for refractory MS(15–17). AHSCT  
129 eradicates autoreactive cell clones and induces sustained self-tolerance by resetting the abnormal  
130 immune system(18). Although the ideal candidate of AHSCT is a young MS patient with aggressive  
131 relapsing-remitting MS, uncontrolled evidence suggests that AHSCT is able to prevent long-term  
132 neurological deterioration even in progressive MS(19–21). The drugs used in AHSCT technology cross  
133 the blood-brain-barrier and penetrate into the CNS, with the potential to target compartmentalized  
134 inflammation. Given the absence of satisfactory treatment options for SPMS, in the last two decades  
135 AHSCT was used off-label for the treatment of 81 patients with aggressive SPMS in 14 Italian MS  
136 centers.

137 The aim of this cohort study was to compare the effect of AHSCT on disability worsening in patients  
138 with SPMS with that of other DMTs in SPMS patients from the Italian Multiple Sclerosis Register.

139

## 140 Methods

### 141 *Study Design*

142 All patients with SPMS(1), treated with AHSCT at 14 Italian MS Centers from 1997 to 2019 were  
143 considered eligible for this study. Patients were treated according to the European Group for Blood  
144 and Marrow Transplantation (EBMT) guidelines, following the decision of the treating physician and  
145 approval of the local Ethics Committee. Although no formal guideline was used for patient selection,  
146 patients had aggressive disease course, characterized by the occurrence of relapses, MRI  
147 inflammatory activity or accrual of accelerated neurological disability despite active treatment.  
148 Detailed information on conditioning regimen and transplant care is reported in the Supplementary  
149 Materials.

150 Control patients with SPMS never treated with AHSCT were collected from the Italian MS  
151 Register(22). Patients were considered eligible: a) if they had a baseline EDSS recording, b) at least  
152 one follow-up visit and c) if a DMT had been started after the diagnosis of SPMS. Untreated patients  
153 were included in a sensitivity analysis.

154

### 155 *Study endpoints*

156 The primary objective was to compare disability worsening as assessed by the EDSS score time course  
157 after baseline in patients with SPMS treated with AHSCT versus those treated with other DMT.  
158 Secondary endpoints were the cumulative proportion of patients with a 6-months confirmed  
159 disability progression (CDP), defined as an increase of 1 point in the EDSS score (0.5 points if the

baseline EDSS score was  $\geq 5.5$ ), the cumulative proportion of patients with a 6-months confirmed disability improvement (CDI), defined as a decrease of 1 point in the EDSS score (0.5 points if the baseline EDSS score was  $\geq 5.5$ ) and the prevalence of disability improvement over time, defined as the proportion of patients who are in an improved status as compared to baseline over time.

164

165 *Statistical methods*

Outcomes were compared between patients treated with AHSCT and patients treated with “other DMT”. The “other DMT” group comprises all the patients satisfying the inclusion criteria and starting any DMT during their follow up. Untreated patients were excluded from the analysis and included in a sensitivity analysis. Descriptive results were reported as mean with standard deviation (SD) or median with interquartile range (IQR) or range.

We applied two different propensity score (PS) approaches to mitigate the differences of baseline characteristics between the treatment groups. First, we matched individual patients on their propensity to receive AHSCT or one of the other DMT. Patients were matched without replacement with a variable ratio up to 5:1 (other DMT : AHSCT) and using a nearest neighbor matching within a caliper of 0.25 SDs of the PS. Second, we applied an overlap weighting (OW) approach(23). This method has the advantage over the n:1 PS matching method that no patients are excluded from the analysis, without modifying the target population(23). The OW method assigns to each patient a weight proportional to the probability of that patient belonging to the opposite treatment group(23). In our analysis, AHSCT treated patients are therefore weighted by the probability to receive one of the other DMT (1-PS) and patients treated with other DMT are weighted by the probability of receiving AHSCT treatment (PS). OW leads to an exact balance on the mean of each baseline covariate included in the PS calculation.

183 For both methods, individual PS were calculated using a multivariable logistics regression model  
184 including age at treatment start, gender, EDSS at treatment start, number of previous DMT, ARR in  
185 the previous year, disease duration and year of treatment start. Only main effects, without  
186 interactions, were included in the regression model. Since MRI data were missing for most of the  
187 patients, they were not included in the primary PS calculation. A sensitivity analysis was run by  
188 adjusting for a PS including MRI variables. Positivity assumption of PS was checked after its  
189 calculation.

190 To assess the degree of unbalance of covariate distribution between the groups, Cohen's  
191 standardized mean differences (SMD) were calculated in the original cohort and after matching or  
192 weighting. A SMD < 0.10 was considered an acceptable balance.

193 All regression models were run on the matched cohorts or weighted according to PS. A linear mixed  
194 model with random intercept and random slope was used to assess the longitudinal EDSS time trend  
195 after baseline. A time\*treatment group interaction term was included into the model to test  
196 differences on EDSS time trend between the two treatment groups. Results were reported as  
197 annualized EDSS change with 95% Confidence Intervals (CI). Differences between treatment groups  
198 on time to CDP and CDI were assessed by mean of proportional hazard Cox regression models. Results  
199 were reported as hazard-ratio (HR) with the corresponding 95% CI. Progression-free survival and  
200 cumulative probability of improvement were estimated by Kaplan-Meier approach and graphically  
201 displayed. The prevalence of CDI was estimated according to the recently reported methodology(24)  
202 and compared between groups by bootstrapping the area under the curve (AUC). Stata (v.16;  
203 StataCorp) was used for the computation.

204

205 *Sensitivity analyses*

206 The following sensitivity analyses were performed:

- 207 i) Inclusion of untreated patients in the “other DMT” group.
- 208 ii) Application of marginal structural models (MSM) to account for potential attrition bias  
209 derived by a different duration of on-treatment follow-up in the matched groups. We  
210 estimated at each 1-year time point the stabilized weights, from the inverse probability to be  
211 censored at fixed timepoints conditional on baseline variables. Then we run a weighted Cox  
212 regression analysis.
- 213 iii) Inclusion of magnetic resonance imaging (MRI) activity in the PS calculation. Two analyses  
214 were performed: one with missing data imputed before the PS calculation using multiple  
215 imputation approach with a logistic regression model and ten imputations. The second  
216 analysis used only the subset with complete MRI information.
- 217 iv) Comparisons between a) patients treated with AHSCT vs patients treated with Interferon beta  
218 1-b and b) patients treated with AHSCT vs patients treated with Mitoxantrone using a  
219 matching without replacement with a variable ratio up to 5:1 (DMT : AHSCT) with the same  
220 rules previously described. These two treatments were the only two approved in Italy for  
221 treatment of SPMS.

222

## 223 Results

224 **Figure 1S** reports the flowchart for SPMS patients’ selection and inclusion. The SPMS cohort treated  
225 by AHSCT included 81 patients from 14 centers. Two patients did not have follow-up information and  
226 were excluded from the analysis. Data on 8465 SPMS patients were extracted from the Italian  
227 Registry. Of these, 4550 were excluded due to the lack of a baseline EDSS assessments, 851 because  
228 of missing follow up EDSS data and 703 since their DMT start date was during RRMS. A total of 2361

229 patients were included in the analysis; of them 1975 (83.7%) started a DMT (“other DMT” group)  
230 while 386 (16.3%) were never treated. **Table 1S** reports the demographic and clinical characteristics  
231 of the three groups (AHSCT, other DMT, untreated). Patients in the “other DMT” group were older  
232 and with a longer disease duration, a lower baseline EDSS and a lower ARR in the previous year as  
233 compared to AHSCT patients. DMT used by SPMS patients were mainly Interferons (38%),  
234 Azathioprine and Glatiramer acetate (both around 20%). The untreated group was made up of older  
235 patients with similar disease duration and EDSS and lower ARR in the previous year as compared with  
236 “other DMT” treated subjects. **Table 1** reports the same characteristics for the matched and the OW  
237 weighted cohorts, showing that both matching and OW weighting consistently reduced the SMD  
238 between the two groups. The mean follow-up of the matched cohort was 5.2 years, with a median  
239 of 3.6 years (IQR:1.8-7.6 years).

240

#### 241 *AHSCT vs “Other DMT” patients*

##### 242 *Yearly EDSS change*

243 **Figure 1** reports the estimated slopes of the EDSS change in the two treatment groups: the mean  
244 EDSS change over 10 years in the AHSCT cohort was estimated as -0.013 EDSS points per year (95%  
245 CI:-0.087, 0.061 EDSS points per year) while in the “other DMT” cohort the mean EDSS change was  
246 +0.157 EDSS points per year; 95% CI: 0.117, 0.196 EDSS points per year) and the difference was  
247 statistically significant (p for time by treatment group interaction<0.001). Similar results were  
248 observed by the OW analysis and the estimated slopes of EDSS change are showed in the  
249 Supplementary **Figure 2S**. The estimated yearly EDSS change was -0.017 (95% CI: -0.099, 0.065) in  
250 the AHSCT cohort and +0.18 (95% CI: 0.15, 0.21) in the “other DMT” cohort (p for time by treatment  
251 group interaction < 0.001).

## 252 *Time to CDP*

253 The time to CDP was significantly longer in AHSCT patients as compared to the matched “other DMT”  
254 group (HR= 0.50; 95% CI: 0.31, 0.81; p=0.005, **Figure 2**) . After 3 years, the proportion of patients free  
255 from CDP was 58.1% (95% CI:50.3-64.9) in the “other DMT” group and 71.9% (95% CI: 58.5-81.5) in  
256 the AHSCT group; after 5 years it was, 46.3% (95% CI: 37.4, 54.5) in the “other DMT” group and 61.7%  
257 (95% CI: 47.5,73.1) in the AHSCT group.

258 Similar results were observed when the OW procedure was applied to the whole cohort (**Figure 3S**).

## 259 *EDSS Improvement*

260 **Figure 3A** shows the Kaplan-Meier curves for time to CDI. In the matched cohorts the improvement  
261 rate was significantly higher in AHSCT patients as compared with the “other DMT” group (HR = 4.21;  
262 95% CI: 2.42-7.33; p<0.001). After 1 year the cumulative proportion of patients who had at least an  
263 improvement event was 30.2% (95% CI: 20.6,42.8) in AHSCT patients and 3.4% (95% CI: 1.6, 7.0) in  
264 the “other DMT” group; after 3 years it was 38.8% (95% CI: 28.0,51.9) in AHSCT patients and 7.8%  
265 (95% CI: 4.2,13.3) in the “other DMT” group . AHSCT patients showed also a higher prevalence of  
266 improvement (**Figure 3B**) over time (p < 0.001) as compared with the matched control group. The  
267 proportion of patients who reached and maintained an improvement status after 3 years was 34.7%  
268 (95% CI: 23.2,46.3) in the AHSCT group, while it was just 4.6% (95% CI: 1.7, 8.6) in the “other DMT”  
269 group; after 5 years 18.7% (95% CI: 7.9,29.8) of AHSCT patients are still improved as compared to  
270 baseline vs 4.1% (95% CI: 1.3,8.3) of patients treated with other DMTs.

271

## 272 *Sensitivity analyses*

### 273 *Inclusion of untreated patients*

274 Untreated patients were added to the cohort of patients treated with other DMT. A total of 72 AHST  
275 patients were matched to 228 patients in the control group (26 untreated, 11.4% and 202 treated,  
276 88.6%). Characteristics of matched patients are reported in **Table 2S**.

277 **Figure 4S** shows the results of the analysis on EDSS change. Results were similar to those reported in  
278 the main analysis: the EDSS increased in the control group (yearly change +0.125; 95% CI: 0.099,0.151  
279 EDSS points) while it was substantially stable in the HSCT group (yearly change +0.017 EDSS points;  
280 95% CI: -0.032,0.066) with a significant difference between the two groups ( $p < 0.001$ ). Results on  
281 time to EDSS progression were very close to those reported in the main analysis (**Figure 5S**).

#### 282 *Marginal structural model*

283 Results of the analysis run by applying MSM to the matched cohort (69 HSCT vs 217 other DMTs)  
284 confirmed those reported in the main analysis. The time to CPD was significantly longer in HSCT  
285 patients as compared to the “other DMT” group (HR= 0.58; 95% CI: 0.35, 0.96;  $p=0.032$ ).

#### 286 *Magnetic resonance (MRI) activity in the propensity score*

287 Data on MRI activity were available for 73/79 (92.4%) patients in the AHST group and for 812/1975  
288 (41.1%) in the “other DMT” group. AHST group had a higher frequency (51/73; 70%) of MRI active  
289 scans (defined as scans with at least 1 Gadolinium enhancing lesion) than the “other DMT” group  
290 (156/812; 19.2%; **Table 1S**). After multiple imputation of missing values, 79 HSCT patients were  
291 matched to 135 patients in the “other DMT” group. The two groups were well balanced (**Table 3S**).  
292 Results on the primary outcome were similar to those reported in the main analysis: the EDSS  
293 increased in the control group (yearly change +0.145; 95% CI: 0.115,0.175 EDSS points) while it was  
294 substantially stable in the HSCT group (yearly change +0.015 EDSS points; 95% CI: -0.034,0.064) with  
295 a significant difference between the two groups ( $p < 0.001$ ). In the complete cases analysis, 71 HSCT

296 were matched to 100 “other DMT” and similar results were observed (EDSS points yearly change  
297 +0.127; 95% CI: 0.091,0.164 in “other DMT” group vs 0.015; 95% CI: -0.038, 0.068 in HSCT; p = 0.001).

#### 298 *HSCT vs Interferon beta-1b*

299 A total of 56 HSCT patients were matched with 63 Interferon beta-1b patients (**Table 4S**). Results  
300 were similar to those reported for the analysis on “other DMTs”. In fact we observed an EDSS points  
301 yearly change of +0.126; 95% CI: 0.078,0.174 in Interferon beta group and of 0.047; 95% CI: -0.011,  
302 0.106 in HSCT with a significant difference between the two groups (p=0.040).

#### 303 *HSCT vs Mitoxantrone*

304 A total of 74 HSCT patients were matched with 138 Mitoxantrone patients (**Table 4S**). Also for this  
305 comparison on the primary outcome, results were similar to those reported previously. An EDSS  
306 points yearly change of +0.129; 95% CI: 0.103,0.155 in Mitoxantrone group and of 0.023; 95% CI: -  
307 0.025, 0.072 in HSCT with a significant difference between the two groups (p<0.001).

308

#### 309 Discussion

310 To date, no prospective clinical trial has been performed to evaluate the efficacy of AHSCT in SPMS.  
311 In this study, we showed that the use of AHSCT for the treatment of SPMS was associated with better  
312 disability outcomes than other DMT. Despite treatment with active DMT, our SPMS control group  
313 exhibited a mean disability accumulation of 0.16 EDSS points per year, with rates of CDP in line with  
314 those reported by other independent cohorts(14,25). Conversely, treatment with AHSCT induced an  
315 average improvement of EDSS over time (-0.013 EDSS points per year). This result translates into a  
316 significant delayed time to first CDP in AHSCT patients compared to matched controls, with a  
317 percentage of patients without CPD at 5 years of 61.7%.

318 Taken together, our findings confirm and extend the results of previous uncontrolled studies which  
319 suggested that AHSCT has the potential to slow down neurological progression in patients with  
320 SPMS(19–21,26). AHSCT has demonstrated a striking effect in abolishing clinical relapses and MRI  
321 signs of inflammatory activity(19,27–32), which have been associated with worse outcomes during  
322 the course of SPMS(7,13). Accordingly, it has been demonstrated that AHSCT is able to reduce CSF  
323 markers of ongoing CNS inflammation and axonal damage(33). The profound anti-inflammatory  
324 effect of AHSCT has been confirmed by pathological studies of MS lesions of patients with  
325 SPMS(34,35), in which a dramatic decrease in T and B cells infiltrates has been described up to 7  
326 years(35). Although residual demyelination and neurodegeneration have been reported after AHSCT  
327 (34,35), it is arguable that the almost complete resolution of compartmentalized inflammation  
328 behind the blood–brain barrier obtained with AHSCT has the potential to slow down disability  
329 worsening in patients with SPMS, as suggested by the positive results of anti-inflammatory B-cell  
330 targeted therapies in progressive MS(36,37). In line with this hypothesis, it has been demonstrated  
331 that anti-inflammatory DMT could also reduce axonal damage in patients with SPMS(38–41),  
332 potentially preventing disability accumulation.

333

334 We have previously reported that superimposed relapses(19) and inflammatory activity at baseline  
335 MRI(20) are favorable predictors of a better outcome after AHSCT in patients with SPMS. Similar  
336 results have been reported in other cohorts of patients with SPMS(13), in which the effect of  
337 immunotherapy in reducing disability progression was significant only in patients with active SPMS.  
338 Therefore, it is still unknown whether immunotherapy, including AHSCT, can be effective in patients  
339 with SPMS without evidence of inflammatory activity. On the other hand, the results of this study

340 support the notion that the presence of inflammation during SPMS represents a treatable target and  
341 requires adequate treatment.

342

343 A very intriguing result was that patients who underwent AHSCT were more likely to experience a  
344 sustained disability improvement. Our data indicate that 18.7% of SPMS patients maintained an  
345 improvement (a lower EDSS than baseline) 5 years after transplant, compared to the 4.1% of patients  
346 treated by other DMT. The possibility to improve in disability and maintain improvement is a crucial  
347 need for patients with a progressive disease, and it is hardly obtained with standard anti-  
348 inflammatory drugs .

349

350 Notably, our SPMS control group did not include patients treated with siponimod or rituximab. In the  
351 EXPAND study(11), siponimod treatment was associated with a delayed time to CDP than placebo,  
352 with CDP rate of 23% over 3 years. Similar results have been published following treatment with  
353 rituximab in SPMS(14), with CDP rates of 25% and 50% over 3 and 10 years, respectively. Baseline  
354 characteristics of these studies were quite balanced, with evidence of MRI inflammatory activity and  
355 relapses in the year before treatment start in about 20% of patients. Although our cohort was  
356 composed by younger patients with a higher baseline ARR, it is noteworthy that the rate of CDP at  
357 10 years was significantly lower in patients treated with AHSCT than in patients treated with  
358 rituximab.

359

#### 360 Limitations

361 The main limitation of the present study relies on its observational nature. Since our AHSCT study  
362 cohort was composed mainly by patients with aggressive, active SPMS and did not represent a

363 standard population of patients with SPMS, we controlled for multiple demographic and clinical  
364 variables to mitigate treatment selection bias. The superiority of AHSCT on disability outcomes was  
365 confirmed using both the propensity score matching and the overlap weighting (in which no patients  
366 are excluded from the analysis, without modifying the target population). As sensitivity analysis, we  
367 also included untreated patients with SPMS and confirmed the protective effect of AHSCT on  
368 disability worsening and time to CDP. The same results were obtained after the inclusion of measures  
369 of MRI activity in the propensity score calculation and from the application of marginal structural  
370 models to account for potential attrition bias derived by a different duration of on-treatment follow-  
371 up in the matched groups. The superiority of AHSCT was also confirmed when considering as a control  
372 group patients treated with interferon beta 1b and mitoxantrone, which were the only two DMTs  
373 approved for the treatment of SPMS at the time of data collection of this study. Finally, although the  
374 EDSS raters were not blinded to the treatment and this could have introduced some bias, the long-  
375 term follow-up has partially mitigated this measurement bias.

376

## 377 Conclusions

378 AHSCT induced a marked slowing of disability progression in patients with active SPMS as compared  
379 to other DMT. Prospective randomized clinical trials are needed to confirm the efficacy of AHSCT in  
380 patients with active SPMS.
